**Figure 4.** Spatial clusters and outliers of opioid poisoning incidence rate by ZIP code, New York State, 2010-2014.

We found that most areas of New York City had lower opioid poisoning hospital visits (Low-Low clusters in blue color) except several scattered high risk areas. Such findings were consistent with the decreasing trend of opioid overdose19 in New York City and the steep rise in opioid hospital visits outside New York City20. Targeted public health interventions might be effective in lowering opioid overdose mortality rates19. However, a small part of Staten Island and most part of southeastern Long Island were identified as high risk areas (High-High clusters in red color).
For the scattered outliers across New York City (High-Low outlier or Low-High outlier), further investigation and intervention efforts may be required in the future.

The spatial clustering analysis tried to answer the question of “where” by identifying potential high or low risk areas. The following question should be finding out why there were higher or lower opioid poisoning hospital visits at the discovered spatial clusters or outliers. We then used spatial regression analysis by linking demographic and socio-economic factors to opioid poisoning.

We did exploratory regression analyses between the opioid poisoning and exemplary demographic and socio-economic factors as shown in Table 4. Among the 13 spatial impact factors, the OLS regression results showed that household income, Asian population and the youth population age 20 to 24 had most significant negative correlation relationship with the opioid poisoning.

We then used GWR to model the local trends of correlation relationship between household income and opioid poisoning rates. The local coefficient map in Figure 5 showed that urban residents who made more money had lower rates of opioid poisoning, while country residents with higher income tended to had higher rates of opioid poisoning.

**Discussion**

There has long been a demand for large-scale data driven approach to discover both spatial and temporal patterns and identity potential causes of diseases. This study provided our preliminary results of a large-scale patient level study on opioid poisoning hospital visits in the New York State. We examined the demographic disparities for the patients with opioid poisoning. We compared the historical trends of opioid poisoning for hospital emergency departments visits and inpatient stays. We used frequent item mining to find co-occurrences of diagnoses for possible causes of poisoning or effects from poisoning. We performed zip code level spatial analysis to detect local spatial clusters, and studied potential correlations between opioid poisoning and demographic and social-economic factors.

This work focuses on a large-scale study of opioid poisoning related hospital visits in New York State. We found that men were more likely to have opioid poisoning hospital visits than women. Whites made 72.2% of patients that was higher than the whites proportion in general population. Asians, however, had a very low percentage of patients. We also found a peak of opioid poisoning hospital visits for young adults (21 to 25, peak at 22). A second peak is for ages
starting from middle age (46-55, peak at 51). We found several diagnoses that were well-established comorbidities of opioid dependence. The spatial clustering analysis showed that most areas of New York City had lower opioid poisoning hospital visit rates compared to that in areas outside New York City. The spatial regression results showed that urban residents who made more money had lower rates of opioid poisoning, while country residents with higher income tended to have higher rates of opioid poisoning.

However, our results were based on the patients with their primary diagnosis as opioid poisoning. In our ongoing work, we will also include the patients with their secondary diagnosis as opioid poisoning. We will examine more types of disease diagnoses and treatments and provide multi-dimensional analysis by grouping patients per their demographic attributes. We will take advantage of the street level location information and the full history of each patient for more fine grained spatial and temporal analysis. For example, after geocoding the patient addresses into latitude and longitude coordinates, we will perform point based spatial clustering analysis. By mapping patients’ residential locations into census block group boundaries, we will link the health records with census data and study potential risk factors with fine-grained spatial resolutions.

**Figure 5.** The choropleth map that visualizes Geographically Weighted Regression (GWR) local coefficient of household Income for opioid poisoning incidence rate by ZIP code in New York State, 2010-2014.

**Conclusion**

Increased accessibility of health data made available by the government provides unique opportunity for data driven discovery of disease patterns and identify potential causes of opioid related deaths. Large-scale patient level analysis could provide new insights and create new forms of value to support governments on decision making. In this paper, we present our analytical results on opioid poisoning related hospital visits using New York State SPARCS data. Our results not only provide quantitative measurements on demographic-based distributions, and spatial and temporal trends, but also present top common co-occurrences of diagnoses with opioid poisoning, which provides a groundwork to study possible causes of poisoning and effects from poisoning. Our results provide essential knowledge and guidelines to support stakeholders for improving prevention, intervention and recovery of opioid poisoning.

Determining Burden of Commuting for Treatment Using Online Mapping Services – A Study of Breast Cancer Patients

Alex C. Cheng, MS MEM, Mia A. Levy, MD PHD
1Vanderbilt University, Nashville, TN

Abstract

For patients with breast cancer who must frequent medical centers for care, commuting is a significant burden. This burden could affect their decisions during treatment. We developed a method to use census tracts and zip codes to determine commuting burden for patients with breast cancer with online mapping services, while protecting patient addresses from third parties. We found that patients who lived farther from Vanderbilt had fewer unique appointment days and more appointments scheduled per day. Total burden decreased over time after diagnosis, but advanced stage patients had sustained high levels of commute time until ten months after diagnosis. Additionally, we found that patients who lived far from Vanderbilt were less likely to receive radiotherapy from Vanderbilt. With the amount of work patients put into traveling for care, understanding commuting burden could help healthcare organizations form strategies to improve access to care and compliance with care plans.

Introduction

Traveling to and from a medical center for treatment is a significant burden to many patients with chronic conditions. In 2014, The Center for Disease Control and Prevention showed that 67% of adults in the United States had at least one encounter with the healthcare system within 6 months of the survey. The percentage of patients who saw a healthcare provider increases significantly for patients with chronic conditions. In 2013, 99% of patients with hypertension had an office-based physician visit and 47% had four or more visits. Similarly, 55% of patients with diabetes visited a physician four or more times in a year. Elderly patients, who often have difficulty traveling for care, had to travel more frequently than the average patient. In addition to the sheer number of times patients must travel to medical centers for care, patients also perceive commuting as a burden. In a survey of 1053 patients regarding factors that contributed to their treatment burden, 41% expressed that they had difficulty adapting to new routines for care that involved planning and organizing travel. Additionally, 30% of patients surveyed indicated they had difficulty with access to health care centers citing distance and parking as barriers to receiving care. Interest in treatment burden goes beyond just providing convenient care for patients. Patients who receive care within their means and are not overburdened tend to be more compliant with their treatment plans which could lead to better outcomes.

Breast cancer patients experience a high level of treatment burden. In our prior work, we demonstrated that stage I-III breast cancer patients receiving care at Vanderbilt underwent an average of 59 appointments over the course of 18 months after their diagnosis. During this time, these patients had to travel to the medical center an average of 39 times and spent approximately 49 hours in clinic. Stage III patients experienced the most time in clinic, followed by stage II and stage I patients. One reason for the intensity of treatment burden in breast cancer patients is the complexity of their treatment. Encounters included radiology diagnostics, laboratory tests, surgery, radiation therapy, and chemotherapy. Furthermore, many patients experienced additional treatment burden due to complications to their care that led to hospitalizations or the need for physical therapy.

Traveling for care is a challenge for cancer patients, particularly those living far from metropolitan areas. Travel also contributes to the burden of treatment through transportation costs. An Australian study showed that the median cancer patient spent 956 Australian dollars (about 727 US dollars) in travel costs over 16 months after diagnosis, which accounted for 71% of all out-of-pocket costs. Distance traveled could even affect patient treatment choices. One study determined that driving distance from a radiotherapy facility resulted in more patients with breast cancer choosing mastectomy instead of breast conserving surgery. While our previous studies looked at burden of treatment due to time spent in inpatient and outpatient encounters, we did not factor in the work patients put into traveling to the medical center for those encounters. The goal of this study was to use web services to calculate commuting burden over the course of treatment for patients with breast cancer.
In addition to the duration of the commute to the medical center, the mode of transportation could also be a factor that healthcare providers should consider. Researchers demonstrated United States counties and English districts where more households had access to a car had a higher rate of screening for cervical cancer. Conversely, breast cancer screening was lower in English districts with higher public transportation usage. While public transportation may be less convenient for patients receiving care for cancer, it may be some patients’ only option. While we assume that most patients who receive care at Vanderbilt arrive by car, we will explore the possibility of commuting by public transportation for our population of breast cancer patients.

Healthcare researchers have used mapping web services to improve the delivery of care. One group from the Netherlands used Google Maps to calculate the difference between driving time and helicopter flight time to help paramedics decide the most effective way to transport patients to the hospital. Services such as Google Maps are excellent at keeping up with changing traffic patterns and new roads that may affect commute times both for driving and public transportation. However, one challenge with using online services in healthcare delivery and research is that sending patient addresses to companies without a Business Associate Agreement (BAA) is a violation of the Health Information Portability and Accountability Act (HIPAA) privacy rules. Additionally, the American Journal of Public Health released an editorial stating that sending patient addresses to a third party is inappropriate and that some method of geographic imputation should be used to protect patient privacy. In our calculations of work due to travel burden, we propose a method of geographic imputation using zip codes, census blocks, and bus stops as landmarks to protect personally identifiable information (PII).

Methods

Validating the Landmarks Method

Our landmarks method is similar to aggregation techniques in public health to anonymize locations. First, we obtained all zip codes and census tract centroid coordinates publicly available on the US Census Bureau website. Nashville Metropolitan Transit Authority (MTA) granted us access to their application program interface (API) where we could pull the list of bus stops and their coordinates. We queried the Google Maps API (Gmaps) for driving times from every landmark to the Vanderbilt University Medical Center (VUMC) and back. Next, we used the Data Science Toolkit (DSTK) geocoder to determine the latitude-longitude coordinates for each of our patient addresses. The DSTK also returns a confidence level for how sure it is that the address is geocoded correctly. We installed the DSTK on virtual machine that ran on a local Vanderbilt computer, thus eliminating the need to send patient addresses to a third party.

To test this method, and to compare the accuracy of the various landmark sets (zip code, census tract, and bus stops), we applied the procedure to a set of homes for sale in the Nashville area. We queried 500 random and publicly available addresses from the Redfin.com real estate listing website on January 30, 2017. Then we compared the coordinates given by the DSTK geocoder with those given by the Gmaps geocoder. Based on the agreement between the DSTK and Gmaps geocoders, we determined a DSTK confidence threshold below which we would not trust. We queried Gmaps for driving times for each of the 500 real estate addresses and compared those to the driving times of each addresses’ respective closest landmark.

Applying the Landmarks Method to Breast Cancer Patient Commutes

After testing the method on the 500 real estate addresses, we applied the best landmark set on a cohort of breast cancer patients obtained from the Vanderbilt Tumor Registry. We included patients with stage I-III breast cancer diagnosed from January 1, 1998 to June 1, 2014. To capture only patients who received most of their first course of treatment at Vanderbilt, we only included patients who had at least three appointments each with a medical oncologist and oncology surgeon. We compared commute times for patients who lived within 100 miles of the main VUMC campus. Patient commute time for any given appointment day was the time it took to drive a round trip from the landmark closest to their home address to the Vanderbilt facility where their appointment was held. To get a characterization of the total burden of traveling, we calculated the total amount of time patients would have to spend traveling to the medical center by car over 18 months after their date of diagnosis. We also compared the behavior of commuting in patients that were farther than the median distance from VUMC with those which were closer than the median distance. We compared the frequency that patients received radiation therapy at a Vanderbilt facility between patients who were closer and those who were farther. With the coordinates of bus stops in Nashville, we analyzed the number of patients that could have feasibly traveled to their appointments via public transportation. Finally, using average commute times, we estimated the cost of commuting per patient. Assuming an average speed
of driving in Nashville of 32.4 miles per hour obtained from Google traffic data\textsuperscript{19}, and a cost of operating a vehicle of 54 cents per mile in 2016, we extrapolated the average total cost of commuting by vehicle per patient. A more accurate method would have been to use direct driving distance based on the Gmaps recommended route. However, due to Gmaps query constraints, we inferred the driving distance using average driving speed. The cost per mile comes from the Internal Revenue Service, which sets mileage rates for the cost of operating a passenger vehicle for charitable and medical purposes\textsuperscript{20}.

Figure 1. Patient addresses from the Vanderbilt Tumor Registry within 100 miles of VUMC were included in driving time calculations.

Results

Among the 500 random real estate addresses obtained from Redfin.com, the DSTK geocoder found 495 latitude-longitude coordinates compared to the Gmaps geocoder which found 483. There was generally good agreement between the coordinates found by DSTK and those found by Gmaps. Among the 425 addresses that were found by both the DSTK and Gmaps, 418 had less than a quarter mile straight-line difference between the DSTK and Gmaps coordinates. To exclude addresses that had major disagreement between DSTK and Gmaps, we only verified landmark driving times for addresses where the DSTK geocoder had at least 80% confidence. DSTK geocoded 427 addresses with at least 80% confidence.

For the addresses found by the DSTK with greater than 80% confidence, we compared driving time to VUMC using the true address and the nearest landmark. Figure 2 shows the difference in round trip driving time as calculated by Gmaps using the true address versus using the zip code centroid, census tract centroid, and nearest bus stop coordinates. Using zip codes in place of true addresses tended to overestimate driving time when the true address was close to VUMC and tended to underestimate driving time when the address was farther away. The difference in estimation time was greater than 20 minutes in some circumstances. With census tracts and bus stops, the difference in times compared to the true addresses was generally less than 10 minutes. Differences between bus stop and true address driving times increased as the distance from VUMC increased.
Figure 2. Differences in round trip driving time to VUMC between real estate addresses and nearest zip codes, census tracts, and bus stops.

For our study of commuting burden in breast cancer patients, we used the nearest census track centroid to calculate driving times. The census tract method was more generalizable and robust for addresses far from VUMC than the bus stop method. We used zip codes for patient addresses where the geocoder had less than 80% confidence. There were 768 patient addresses within 100 miles of the main VUMC campus. Among those, we used the nearest census tract to calculate commute time for 644 patients, and used zip code for 124 patients.

Figure 3. Cohort selection

The distribution of patients within 100 miles by stage was similar to the overall distribution for all stage I-III patients. There were 374 stage I patients, 273 stage II patients, and 121 stage III patients within 100 miles of the main VUMC campus. Among these patients, there was not much differentiation between stages in the distribution of a single round trip driving time from VUMC. The median driving time to and from VUMC across all stages was 76 minutes and the median straight-line distance from VUMC was 20 miles.
Figures 4 and 5. Number of patients per stage included in analysis and distribution of round trip driving times from patient addresses to main VUMC campus.

Figure 6 shows that overall burden, consisting of the sum of time in appointments, waiting time between appointments, and driving time, decreased for patients of all stages over the course of 18 months after diagnosis. Stage I and II patients saw peaks in overall burden in the first and fourth months. Overall time spent on encounters reached about 14 hours per month for stage I patients and 15 hours for stage II patients. Stage III patients had more sustained burden through the first eight months of treatment with a peak of seven hours of commute time in month eight.

Figure 6. Hours spent in appointments, waiting, and commuting over 18 months after diagnosis by breast cancer stage.

In Figure 7, there is clear differentiation in the number of unique appointment days over 18 months between patients who lived closer and farther than the median distance from VUMC. Patients who lived farther made fewer trips to a Vanderbilt facility compared to their closer counterparts in all three stages. Figure 8 shows that patients farther away also had more appointments per trip to a Vanderbilt facility across all stages.
Figure 7. Distribution of unique appointment days over 18 months for patients closer (within 20 miles) and farther (greater than 20 but less than 100 miles) from VUMC by stage.

Figure 8. Distribution of mean number appointment per unique appointment day per patient by stage and distance from VUMC.

The percentage of patients who received radiation therapy at Vanderbilt could be indicative of how commute time affected where patients decided to receive care. Table 1 shows the percentage of patients who received radiotherapy at a Vanderbilt facility compared to all patients in that group. Assuming patients within each stage required radiation therapy at approximately the same rate, stage I and stage II patients who lived closer to VUMC received radiation therapy at Vanderbilt at a rate about three times higher than those who lived farther. Stage III patients close to VUMC received radiation therapy at Vanderbilt at a rate five times higher.

Table 1. Percentage of patients who received radiotherapy at a Vanderbilt facility by stage and distance from VUMC.

Discussion

Through our attempt to calculate the burden of treatment related to commuting for patients with breast cancer, we succeeded in developing a method for calculating driving times using online mapping services that did not compromise patient PII. When deciding what type of landmark to use in our method, we decided to use a mixture of census block and zip code centroids instead of bus stop coordinates. While Figure 2 shows that bus stops are somewhat more accurate than census blocks for the real estate addresses, the accuracy gets worse the farther the address is from the city center. This effect may be because bus stops fall along major roads which become farther apart in suburban and rural areas. Additionally, since not all cities have a public transportation system, using census tracts and zip codes makes our method more generalizable.

Geomasking methods such as random perturbation or donut masking attempt to hide patient addresses by randomly moving the patient address in a radius around the true address\(^{16}\). These methods of protecting PII have the potential to be more accurate than our landmarks method since the size of the radius is dependent on the population density around the patient’s location. We did not consider using one of these methods since they each require the researcher to define a level of k-anonymity, which is the minimum number of people from which any research subject could be re-identified from\(^{21}\). It is difficult to define such a k-anonymity level that would be necessary to protect patients from an internet service. However unlikely, Google could easily target cancer treatment relevant advertisements to hundreds of people for the 1/k chance that the cancer patient in the area would receive the advertisement. Additionally, geomasking may be more useful in public health studies where spatial precision is necessary to identify sources of outbreaks\(^{22}\), but is less essential for calculating estimated driving times. As demonstrated from the comparison of commute times between true real estate addresses and census blocks, there is only a small effect on the overall commute time.

One major constraint in using online mapping services such as Google Maps for calculating driving distances is that there is a limit on the number of free requests per user. In early 2017 when we performed this study, Google Maps allowed users to make 2,500 free requests per day, with requests over that quota costing $0.50 per 1000 queries\(^{23}\). In order to maintain full de-identification for PII, we had to request driving times from every census tract and zip code centroid to every Vanderbilt location. The constraint of request quotas limited the scope of this project in several ways. Including only patients within 100 miles of Vanderbilt is reasonable since patients who live farther away may not commute daily from home. However, anecdotally, we have seen that patients who live as far as 200 miles away are driving from their homes to Vanderbilt for care. Our method included the 829 census tracts within 100 miles of...
VUMC, which could be queried for one Vanderbilt location in one day. This number jumps to 3639 census tracts within 200 miles which would require three days of free queries per Vanderbilt location (driving times to and from a location count as two requests). As we build a database of driving times, future work will include patient addresses that are farther away.

Another interesting question that we could answer with more Google Maps queries is the effect of traffic on patient commute times. One of the reasons we chose not to use open source projects such as the Open Source Routing Machine (OSRM) is because they do not have the means to collect live traffic information. Geographic Information System (GIS) software such as ArcGIS has a live traffic feed available, but only through a paid subscription. One powerful feature of modern web mapping applications is that they track typical traffic patterns to provide driving time predictions that factor in road congestion. However, ten of the census tracts within 100 miles of VUMC had fewer than 20 people living in them according to the 2010 census. The presence of low population census tracts means we would have to query every census tract for every appointment time in order to achieve full anonymity, which would become expensive to do with Google Maps. Future work could gradually save hourly driving times with traffic data to get an idea for how much traffic affects the work patients put into their care. Alternatively, we may establish a BAA with Google or another company that provides live driving time predictions.

Despite the limitations, we made several observations about the effect of commute time on cancer treatment. Aside from confirming that stage III patients experienced a higher treatment burden than stage II and stage I patients, we observed in Figure 6 that the pattern in commute time over months after diagnosis was different for stage III patients. Stage III patients experienced increased commute times in months six through eight after diagnosis despite a decrease in appointment time during that period. This increased commute time, coupled with the decrease in appointment and waiting time, may be associated with the observation that many stage III patients underwent radiation therapy after surgery. Radiation therapy procedures are typically 15 minute appointments that occur daily in rapid succession. The fact that these encounters are short but still require patients to travel to the medical center could explain the increase in commute time relative to appointment time.

Table 1 showed that patients farther from Vanderbilt received radiation therapy less often at Vanderbilt than their counterparts that lived closer. The rate that patients received radiation therapy may be high overall due to our cohort already being biased toward patients who received a majority of their care at Vanderbilt with the constraint that all patients have at least three appointments with a medical oncologist and oncology surgeon. If we assume that patients of a given stage of breast cancer require radiation therapy at approximately the same rate, then we can conclude that more patients who live farther from Vanderbilt are getting radiation therapy at other institutions. This finding supports the conclusion of Goyal et. al. that driving distance to a radiation therapy center influences breast cancer patients’ treatment path decisions. This type of information would be useful to healthcare organizations that are considering opening new radiation therapy clinics. If a new clinic knew that patients are three to five times more likely to choose to receive radiation therapy at Vanderbilt with a more convenient location, the clinic could plan capacity to meet that demand.

In discussing patient experience for commuting, one important consideration is determining patient capacity to handle a long trip to the doctor. In cities such as Nashville where a typical commute to work was more than 30 minutes in 2014, medical centers may be able to expect patients travel farther for care. However, in a city where traffic is less onerous, patients may be more sensitive to commuting long distances to a medical center regularly. Nevertheless, our calculated round trip to VUMC for the median patient was 76 minutes. This result means that even without traffic, the median patient within 100 miles of VUMC would have to drive longer than the average work commuter during rush hour.

Figures 7 and 8 have implications for care coordination in patients with cancer. The fact that patients within each stage who were farther from VUMC had fewer unique appointment days and more days per appointment suggest that some effort is being made to coordinate appointments to occur on the same day for patients who live farther away. While it may be hard to determine whether the patient or medical center staff is putting in the coordination effort, being able to track outpatient appointment coordination allows organizations to identify areas for improvement. It might be prudent for patient care coordinators or navigators to examine upward outliers in Figure 8 to see what strategies are working for patients who average more than three appointments per visit.
There are several assumptions we made in our study. First, we assumed that patient addresses in the tumor registry were accurate at the time of their diagnosis, and that patients did not move during the first 18 months of treatment. We also assumed that patients traveled from their home address each unique appointment day. It is possible that patients stayed in hotels or with relatives during the more intense parts of their treatment, which would cut down on burden related to commuting. It is also possible that the patient traveled to VUMC from their work address. There were some locations listed in the appointment record that were not primary Vanderbilt locations and thus, we did not have driving time data for them. These appointments were excluded from our analysis. Only one patient had more than 7 appointments at a non-Vanderbilt listed location. That patient still received 89% of their appointments at a Vanderbilt facility and so the influence of this outlier should negligible.

With regards to public transportation in patient commuting, the main takeaway from Table 2 is that only a small proportion of Vanderbilt’s breast cancer population would be able to take advantage of public transportation. Even if patients were willing to walk two miles to their nearest bus stop, only 263 patients would have access to public transportation. Future work might consider what is the maximum reasonable distance to expect patients with different conditions such as cancer to walk before and after their appointments. Additionally, it would be interesting to see whether there is improved access to healthcare facilities via public transportation in more densely populated cities.

Healthcare organizations could also use this method to predict patient commute times on the day of patients’ appointment. These predictions can be used to warn patients who may need to leave their homes earlier in order to avoid traffic, or to anticipate which patients may be late due to abnormal traffic conditions. Informaticians can also use calculations of commuting burden to develop tools that benefit patients. Providing patients with a mobile application to automatically calculate travel time to appointments would require consent to track their locations. However, such an application could help to alert patients of when they should leave their homes to arrive at their appointments on time. With real-time traffic conditions integrated with the appointment record, an online navigation service could recommend a driving route that avoids traffic and minimizes commuting burden.

Finally, being able to track work related to driving could also allow organizations to identify patients who may be overburdened. For example, patients who are high outliers for overall burden from appointments and procedures may benefit from a home visit from a nurse in lieu of outpatient appointment. In addition to the time requirements of cancer care, financial costs for cancer patients may lead to extreme financial distress and worse outcomes, a phenomenon known as financial toxicity. Foundations such as Susan G. Komen provide support to breast cancer patients who have difficulty affording their care. One of the programs provides financial relief to qualified breast cancer patients by giving them gas card vouchers. A healthcare organization could use information from Table 3 to request a grant from the Komen Foundation for patients under their care based on stage of cancer and travel distance.

**Conclusion**

We developed a generalizable method to calculate approximate driving times from patient addresses to VUMC locations using a third party online mapping service without sending PII to that third party. We used this method to determine the burden of treatment related to commuting for patients with breast cancer receiving care at VUMC. We found that radiation therapy made a significant impact on commuting burden due to the frequency of treatment. Also, patient’s living farther from VUMC tended to receive radiation therapy more at other medical facilities compared to those living closer to VUMC. We discovered that patients farther from VUMC had more appointments per unique appointment day, showing that their care was better coordinated. Future applications for travel time computation could equip organizations to better address the needs of their patients and help patients reduce the disruption of treatment on their lives.

ABSTRACT
Incidence of Acute Kidney Injury (AKI) has increased dramatically over the past two decades due to rising prevalence of comorbidities and broadening repertoire of nephrotoxic medications. Hospitalized patients with AKI are at higher risk for complications and mortality, thus early recognition of AKI is crucial. Building AKI prediction models based on electronic medical records (EMRs) can enable early recognition of high-risk patients, facilitate prevention of iatrogenically induced AKI events, and improve patient outcomes. This study builds machine learning models to predict hospital-acquired AKI over different time horizons using EMR data. The study objectives are to assess (1) whether early AKI prediction is possible; (2) whether information prior to admission improves prediction; (3) what type of risk factors affect AKI prediction the most. Evaluation results showed a good cross-validated AUC of 0.765 for predicting AKI events 1-day prior and adding data prior to admission did not improve model performance.

INTRODUCTION
Acute Kidney Injury (AKI) is a common clinical event among hospitalized patients, affecting 10% to 15% of all hospitalized patients and >50% of patients in intensive care units (ICUs)1-3. AKI is most easily detected on the basis of the acute sustained rise of serum creatinine (SCr). Using a large consecutive sample of 19,982 adults, Chertow et al. found that an increase in SCr of ≥ 0.5 mg/dl is associated with a 6.5-fold increase in the odds of death, a 3.5-day increase in in length of stay, and nearly $7,500 in excess hospital cost4. Over the past two decades, the incidence of AKI has increased significantly in North American and Europe, particularly within the United States, because of the rising prevalence of acute and chronic conditions, such as sepsis, heart failure, and diabetes5-9. Moreover, the role of medications in the changing epidemiology of AKI has increased from 7% to 16% over a 17-year span because of the wide availability of potential nephrotoxic drugs2, 10.

Unfortunately, the current care of patients with AKI is suboptimal characterized by numerous deficiencies and systematic failings that may be avoidable11. In a 2009 review of the care of patients who died in hospital with a primary diagnosis of AKI, an unacceptable delay in the recognition occurred in 43% of the patients and 20% of the cases could have been prevented with early detection12. It is however difficult for clinicians to recognize at-risk patients prior to their AKI episodes. Once an AKI episode occurs, there is no treatment to mitigate or cure AKI13-16. According to the International Society of Nephrology17, recognizing patients at risk of developing AKI and managing these patients according to their susceptibilities and exposures is likely to result in better outcomes than merely treating the established AKI. Therefore, the ability to predict AKI in hospitalized patients and monitor them at an early stage is crucial to AKI prevention.

Safety tools based on electronic medical records (EMRs) for in-hospital AKI surveillance covering kidney injury triggers have been developed; examples include the Global Trigger Tool18, a tool that uses the Acute Kidney Injury Network (AKIN) definition to monitor AKI19, and dosing tools for improving compliance with renal-dosing of medications20, 21. EMR-based AKI monitoring can expedite interventions and lead to a high percentage of patients retaining their baseline kidney function22, 23. However, as the major limitation of these tools, physicians can only react after observing signs of damage. By contrast, risk prediction would recognize high-risk patients for tailored early management. Most existing AKI risk prediction models focus on predicting adverse outcomes following AKI24 or predicting AKI after specific surgeries and interventions1, 3, 25, 26. There exists some predictive modeling work performed on the critical care populations27-29, but much less work on the general inpatient population30. Matheny et al31 proposed the first study to predict general in-hospital AKI using logistic regression models. Recently, Kate et al32 built machine learning models to examine the difference in prediction vs. detection of AKI in hospitalized older adults.
This study aims to build machine learning models to predict the development of AKI among general patient hospitalizations at daily intervals prior to the event. The primary objective is to assess how early and accurately the development of inpatient AKI can be predicted. The secondary objective is to assess whether clinical data prior to admission enhance the predictive models.

METHODS

Data Collection

A retrospective cohort of 60,534 patients was collected by including adult admissions (age at visit between 18 and 64) to a tertiary care, academic hospital (the University of Kansas Medical Center – KUMC) from November 2007 to March 2016 with a length of stay of at least 2 days. Given that a patient may have multiple admissions (encounters) of at least 2 days and develop AKI during one but not another, this study is conducted at the encounter level with the initial cohort of total 109,319 encounters. For each encounter, we queried the KUMC de-identified clinical data repository HERON (Health Enterprise Repository for Ontological Narration) that integrated electronic health records, billing, clinical registries, and national data sources to obtain structured data on admission and discharge dates, patient demographics, medications, laboratory values, vitals, comorbidities and admission diagnosis.

Cohort Inclusion/Exclusion Criteria

From the initial cohort of 109,319 encounters, we selected an analysis cohort of encounters by excluding those (a) missing necessary data for outcome determination – less than two serum creatinine measurements and (b) had evidence of moderate or severe kidney dysfunction – estimated Glomerular Filtration Rate (eGFR) less than 60 mL/min/1.73 m² or abnormal serum creatinine (SCr) level of >1.3 mg/dL within 24 hours of hospital admission. The final analysis cohort consisted of 48,955 encounters (33,703 patients).

AKI Definition

AKI was defined using the Kidney Disease Improving Global Outcomes (KDIGO)-based modifications of the AKIN and Risk, Injury, Failure, Loss, and End-Stage (RIFLE) Kidney classification criteria. According to KDIGO, adults who demonstrate any of the following are undergoing an AKI episode:

- Increase in SCr by ≥ 0.3 mg/dL (≥ 26.4 micromol/L) within 48 hours
- Increase in SCr by ≥ 1.5 times the baseline within the previous 7 days

The baseline creatinine level was set as either the last measurement within 2-day time window prior to admission or the first available measurement during the stay. All creatinine measurements between admission and discharge were evaluated to determine the occurrence of in-hospital AKI. Based on the above AKI definition, this study classifies each encounter as ‘with AKI’ (positive) or ‘without AKI’ (negative). Out of total 48,955 encounters in the final analysis cohort, patients acquired AKI during 4,405 (8.99%) encounters.

AKI Risk Factors

A list of clinical variables used in building the AKI prediction models is described in Table 1. We referred to Matheny et al. to select laboratory tests that may represent potential presence of a comorbidity that is correlated with in-hospital AKI. For example, an elevated white blood cell count (WBC) is associated with bacterial infection that may cause AKI. Serum creatinine was not included as a variable as it was used to determine the positive and negative samples. For laboratory tests and vitals, only the last recorded value before a prediction point was used and their values were categorized. Laboratory values were categorized as either “present and normal”, “present and abnormal”, or “unknown” according to standard reference ranges. Vitals were categorized into groups as shown in Table 2. Missing values in vitals and lab tests were captured as “unknowns” because information may be contained in the choice to not perform the measurement.

Medication variable included inpatient (i.e., dispensed during stay) and outpatient medications (i.e., historical meds). All medication names were normalized by mapping to RxNorm ingredient. Comorbidity and admission diagnosis, i.e., all patient refined diagnosis related group (APR-DRG) variables were collected from the University Healthsystem Consortium (UHC) data source in HERON. Comorbidity, medication, and admission diagnosis variables took either “yes” or “no” values.

In the final dataset, vitals, lab test, and medication variables were time-stamped (with resolution to the hour and minute) relative to the admission date, referred here as time-dependent variables. Comorbidities, admission diagnosis, and demographics were presumed to be available at admission and not time-dependent.

Evaluation Design

Model evaluation was designed to answer three specific questions: (1) Will data prior to admission improve predictive models’ performance; (2) How early and accurately can AKI be forecasted; (3) How strong each type of risk factors affects the model performance. In this study, we introduced a data collection window, denoted as \([\text{lower\_bound}, \text{upper\_bound}]\). For the first question, we assessed model performance by varying the window’s lower bound with a fixed max upper bound set at 1-day prior to AKI event, i.e., making AKI prediction 1-day prior using different amount of clinical data (Figure 1). The initial data collection window’s lower bound is set at admission and we increased its width with resolution to the day.

![Figure 1. An illustration of adjusting the lower bound of data collection window before the admission date](image)

For the second question, we assessed model performance by lengthening the interval between the prediction time and AKI event (Figure 2). For AKI encounters, AKI event date was used as an anchor for moving the prediction point. For non-AKI encounters, discharge date was used as the anchor point.

To illustrate with an example, patient X was admitted to the hospital on 2015-06-05 (\(\text{Admission\_date}\)) and developed AKI on 2015-06-07 (\(\text{AKI\_date}\)), then the initial data collection window for prediction 1-day prior to AKI occurrence would be \([\text{Admission\_date}, \text{AKI\_date} - 1]\) which is [2015-06-05, 2015-06-06]. For a non-AKI example, patient Y
stayed at the hospital between 2014-02-15 (Admission_date) and 2014-02-18 (Discharge_date), then the data collection window for prediction 1-day prior would be [2014-02-15, 2014-02-17]. To assess whether adding data 1-day prior to AKI would improve predictive performance, the data collection window becomes [Admission_date – 1, AKI_date – 1]; thus for patient X, it becomes [2015-06-04, 2015-06-06]. To assess whether an accurate prediction can be made 2-days prior to AKI, the window upper bound will be AKI_date – 2. In conclusion, there are two parameters to adjust for evaluation: Admission_date – m is the mth day before the hospital admission date and AKI_date – n is the nth day before AKI occurrence date.

For the third question, we adopted two approaches to evaluate the strength of each group of risk factors (i.e., demographics, labs, vitals, medications, and comorbidities) used in the model. In the first approach, we removed one group of attributes and trained the predictive models on the remaining four groups of attributes, resulting in five transformed datasets. In the second approach, we trained the predictive models with only one group at a time. Thus, another five transformed datasets were obtained, each of which only contains one group of attributes.

**Experimental Methodology**

Three different machine learning methods – Logistic Regression37, Random Forest38, and AdaboostM139 were used for building predictive models using the Weka software library40. The number of decision trees in Random Forest model was 100. For AdaBoostM1, the iteration number was 500, using DecisionStump as the base learner. All models were evaluated using the standard 10-fold cross-validation.

The area under the receiver operating characteristic curve (AUC), precision and recall are used to report and compare performance of the models. AUC provides a single measurement of the performance of an ROC curve, which is a graphical plot of the sensitivity or true positive rate against the false positive rate (1 - specificity). Sensitivity is the proportion of actual positives that are correctly identified as such (i.e. SN = TP/(TP+FN)) and specificity measures the proportion of actual negatives that are correctly predicted as such (i.e. SP = TN/(TN+FP)). Precision is the proportion of true positives against all predicted positive results (i.e. P = TP/(TP+FP)). Recall is the same as the true positive rate or sensitivity.

Our datasets are highly imbalanced with an approximate 1:10 positive (AKI) to negative (non-AKI) ratio. With such an imbalanced dataset, most classifiers will favor the majority class (non-AKI) because they are designed to maximize the overall number of correct predictions, thus resulting in poor accuracy in the minority class (AKI) prediction. Current state-of-art correction techniques to account for class imbalance are generally data-based and algorithm-based approaches41. The data-based approach uses sampling technique by either under-sampling the majority class or over-sampling the minority class. The algorithm-based approach modifies the classification algorithm such as through adjusting decision threshold. In this study, we under-sampled the majority class by randomly selecting a subset of non-AKI samples such that AKI to non-AKI sample ratio is 1:1. Hence a model performing better than random classifier must achieve an AUC larger than 0.5.

**RESULTS**

**Data Characteristics**

Distribution of patient demographic variables in AKI and non-AKI encounters is listed in Table 3. In our cohort, the odds ratio between AKI and non-AKI is not significant for all age groups; however, it does increase with age which is also observed in Matheny et al31. Odds ratios for gender and race are also within similar range as reported31.

Table 9 and Table 10 show the experimental results of the Random Forest model on processed data by removing one group of attributes and by reserving one group of attributes respectively. These two series of experiments were performed to assess the range of the affect size of each risk factor group on prediction.

**DISCUSSION**

In this study, we built machine learning based AKI prediction models using structured EMR data for patients admitted to a hospital. Experimental results showed a good cross-validated discrimination performance, best AUC of 0.76 achieved by Random Forest for predicting AKI event 1-day prior, which was similar to other AKI risk stratification models that have been created for general inpatients (0.75)\(^{31}\), elderly (0.66)\(^{32}\), more specific clinical scenarios (0.74 to 0.77), and patients who have undergone coronary artery bypass grafting (0.72 to 0.81)\(^{1,3,25,26}\). To ensure that the classifier output is not affected by the different splits generated by the 10-fold cross-validation, we
examined variance of the AUC, precision, and recall measures by applying the Random Forest model on dataset with a collection window of \([\text{Admission\_date}, \text{AKI\_date} – 1]\). The standard deviations of AUC, precision and recall are 0.01, 0.01, and 0.02 respectively, which shows that there was no great variance in the 10-fold cross-validation.

For the primary objective, we assessed how early and accurately general inpatient AKI can be predicted. Results in Tables 7 and 8 showed that model performance indeed degrades as the time window between the prediction time and AKI event time lengthened, from Random Forest’s AUC of 0.76 at 1-day prior to 0.67 at 5-days prior. While comparing different machine learning algorithms, results in Table 7 showed that Random Forest achieved the best cross-validated AUC of 0.76 for predicting AKI 1-day prior but when the time to event horizon is lengthened to 4 or 5-days prior, AdaBoostM1 had a slightly better AUC than Random Forest. However, in terms of precision and recall in Table 8, Logistic Regression actually had better precision with the same or better recall compared to Random Forest for 1 and 2-day prior, respectively.

In order for a predictive model to be clinically useful, the 15th Acute Dialysis Quality Initiative (ADQI) consensus conference\(^{30}\) in 2016 recommended forecasting AKI events with a horizon of 48 to 72 hours. Although it would be advantageous to predict AKI events as early as possible, lengthening the prediction time to event horizon will reduce accuracy and the ADQI consensus group believes that 2 to 3 days would give physicians adequate time to modify practice, optimize hemodynamics, and mitigate potential injury without sacrificing too much in predictive power\(^{30}\). Our study showed that the best performing model with Random Forest can forecast AKI 2-days and 3-days prior with AUC of 0.73 and 0.70, respectively.

For the secondary study objective, we assessed whether adding data prior to admission would improve model performance where the data collection window was extended to 1, 7, 15, and 30 days before admission. One would intuitively think more data is better, but the contrary was observed in results (Table 5 and 6). As the study cohort contains encounters with various length of stay and the number of days AKI occurs relative to admission in the positive samples varies greatly from 1 day to 359 days, we suspect additional data prior to admission may impact model performance differently for patients who develop AKI on the day after admission vs. five days after because amount of data available during stay is dramatically different. Therefore, we conducted an analysis on encounters in which AKI occurred 1 day after admission, comparing Random Forest’s performance with (i.e., 1 and 7 days) and without data prior to admission. Interestingly, analysis results on this sub-cohort exhibited the same trend as observed in the complete cohort, where AUC for only using data after admission is 0.84 vs. AUC for adding data from 1-day before admission is 0.81 and 7-days prior is 0.80. This implies adding data prior to admission does not improve AKI prediction performance in the general inpatient AKI population. This prompts us to further analyze the impact of using data from the entire encounter vs. only previous day on prediction performance.

We further screened data with the time window \([\text{AKI\_date}-1, \text{AKI\_date}-1]\), i.e. using data on the day of prediction and compared the performance with using data collected within \([\text{Admission\_date}, \text{AKI\_date}-1]\). Based on results in Table 11, it seems to imply that prediction using the most recent one-day data can improve AUC and precision at the expense of degrading recall ratio. F-score decreased from 0.701 to 0.687 in contrast to the AUC increase from 0.765 to 0.783. However, this may also suggest the models were overfitting the temporal clinical variables relative to the static demographics, admission diagnoses, and comorbidities. Evaluating the contribution of each clinical variable and refining their representations are future directions for this research.

**Table 11.** Comparing performance (AUC/Precision/Recall) on entire hospitalization data vs. recent one-day data

<td>0.768 / 0.709 / 0.709</td>
</tr>
</tbody>
</table>

For the third objective, we assessed the effect size of each risk factor type in AKI prediction by applying the Random Forest model on datasets with a collection window of \([\text{Admission\_date}, \text{AKI\_date} – 1]\). Based on results in Table 9 and Table 10, medications play the biggest role in the 1-day prior AKI prediction performance followed by the combination of admission DRG and comorbidity. This is promising as medications are modifiable and clinicians may consider alternative therapies. The demographics variables had the least effect on prediction performance, which may be due to the fact that we limited our cohort to a younger cohort of 18 to 64 year olds and utilized encounter-level rather than patient-level data for prediction. A patient may have multiple hospital encounters that satisfy the cohort inclusion criteria and he/she may experience AKI in one encounter and not in another. Thus, the
same patient can belong to both the AKI and non-AKI class, making it difficult for algorithms to distinguish the two classes based on the patient-level demographic information.

**Limitations**

There are several limitations in the interpretation of results in this study. First of all, the predictive models were based off a younger cohort (18 to 64 years old at admission), which may not be generalizable to an older cohort. Elderly is known to be at increased risk for AKI due to longer exposure to chronic diseases and nephrotoxins, thus our future studies will conduct independent subpopulation analysis for the elderly. Second, we limited the analysis to patients who were admitted to the hospital with a minimum eGFR of 60 mL/min/1.73m² and must have normal serum creatinine on the day of admission. Although patients with reduced eGFR are at increased risk for AKI, it is difficult to determine which of these patients had hospital-acquired vs. community-acquired AKI. Third, comorbidity data utilized in the predictive models were obtained from UHC, which is widely known to be well adjudicated, but not immediately available. This study treated UHC comorbidities as non-time dependent as if the clinical team would know all comorbidities at admission, which may misrepresent comorbidities that developed during the admission. Future studies will evaluate the performance of diagnosis codes from the EMR problem list relative to comorbidity information derived from billing systems. This may change the results we observed in this study that data prior to admission does not improve performance and also more accurately represent the information available to the clinical team to support adverse event surveillance. Last but not least, the study did not use urine output to define AKI nor include it as a risk variable. Although urine output is one of the diagnostic criteria of AKI, many members of the Acute Kidney Injury Network (AKIN) concerned that urine output is not specific enough for the designation of AKI because it can be influenced by factors other than renal health.

**CONCLUSIONS**

Predicting AKI early and accurately allows clinicians to take timely preventative or therapeutic measures. This study investigates the impact of data completeness and prediction time points on the performance of forecasting in-hospital AKI in a general inpatient population. Three machine learning algorithms, Random Forest, AdaBoostM1, and Logistic Regression, were built on clinical datasets screened with different data collection windows. The Random Forest classifier outperformed Logistic Regression and AdaBoostM1 with AUC values for 1, 2, and 3-days prior being 0.765, 0.733, and 0.709, respectively. In this study, the data prior to hospital admission did not improve prediction performance and medication played the biggest role in prediction performance.

Specifications of Clinical Quality Measures and Value Set Vocabularies Shift Over Time: A Study of Change through Implementation Differences

Raja A. Cholan, BS, Nicole G. Weiskopf, PhD, Douglas L. Rhoton, Nicholas V. Colin, MA, Rachel L. Ross, BA, Melanie N. Marzullo, BS, Bhavaya Sachdeva, MPH, David A. Dorr, MD, MS; Oregon Health & Science University, Portland, Oregon

Abstract

Clinical quality measures (CQMs) aim to identify gaps in care and to promote evidence-based guidelines. Official CQM definitions consist of a measure’s logic and grouped, standardized codes to define key concepts. In this study, we used the official CQM update process to understand how CQMs’ meanings change over time. First, we identified differences between the narrative description, logic, and the vocabulary specifications of four standardized CQMs’ definitions in subsequent versions (2015, 2016, and 2017). Next, we implemented the various versions in a quality measure calculation registry to understand how the differences affected calculated prevalence of risk and measure performance. Global performance rates changed up to 5.32%, and an increase of up to 28% new patients was observed for key conditions between versions. Updates to definitions that change a measure’s logic and choices to include/exclude codes in value set vocabularies changes measurement of quality and likely introduces variation by implementation.

Introduction

From a public health perspective, the central goal of the health care system is to increase population health; one way of measuring that effect is by determining the quality of care delivered. The Institute of Medicine defines “health care quality” as “the degree to which health care services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge.”1 Electronic clinical quality measures (CQMs) intend to measure quality by tracking various evidence-based elements of structure, process, and outcomes using clinical data recorded in Electronic Health Record systems (EHRs).2, 3 Although this measurement quality goes back more than a decade, CQMs have become fundamental parts of payment and health care; for instance, the Quality Payment Program, following the Medicare Access and CHIP Reauthorization Act of 2015, proposes to adjust clinicians’ Medicare payments in 2019 between -9 and +9% depending on CQM data submitted by individual clinicians in 2017 and 2018.4

Quality-based payment programs like the Quality Payment Program, typically require measures that are endorsed by the Centers for Medicare and Medicaid Services (CMS), and/or the National Quality Forum (NQF), in order to improve the reliability and validity of CQMs.5-7 These standardized electronic measures have specific definitions and logic encoded in the “Health Quality Measure Format” (HQMF), a Health Level Seven International standard for representing CQMs. HQMFs include machine-readable specifications encoded in Extensible Markup Language, as well as human-readable descriptions of the measure logic and components.8 The HQMF for a CQM assessing the use of aspirin or another antithrombotic for patients with ischemic vascular disease (CMS164; NQF0068), for example, provides computable and human-readable definitions of the measure’s denominator criteria (e.g., patients aged 18-85 years of age with ischemic vascular disease), those who meet the measure’s numerator criteria (e.g., patients taking aspirin medication), and those who are excluded from the measure’s calculation (e.g., patients taking anticoagulant medications). Official CQMs are also defined using value sets, which encode pertinent clinical concepts into controlled terminologies. Value sets are grouped codes from standardized vocabularies (e.g., SNOMED CT, RXNORM, ICD-10-CM, LOINC) in the Quality Data Model and consist of clinical concepts (i.e., value set names), and concept definitions (i.e., code groups) to define a measure’s specifications.

Each year, CMS updates the electronic specifications of the CQMs it approves for submission to its various reporting programs and publishes updated HQMFs in their “eCQM Library”.9 The National Library of Medicine’s Value Set Authority Center (VSAC), subsequently, in collaboration with the Office of the National Coordinator for Health Information Technology, updates its electronic value set definitions at regular intervals, based both on these annual updates and on changes in the terminologies themselves.10, 11 For the aforementioned Aspirin measure, between 2015 (i.e., CMS164v4) and 2017 (i.e., CMS164v5), the HQMF was updated once with new exclusion criteria (patients taking anticoagulant medications) – evidence shows that these patients have an increased risk of bleeding.12 The value sets that define the concepts “ischemic vascular disease” and “acute myocardial infarction” also changed twice between versions with the addition of several ICD-10-CM, ICD-9-CM, and SNOMED CT codes.

A CQM is implemented by mapping the right clinical data from the right sources in the EHR to generate a CQM performance score. Many clinics may not have the skills to interpret the encoded HQMFs/value sets, or the technical capacity to implement custom queries for generating CQM performance data. Therefore, they might increasingly rely on the use of Office of the National Coordinator Certified EHR Technology, or a recognized quality
measure calculation registry, such as the American Board of Family Medicine’s PRIME Registry, for CQM reporting. Regardless of the data source used to generate CQM data – whether it is a certified EHR, registry system, or custom query – CQM implementations should reflect the most up-to-date standards and specific criteria encoded in official HQMFs and value sets. However, for clinics that rely on external measure implementers, it can be difficult to verify whether or not CQM specifications align with the standardized, most-updated CQM definitions and versions. As technical assistance providers for a large primary care practice transformation initiative, we helped 93 clinics in Oregon leverage technology to produce and improve CQMs. Of these clinics, 77% have generated and reported aggregate, practice-level data for the Aspirin measure. Of these (as of Quarter 1, 2017) roughly 1/4 have updated to the 2016/2017 version definition and 3/4 still use the 2015 version. Additionally, sampling the 23% that have custom CQM implementations demonstrate partial value sets and approximate measure logic due to current report-building system limitations. EHR and registry vendors, meanwhile, typically include official CQM identifiers (e.g., NQF ID, CMS ID) but do not always explicitly provide a measure’s version, and rarely provide details about query logic, or specific code sets used. As CQM reporting continues to be operationalized, clinicians could unknowingly have outdated implementations of CQMs, and innocuously report these data with the intent of reporting current CQM versions; and, CMS could unknowingly compare data from different versions of the same CQMs to benchmark clinics and adjust Medicare payments. National quality reform programs and practice transformation efforts need standard representations of CQMs to enable consistent reporting and comparison between clinics across the country. However, the impact of these implementation variations is unknown and dependent upon how substantial the differences between versions are.

Many of these version changes are related to terminology design and evolution, while others may be related to actual evidence changes. Vocabularies like ICD-10-CM, RxNorm, and SNOMED CT, for instance, have a strict hierarchical structure – with differing levels of granularity, concept orientation, and consideration of redundancy – to define various clinical concepts. Value set authors and measure developers, therefore, make choices about the specific codes to include/exclude when defining broad clinical concepts such as stroke or diabetes, for example. In previous work, we identified that key differences in the value set creation process for two similar definitions of the same CQM led to variations in the calculated prevalence of patients at high-risk from key conditions. More challenges arise when value set vocabularies are periodically updated, as some terms and codes may change meaning over time. Cimino noted this previously: “if a concept is changed in such a way as to alter its meaning, what happens to the ability of the aggregated patient data that are coded before and after the change?” Yu and Cimino studied code changes to annual ICD-9-CM codes and found that the meaning of terms may drift, but the original codes in the clinical data remained the same: “researchers who make use of multi-year ICD-9-CM data are actually unaware that the meaning of their data are changing over time.” Other changes may reflect evidence changes, such as recommendations to treat patients with coronary artery disease with antiplatelet agents when they are also on antithrombotics.

With the advent of the Quality Payment Program, regular CQM reporting will continue to increase in importance. Standardized and up-to-date CQM implementations are crucial for quality-based reform programs to compare impact on population health and to facilitate performance improvement, but the reality in clinics is that CQM implementations may not always adhere to the latest versions. Studying the impact of CQM definition updates, and examining code drift, and taxonomy shifts, in value set vocabularies might help in understanding one aspect of the vast variation that exists in current CQM implementations. In this study, our objective is to use the official CQM update process to better understand how updates to official CQM definitions and value sets may change the interpretation of CQMs’ meanings over time. Our aims are to:

1. Identify the common differences for select CQM definitions that may occur as part of regular updates;
2. Understand how variations in old and current HQMFs and value sets for the same CQMs change a measure’s meaning through implementation differences in a CQM calculation registry;
3. Discuss suggestions for disseminating updates to CQM definitions and value sets to implementers.

Our hypothesis was that the variation caused in the CQM definition and value set annual update process would lead to differences in measure populations and performance estimates.

**Methods**

**Overview:** We identified differences between the narrative description and logic of four CQM definitions from the 2015, 2016, and 2017 versions of the measures. We then identified differences in the vocabulary specifications – unique identifiers, concepts, code groups, and coding systems – between the various value sets used to define the same global concepts in each annual version. Next, we implemented the various versions in a quality measure calculation registry to understand how the differences in the annual value sets and measure logic affected calculated prevalence of risk and measure performance.

Measure Inclusion: We first selected four standardized CQMs listed in Table 1 to include in this study. Each of these are included in the Quality Payment Program’s Merit-based Incentive Payment System as official 2017 CQMs. We chose these specific measures because they include value sets defining a variety of key conditions: ischemic vascular disease and overlapping cardiovascular disease, diabetes, and heart failure. In this study, we assessed implementation changes between older and newer versions of these four measures, and explored specific code variations of the value sets used to define the clinical concepts, and related them to taxonomy structure.

HQMF and Value Set Analysis: We compared the human-readable definitions contained in HQMFs of the four measures listed above, and noted any changes to the narrative description or encoded logic in the measures’ criteria between three subsequent versions – 2015, 2016, and 2017. We then searched for the four CQMs in the VSAC and downloaded each annual value set included in each version’s specifications. Next, we counted the unique object identifiers (OIDs) used to specify distinct concepts, and the codes from standard vocabularies that define each category.

Measure Implementation and Comparison: Next, we implemented the various versions of the four measures in the Integrated Care Coordination Information System (ICCIS), a quality measure calculation registry, to understand how the differences in the measure specifications affected calculated prevalence of risk and measure performance. ICCIS contains data mapped from a variety of sources from over 500,000 patients into a star database format that facilitates value set queries. Implementation of CQMs in ICCIS currently requires processing of human-readable CQM definitions and writing queries in Structured Query Language (SQL) against clinical sources to calculate CQM performance. After interpreting the HQMFs for the four selected CQMs, we implemented queries in ICCIS following the specific criteria for each annual version, and queried against the specific OIDs used in each version. Then, the “Aspirin Use” and “Cholesterol Management” CQMs – two of the more complex measures – were divided into sub-measures for each aggregate clinical concept to see which concepts, taxonomies, and individual codes were most responsible for the performance rate.

Data Inclusion Criteria: The measures were implemented against data from two primary care clinics serving approximately 25,000 patients in Portland, Oregon. The clinicians in each clinic used a fully functional EHR in their ambulatory work. We chose to implement the measures using data from these two clinics because they had high quality, suitable, structured data in the ICCIS database to generate reliable quality measure performance rates. The
clinics excluded from our analysis did not have an adequate average number of medications per patient stored as structured data in the ICCIS database; therefore we could not have reliably queried whether the patients were taking aspirin, statin, anticoagulant, or beta-blocker medications.

**Analysis.** To compare the changes in the measure definitions over time, we counted the individual codes in each value set, the taxonomies included, and measured the percent change of the value set codes (newly included and excluded codes) from 2015 to 2017. We then calculated performance rates at the same point in time with a 1 year measurement, or look-back period, and compared the included populations, the exceptions/exclusions, and overall performance.

**Results**

Of the four CQMs, the Aspirin measure’s HQMF was the only one with a change in its logic (added exclusion criteria) between 2015 and 2017 versions. The other three measures’ HQMFs remained constant. There were, however, changes in all four measures’ value set vocabulary definitions. An overview of the clinical concepts with code group changes between the 2015, 2016, and 2017 versions of the measures are found in Table 2. Overall, there were 64 concepts that remained constant between versions, and 11 concepts with code changes, of which eight (73%) resulted in an increase in count of codes, and three (27%) decreased in codes between 2015 and 2017 versions. Of those that changed, five (46%) concepts represented denominator criteria, two (18%) were for exceptions, one (9%) was for exclusions, and three (27%) represented numerator criteria. The seven value sets which represented denominator and exception criteria defined key diagnoses and were made up of ICD-10-CM, ICD-10-PCS, ICD-9-CM, and SNOMED CT codes. The concept “Percutaneous Coronary Intervention” (PCI) had the biggest increase in code count with the addition of 96 inpatient procedure (ICD10PCS) codes used to describe “dilation of coronary arteries”. The diagnosis “diabetes” increased in code count by 74%, with 167 new codes, of which 157 were ICD-10-CM codes describing specific diabetes diagnoses involving retinopathy, and the remainder were generic ICD-9-CM codes. The concept “acute myocardial infarction” (AMI) had a 58% increase in code count; all of the newly added codes were ICD-10CM codes.

Table 2. Differences in CQM vocabularies by concept and criteria for 2015, 2016, and 2017 versions
and ICD-9-CM codes describing “subsequent ST elevation (STEMI)”, “septal defects”, and “other current complications from AMI”. The codes used to define “ischemic vascular disease” (IVD) also increased by 40% with several new ICD-9-CM and ICD-10-CM codes to describe “atherosclerosis of bypass graft(s)”, “cerebral infarction”, and “unspecified atherosclerosis”. While the Aspirin and Cholesterol measures had a net increase in the number of codes included in their respective aggregate value sets, both also had codes deleted between the 2015 and 2017 versions. The Aspirin measure had nine codes removed: two were ICD-9-CM/ICD-10-CM codes to define “angina pectoris” for the concept IVD, and seven were RXNORM codes (Semantic Clinical Drugs or SCDs) to define various dosages of oral aspirin tablets/capsules. In the Cholesterol value sets, 14 ICD-9-CM/ICD-10-CM codes were removed for “pregnancy diagnoses”, “IVD” (2 codes for “angina”), “ischemic stroke” (1 code describing general cerebrovascular disease), and “hemorrhagic stroke” (3 codes describing nontraumatic subarachnoid hemorrhage); three SNOMED CT codes were also deleted for “CABG surgeries” (“aortocoronary artery bypass graft”), “ischemic stroke” (‘other cerebrovascular disease’), and “medical reason” (‘history of drug allergy’). The Heart Failure measure had 15 deleted codes: seven were SNOMEDCT codes to define “CABG surgeries” (‘aortocoronary artery bypass graft’), “ischemic” stroke (‘other cerebrovascular disease’), and “medical reason” (‘history of drug allergy’). The Heart Failure measure did not have any codes deleted between versions.

Table 3 shows the CQM performance results between the 2015 and 2017 versions of various implementations of the composite measures and aggregate concepts; it also shows the number of newly included and excluded patients between versions. The results in Table 3 only reflect performance data for the CQM implementations which exhibited a change in performance rates between versions. The 2017 version of the Aspirin measure, with the added exclusion criteria, had a 5.32% better performance rate than the 2015 version, and the denominator returned 119 (9%) fewer patients. The stand-alone implementation of the Aspirin measure for the AMI concept returned 24 (17%) more patients in version 2017 with an increase in performance rate of 2.62%. The composite Cholesterol measure had similar results between versions, with virtually identical adherence rates and denominators. The AMI-only version of the Cholesterol measure returned 37 more patients (27%) in the 2017 version, while the performance rate decreased by 2.31%. The stand-alone implementations of the Cholesterol measure for IVD and Diabetes had similar results with performance rates increasing by less than 1% between versions. We also implemented stand-alone versions of the Cholesterol measure for the aggregate concepts “ischemic stroke” and “PCI”; however, these versions did not change between 2015 and 2017 versions and the results are not included in Table 3. The Diabetes CQM had very similar performance rates between versions, with the 2017 version increasing in performance rate by 0.14%. The Heart Failure measure is not included in Table 3; it had identical performance results between versions with adherence rates of 83%.

Table 3. CQM performance that changed between 2015 and 2017 versions by composite measures & sub-concepts
Figure 1 shows the amount of overlap, the number of newly included patients, and the number of dropped patients between the 2015 and 2017 versions of the Aspirin composite measure. The 2017 version of the Aspirin denominator included 13 (1.1%) new patients, while dropping 132 (10.2%) patients included in the 2015 version. The 2017 version of the Cholesterol measure included 14 (<1%) new patients while dropping 10 (<1%) patients from the 2015 cohort. For the Diabetes measure, 11 (<1%) new patients were included in version 2017; 0 patients were dropped from the denominator.

Figure 1. Overlap of patients included in denominators between 2015 and 2017 versions of composite Aspirin CQM

The differences in the distinct patients between the 2015 and 2017 versions’ denominators are attributed to the codes in one version’s value set that are not included in that of the other (in addition to the Aspirin measure’s new exclusion criteria). Tables 4a and 4b show some of the distinct ICD-9-CM/ICD-10-CM codes between versions and their prevalence in the composite measure results, and the prevalence in newly added/dropped patients. For the AMI concept, one newly added ICD-10-CM code (I25.2) accounted for 2.58% of all patients included in the 2017 Aspirin composite denominator, and 92% of the newly added patients in version 2017. In the Cholesterol measure, the code details and prevalence in measures.

Tables 4a & 4b. Distinct ICD-9-CM and ICD-10-CM code details and prevalence in measures
the same ICD-10-CM code for AMI, I25.2, accounted for 1.51% of the overall 2017 denominator, and 71% of the newly added patients in version 2017. For the diabetes measure, two newly added ICD-9-CM codes (250.4, 357.2) made up about 64% of the newly included patients in version 2017, and almost 11% of the composite denominator.

Finally, the three numerator value sets with code changes (“Aspirin and Other Antiplatelets”, “Beta Blocker Therapy”, “Beta Blocker Therapy Ingredient”), and the exclusions value set with code changes (“Anticoagulant Medications”) all represented drugs, and therefore solely consisted of codes from the RXNORM hierarchy. Most of the changes to these RXNORM concepts between 2015 and 2017 versions involved the addition of Semantic Clinical Drugs (SCDs) in the newer value sets. The Heart Failure CQM, however, had one code deleted in the 2017 version at the ingredient level, removing “Hydrochlorothiazide” from the value set. The Aspirin measure had one Generic Clinical Product (GPCK) in its newly added value set for “anticoagulant medications”. Figure 2 shows the RxNorm hierarchy and the counts of codes at various levels for the Aspirin measure and Heart Failure measure for the concepts “Aspirin” and “Beta Blocking Therapy”. In total, all four measures’ 2017 version value sets consisted of 297 distinct SCDs, but only 69% (187) of these were mapped in the clinics’ EHR from which the data in ICCIS was extracted. Of the mapped SCDs, 57% (106) are used in the clinics, and returned patient IDs in the ICCIS database. The top 20 SCDs, of those mapped and used, account for 53% of patients who are associated with one of the mapped codes.

**Discussion**

**Shifts in Knowledge.** In this study, we examined two types of shifts that may occur as part of regular updates to standardized CQM specifications. The first is a shift in knowledge. For example, the Aspirin measure was updated to adhere to the evidence-based guideline to exclude patients who are taking anticoagulants from aspirin therapy. We identified substantial differences between the 2015 and 2017 implementations of the composite Aspirin measure: the performance percent increased by 5.32%, 132 (10.2%) of the patients included in 2015 were dropped, and 13 (1.1%) new patients were included in 2017. As CQM definitions are updated to reflect new evidence-based guidelines, these types of changes in global performance might be expected if the changes to logic are significant. Currently, in order to know whether or not a CQM has been impacted by a knowledge shift, CQM implementers must download the HQMF from CMS’ eCQM Library and open the human-readable or encoded file to identify changes. It would be helpful if CMS or measure developers published an overview highlighting any updated logic in new versions, so that implementations could be easily identified for editing. CMS does publish “Technical Release Notes” at regular intervals announcing updates; however, processing this file requires downloading a PDF, searching for the measure(s) in question, and interpreting all of the listed changes to identify those to measure logic. An emerging Health Level Seven International standard, which might help with electronic processing of these logic updates, is the Clinical Quality Language (CQL), a new specification that focuses on a common model for representing expression logic for CQMs and Clinical Decision Support. According to CMS’ eCQI Resource Center, CQL will be used in all HQMFs in the future, will replace the Quality Data Model, and is intended to reduce the burden on implementers for consuming measure artifacts. System vendors and measure implementers need to evolve to adhere to this standard, thereby reducing variation caused by knowledge shifts in older and newer versions of CQMs. The eCQI proposes to officially publish the transition to CQL in spring of 2018, with CQL measure development launching in the fall of 2017.
Ideally, these types of logic changes could be made automatically to all CQM implementations; however, this is currently difficult due to the various networks, communication channels, set of transformations, and different organizations of clinical data that currently exist. Therefore, moving away from local measure implementations and towards a more centralized measure calculation system might solve these problems. Clinics currently have access to CQM calculation registries and some companies offer services at what seems to be an affordable price for clinics. As new quality-based reimbursements from the QPP/MIPs are rolled out, we will learn whether the net reimbursements received will enable a sustainable business model for practices, CQM registry companies, and for the healthcare system at large. As we wait for new data standards such as CQL and for a potential transition to centralized measure calculations, an interim solution would be to enhance workforce training in Health IT around implementing measure logic and emphasizing a process and timeline for updating to new versions when they are released.

*Shifts in Taxonomies.* The second type of shift we observed in the CQM update process is a shift in taxonomies. We identified changes in the inclusion/exclusion of codes at various levels of the ICD-9-CM/ICD-10-CM, SNOMED CT, and RxNorm hierarchies. When the CQMs were divided into aggregate clinical concepts, we identified differences in the number of patients included for the clinical concept “acute myocardial infarction”. There were 38 (28%) newly included patients in the 2017 AMI-only implementation of the Cholesterol measure, and 35 (25%) newly included patients in the 2017 AMI-only implementation of the Aspirin measure. In fact, one ICD-10-CM and one ICD-9-CM (both describe “old myocardial infarction”) accounted for over 70% of the newly included patients in the 2017 version of the Cholesterol measure, and over 90% of the new patients included in version 2017 of the Aspirin CQM. Interestingly, the 2017 version of the AMI-only Cholesterol measure decreased in performance rate by 2.13% using the updated AMI code group. The 2017 version of the standalone AMI Aspirin measure only increased in performance by 2.62%, while the 2017 version of the Aspirin composite and the 2017 version of the IVD-only Aspirin measures both increased in rate by greater than 5% between versions. Based on these performance changes alone, one might wonder if the new AMI code group (and the code for “old myocardial infarction” in particular) may be too broad and might include patients not appropriate for statin and aspirin therapy. From a clinical standpoint, however, including old AMI seems appropriate in that having a heart attack in the past does relate to increased risk of subsequent events. Therefore, patients with “old AMI” may represent a care gap for the use of Aspirin for these two clinics. The process for making the choice to include/exclude new codes, and the methods for evaluating impact in the decision-making process, are unknown. Across all four measures, no logic was provided about the decisions made to include/exclude codes. If value set developers provided rationale for the inclusion of the new AMI codes, it might help with interpreting these types of performance changes in the AMI-only implementations, and determining whether or not the changes in patient populations are appropriate. In particular, we found it was difficult to traverse the various taxonomies (especially SNOMED CT and RxNorm) to understand the choice of codes at different levels of the hierarchies. This study shows that the consequence of these choices is that they may impact the number of patients included/excluded in a measure’s denominator, and could decrease (or increase) CQM performance rates. Measure developers should examine these potential implementation changes against EHR data before making changes to value set specifications to help understand the impact of taxonomy drift. One way to potentially reduce the variation on CQM data caused by taxonomy drift is to promote the use of application programming interfaces (APIs) to the VSAC which allow for automated downloads of value set expansions. The development of vendor-specific APIs between specific system vendors and the VSAC is needed to make automated terminology updates possible.

*Impact on population health and improving quality.* Compared to the Aspirin measure, there are minor differences in the CQM performance results between the 2015 and 2017 versions of the composite Cholesterol, Diabetes, and Heart Failure measures. The Heart Failure measure was identical between versions, and the Cholesterol and Diabetes measures had very similar results in version 2015 and version 2017. However, the new and old versions of the Cholesterol and Diabetes measures included distinct patients in version 2017 who were not included in version 2015, and the Cholesterol measure included patients in version 2015 who were not included in version 2017. Because CQMs intend to promote evidence-based clinical processes, variations in CQM data caused by having antiquated implementations may impact the ability of clinicians to assess care and improve quality. Jean-Jacques et al showed that health information technology-supported quality improvement (QI) initiatives can decrease disparities for some chronic disease management and preventive measures; and as technical assistance providers, we observe data-driven QI efforts that heavily rely on patient-level data (i.e., lists) generated by CQM reports. If clinicians rely on old implementations of CQMs, then they may have lists with patients intended to be excluded from a measure, and may therefore, target inappropriate patients for therapies, such as recommending aspirin use for someone at high-risk for a fatal bleeding event. Furthermore, their lists will not include the newly added patients who may need certain therapies to improve outcomes. Assuming that the version 2017 specifications of a measure improved to represent “perfect” inclusion, then every newly included patient can be thought of as needing the evidence-based therapy (such as aspirin)
in order to avoid bad outcomes. Under the same assumption, every dropped patient between versions of a measure can be thought of as avoiding potential harm caused by the promoted therapy. For aspirin use, Number-Needed-to-Treat (NNT) statistics show that of patients with known cardiovascular risk who took aspirin, 1.3% were helped by preventing a non-fatal heart attack, and 0.25% were harmed by a major bleeding event. In this study, 121 (92%) of the patients dropped in the 2017 version of the Aspirin measure were also taking an anticoagulant medication, so the Number-Needed-to-Harm (NNH) statistic for this subset of patients is likely much higher, and for these clinics, 1 to 2 people may have been harmed if the old definition persisted, as Hansen et. al showed that patients with combinations of aspirin, warfarin, and clopidogrel are associated with up to a three-fold higher risk of bleeding for patients on dual therapy and triple therapy. With statin therapy, 1 in 21 people have a repeat heart attack, stroke or death avoided, so even 10 missed people have significant risk of events. Similarly, 10% were harmed by muscle damage or pain, or ~1 of the 14 inappropriately included. Even in this small study, failure to include or exclude patients could have led to real harm. With CQM implementation and QI infrastructure increasing, the problem of having, and using, antiquated CQM versions could have significant potential negative impact on population health by not avoiding events, and avoiding harms for patients.

Limitations. Another type of shift that may impact various versions of CQM implementations can be categorized as “usage shifts”, since the use of specific codes by clinicians might change over time. In this study, we did not aim to look at usage shifts. Despite the fact that the use of codes might have changed between 2015 and 2017, we still sought to understand the differences caused by knowledge shifts and taxonomy shifts by implementing the 2015 and 2017 versions of the measures. Another limitation is that this study only includes data for CQMs implemented against data for two primary care clinics in Oregon. Future analysis could include data from several other clinics, potentially from other parts of the country, to further assess the differences in the performance rates, number of patients included, and distinct patients. Additionally, we could have tested whether each difference between CQMs versions was statistically different. But, the primary goal of this paper was to show the differences themselves when CQMs fail to update, and whether these differences were large or small. For the case of the Aspirin measure, a chi-square test does show a significant difference in performance between versions, and this difference may be important clinically.

Conclusion

We discovered changes in the official update process for four standardized CQMs. Between older and newer versions, CQM definitions can shift in logic, and value sets can change in their inclusion/exclusion of certain codes to define clinical concepts. Both of these changes can result in differences in CQM performance results and impact the patients included. Without more integrated updates to the latest CQM versions, comparability of CQMs for payment programs and utility of CQM data for targeted quality improvement may be limited. Therefore, we need CQM implementations with standard representations, maintained by automated updates. To help minimize variations in CQM implementations, we suggest that system vendors, payers, policymakers, informaticians, measure developers/authors, and developers should work on: (1) validating new data interoperability standards for representing CQM logic to facilitate standardized implementations; (2) assisting measure developers with making/explaining choices at the various hierarchies, and validating value sets against extant EHR data sets prior to dissemination; (3) supporting a sustainable model to pragmatically provide centralized CQM calculation; (4) developing vendor-specific API queries to the VSAC and/or enhanced VSAC API documentation to facilitate automated value set updates; and, (5) enhancing the Health IT workforce to help achieve more standard and timely CQM implementations and updates.

Abstract

Supplementing patient education content with pictographs can improve the comprehension and recall of information, especially patients with low health literacy. Pictograph design and testing, however, are costly and time consuming. We created a Web-based game, Doodle Health, for crowdsourcing the drawing and validation of pictographs. The objective of this pilot study was to test the usability of the game and its appeal to healthcare consumers. The chief purpose of the game is to involve a diverse population in the co-design and evaluation of pictographs.

We conducted a community-based focus group to inform the game design. Game designers, health sciences librarians, informatics researchers, clinicians, and community members participated in two Design Box meetings. The results of the meetings were used to create the Doodle Health crowdsourcing game. The game was presented and tested at two public fairs.

Initial testing indicates crowdsourcing is a promising approach to pictograph development and testing for relevancy and comprehension. Over 596 drawings were collected and 1,758 guesses were performed to date with 70-90% accuracies, which are satisfactorily high.

Introduction

Patients, especially those with limited health literacy skills, often experience difficulty understanding health information¹,². Some health information can be represented efficiently using graphics that are easier to understand. In consumer health informatics research, pictographs have been used to improve patient comprehension and recall. In their review of the literature regarding the role pictures play in improving health communication, Houts et al. found that “pictures closely linked to written or spoken text can, when compared to text alone, markedly increase attention to and recall of health education information”¹.

We have conducted several studies related to the development and testing of pictographs to be used in patient instructions³⁵. Our findings confirmed the value of enhancing patient education materials with pictographs for health communication. At the same time, generating informative and comprehensible pictographs for a diverse population is a time consuming and costly process.

People from diverse cultural backgrounds have different communication styles and standards. Some health topics or
images that are part of the vernacular for one group of people may be offensive or culturally taboo for others. Individuals can be challenged to interpret pictures from various cultural and educational backgrounds. The symbol for *prescription*, commonly seen on medication labels, for example, was taken to mean *rubbish bin* by a low-literate South African population with limited English proficiency. A library of high quality, culturally appropriate pictures could address these differences.

The Doodle Health crowdsourcing game was designed to engage a diverse population, including under-represented, vulnerable, and disadvantaged populations, to elicit and test health-related pictures in an effort to build this library. By engaging under-represented minorities in the co-design and evaluation of pictographs, thereby getting their active involvement in the production of the health education material intended for their use, we hope to increase the likelihood that the information they receive will be relevant and meaningful.

**Methods**

**Focus Group**
At the beginning of the design process, we conducted a focus group study to assess the health information needs of group members from under-represented communities, and to obtain their thoughts regarding development of the crowdsourcing game. We recruited 11 participants from a partnership representing five diverse demographic communities residing in the Salt Lake Valley and scientific researchers from the University of Utah and the Utah Department of Health.

The focus group demographics included African Americans, refugees from Africa, Hispanic members, Pacific Islanders, and Native Americans. The participants ranged from 30 to 69 years of age. The majority had acquired education beyond the 12th grade. By race and ethnicity, two American Indians participated (18.1%), as well as five Black or African Americans (45.4%), and two Pacific Islanders (18.1%). English was the primary language spoken by the majority (72.7%), while one person reported knowing English and Tongan equally well (9%); there were two native Spanish speakers (18.1%), and one person told the study team that “African” was their first language.

The two-hour focus group discussion was transcribed and qualitatively analyzed. The focus group helped us identify points of cultural sensitivity. For instance, health-related images or topics that are part of the vernacular for some groups may be offensive or culturally taboo for others. In a healthcare setting, topics of sexuality, conception, and reproduction must be approached delicately.

The group expressed their interest in long-term community health. They wanted to prevent common diseases in their populations, namely heart disease and diabetes, and they wanted to promote healthy behavior, diet and lifestyle choices. They noted that socioeconomic (and sociogeographic) factors are crucial to consider when tailoring health education materials, and they desired information for their communities about the health insurance market and other financial resources to help them overcome barriers to receiving quality healthcare.

We consulted with community representatives after the focus group concluded at regular intervals throughout the game development process. Researchers attended monthly meetings with them in order to report on study progress and obtain feedback.

**The Design Box**
Informed by the results of our focus group, we conducted two iterative Design Box meetings. The Design Box is a conceptual tool for brainstorming and refining game design ideas. The four constraints, presented as four sides of a square, were: Technology, Aesthetics, Audience, and Theory. Technology refers to the digital technical systems of the game. Aesthetics are the formal elements of the game content the game user will interact with, and this category focuses on the emotions they may encounter. The Audience wall of the Design Box is concerned with those who will
play the game. In this case, the target audience is the under-represented communities. Theory refers to the research problem: crowdsourcing pictographs for under-represented populations through gaming.

The Design Box setting encouraged interaction among collaborators. In one Design Box meeting, the Entertainment Arts and Engineering team dialogued with informatics researchers, health sciences librarians, and clinicians. In a separate session, individuals from the five communities recruited for the initial focus group session completed the process. The meeting participants worked together to define the purpose of the crowdsourcing game and to focus the constraints of the Design Box.

**Game Design**
Our game design was based on general game design principles as well as the results from the focus group and Design Box meetings. A key consideration for us was to keep the design simple. In our target audience, many are occasional gamers who require easy-to-use gaming mechanisms. The popularity of games such as Angry Birds™ and Draw Something™ also showed us that simple interface design is attractive to consumers. Short, gradually increasing levels of difficulty, interesting sound effects and colorful graphics are also factors in successful games. The final Doodle Health design is modelled after the Draw Something™ app and the board game Pictionary™, both of which engage participants in the drawing and guessing of pictures. In addition, Pictionary™ is well-known to most of our target audience, and many in the younger audience are also familiar with the Draw Something™ app.

**Implementation**
The Doodle Health game was implemented to run on a variety of mobile devices, standard desktop and laptop computers. The front-end user interface was written in HTML5, CSS3 and Javascript. The Bootstrap framework was selected to make the web pages have a standard appearance across different browsers. jQuery was used to add additional AJAX and dynamic interactivity to the web pages. The canvas element of HTML5 was used for the drawing page, making it so that very little needs to be downloaded to a browser in order for a user to create drawings. PHP scripts were created for the backend of this web application. These PHP scripts used the standard MySQLi library to connect to a MySQL database. Seed image files were uploaded to the server through one of these PHP pages as a stream in order to control what could be uploaded. The result of this architecture (Figure 1) is an adaptable application that can be run on any web browser.

Two versions of the Doodle Health game exist online presently. We tested the version that is open to the public at two local fairs, while the other version was tailored to meet the needs of our individual community partners (Figure 2).

**Game Flow**
For the purposes of the pilot testing, the game first asks the user to self-identify with a community. In the game testing, we listed seven racial/ethnic groups which allows us to link drawings with racial/ethnic backgrounds. Following the advice of our minority community partners, there is no user name or password created and as such players have total anonymity. The player continues by selecting “Draw”, or they can choose to “Guess” a health-related term. For either function there are easy, medium, and hard levels as options.

Upon selecting “Draw”, a player is prompted to draw a word or a phrase (Figure 3). Players working on a touchscreen device, such as a tablet, use a stylus or finger for drawing, while those on a non-touchscreen computer use a mouse to draw. There is a palette of colors and line thicknesses to choose from on the left bottom corner of the drawing screen, and a player is given the options to “Skip” a term, “Clear”, or “Save” and submit their drawing. The Doodle Health user can skip terms up to three times if they don’t feel comfortable drawing them, or if they don’t understand them.
Once a drawing is submitted a progress screen is displayed (Figure 4) showing the points they have earned for their community. The player may continue by selecting “Draw” or “Guess” again.

A player guesses what an image represents by clicking on the corresponding term from a multiple-choice list. The person views a screen showing if their guess was correct and the points earned for their community so far (Figure 5). Because some users make wrong guesses because the pictograph was not easy to understand, they are also given the option of contributing their own drawing for the same term.
To jump start the game, we originally uploaded a set of 50 professionally drawn seed images (from our previous pictograph studies) for guessing. Drawings from the crowdsourcing participants themselves were added to the pictograph library as the game progressed. Because obscenity is a concern when anonymous players are allowed to submit content for others to view, all drawings must be reviewed and approved by a moderator.

Preliminary Testing and Feedback

We tested the Doodle Health crowdsourcing game at two public fairs (Be Well Utah health fair and the Utah State Fair) using tablet computers. A convenience sample was recruited to take part in the study. The participants were asked to play the Doodle Health game for as long as they wanted. Following the play, each participant was asked to fill out an anonymous, Likert-scale survey questionnaire. They were also given the opportunity to provide additional comments about the game. Personal identifying information was not collected from participants and compensation was not provided. Additionally, we kept the Doodle Health game online and invited the fair participants to continue playing the game. We also handed out flyers at the fairs to invite those who could not participate on-site to try out the game at home. To make the testing experience more inviting in this preliminary stage, we did not collect individual demographic information.

Figure 5. Guessing Progress Screen

Results

A combined total of 114 volunteers were recruited via the fairs. We could not ascertain the number of users during the three-month open testing phase. In all, 596 pictures were drawn. 176 were not approved for guessing because they were poorly drawn, unfinished, or because they contained inappropriate content. The data for the images drawn by the community during this time period is shown in Table 1. Some of the drawings we received from crowdsourcing participants were artistic and complex, while others were rendered as basic stick figures. Commonly understood words, such as *ambulance*, yielded similar interpretations from game users (Figure 6). Stranger terms, such as *pinkeye*, showed more variation among drawings (Figure 7).

A total of 1,758 guesses were made. 1,488 matched the correct terms, while 270 were incorrect. Many more guesses were made than drawings, because guessing appears to be simpler and easier for people to do than drawing. The images we included in the game as drawn by community members were largely recognizable by other players. One game tester commented, “I am comfortable guessing drawings and less effective at drawing.” Some of the images, however, were easier for participants to guess than others. The pictures guessed correctly most often were concrete terms like *ambulance*, *loose tooth*, *vegetables*, and *wash hands*. Those frequently missed were conceptually more difficult words and phrases to interpret, such as *fatigue*, *nausea*, *depression*, *mealtime*, and *cool down*. This correlates with our prior research in pictograph development. The number of guesses made by community members is shown in Table 2.

Fair participants answered usability questions. Most people were comfortable with the technology used for the game and they were able to play it without difficulty. The details are shown in Figure 8 and 9.
We received 37 additional comments from fair participants. They were sorted into four main groups and qualitatively analyzed (Table 3.). The fair participants also identified a few software bugs. For instance, it was discovered that a vertical screen orientation was necessary to see all of the buttons on a tablet interface without having to scroll down.

Discussion

We developed the Doodle Health game to crowdsource the pictograph development and testing tasks while providing entertainment value to players. Without any compensation, and only being marketed at two local public events, the game was able to collect 596 drawings over a three-month testing period. The drawings were evaluated using the same game 1,758 times. Given the 70 to 90% of the guess accuracies, the quality of the drawing and guesses are satisfactorily high.

Based on our prior experience, traditional pictograph creation and testing is a very time-consuming process. Even experienced graphic designers and medical illustrators are limited by their own cultural biases. Using a crowdsourcing game to engage the larger community allows us to rapidly gather and test pictures from diverse backgrounds. Through crowdsourcing, under-represented healthcare consumers are able to contribute to the development of culturally-sensitive and understandable pictographs for health communication.

The results we have gathered show that the Doodle Health game is a promising approach to crowdsourcing for pictograph development and validation. The feedback we collected from those who tested the game was quite positive. Most participants found the game engaging and easy-to-use. Most felt they would like to play it again. These ratings are consistent with the enthusiastic comments we received from the game testing participants.

We hope this game may indeed result in a more meaningful resource library of easily comprehended pictographs for use in health communication materials. The online library of pictographs developed through the crowdsourcing game will be freely available to clinicians and other health care workers to supplement text in patient discharge instructions, for example, and other health-related education materials. The ultimate goal of this project is to have a positive impact on clinical practices by facilitating and enhancing communication between health care providers and consumers.

One limitation of the Doodle Health game is that it is not suitable for medical concepts or content that is totally unfamiliar to an audience. For instance, the ability to draw and/or guess the word *defibrillator* requires specialized knowledge. Moreover, it is unlikely that we will be able to incorporate publicly-drawn images directly into the pictograph library, as many people with high representation may not be expert illustrators. We can identify relevant concepts and cultural sensitivities with the game, and we can develop pictographs through iterative cycles of game play and data analysis.
We asked the crowdsourcing participants in this study to self-identify their community affiliation, because African Americans, American Indians/Alaska Natives, Asian Americans, Hispanics, and Native Hawaiian/Pacific Islander populations carry a disproportionate burden of disease, premature death, and disability. They also receive poorer health care overall, as compared to other ethnic or racial groups \(^{10}\). On the other hand, the needs of each community vary greatly. A Spanish version of the game is needed, for instance, for non-English speaking Hispanics.

To minimize the burden on our game testers and maximize the number of participants, we did not collect demographic information such as age and gender. At the advice of our community partners, we only asked players to identify one community they would like to play for (to earn points for the community), because some people are turned off by the question of race/ethnicity. At the fair, our observation is that the participants were reasonably diverse in terms of race, ethnicity, gender, and age. In future formal trials, we will offer voluntary demographic surveys for crowd sourcing participants.

We are trying out novel applications for the Doodle Health game and experimenting with various promotional ideas and incentives. We have installed a gallery, to present drawings and award crowdsourcing participants, and we are exploring social networking as a tool for marketing the game within particular communities.

**Acknowledgements**
The authors of this paper would like to thank the National Institutes of Health (NIH) for grant support of this project (G08 LM011546-03 Graphics to Enhance Health Education Materials for Underrepresented Populations).

**Conclusions**
*We created a Web-based game, Doodle Health, for crowdsourcing the drawing and validation of pictographs. Initial testing collected a large number of drawings and guesses, with positive user feedbacks, demonstrating the approach to be feasible and promising.*

Abstract

Introduction. Although Electronic Health Record (EHR) adoption has increased in the U.S., our understanding of how it affects health care organizations is still limited. Current literature has produced mixed-results due to the use of simple, non-standardized measurements and poor research designs.

Methods. We propose the use of a systematic methodology that combines measures of quality, productivity and safety processes, tracked over time using an interrupted time-series design with multiple control sites.

Results. Our methodology successfully detected performance changes during an EHR implementation on 17 (77%) outcomes, including a significant increase in Emergency Department length of stay immediately after go live by 0.19 hours [95%CI (0.12, 0.27), p<0.001], and an improvement in time to complete radiology tests, which significantly decreased per month by 0.19 minutes [95%CI (-0.26, -0.12), p<0.001].

Conclusion. The proposed methodology was able to detect several changes immediately after an EHR implementation and over time. The method is a promising and robust approach to assessing the impact of EHR implementations on a wide range of health care quality, productivity, and safety care processes.

Introduction

Health Information Technology (health IT) Adoption in the U.S. Previous studies have demonstrated advantages associated with Electronic Health Record (EHR) systems adoption, such as improving quality and productivity outcomes, and decreasing errors and health care cost1-4. Such improvements have attracted attention from government agencies and policy makers5. In 2004, the U.S. federal government issued an executive order to provide financial incentives to increase health IT adoption in the U.S.6, and in 2009, the Health Information Technology for Economic and Clinical Health (HITECH) act was signed into law establishing the Meaningful Use program7. The program contributed to increasing EHR adoption among U.S. care delivery systems, and, as a result, the literature in this area is also rapidly increasing8. Several systematic reviews have analyzed studies on the impact of health IT. The studies report on different outcomes, such as quality, productivity and safety; review different health IT tools, including multifunctional EHRs; cover both ambulatory and non-ambulatory care settings; and include U.S. and non-U.S. health care organizations8-11. Such reviews found that health IT adoption studies more frequently report positive outcomes associated with EHR adoption and use8, 11, and that the Meaningful Use program has contributed to the increased positive outcomes reported11. However, despite the increasing number of health IT evaluations and positive findings, the same reviews also found several studies that produced mixed or negative results, leaving unanswered questions on the full impact of IT interventions in health care8, 11.

The problem. The lack of a more complete understanding of health IT impact has several contributing factors. Studies available frequently report simple, non-standardized measurements, creating obstacles to the comparison of health IT outcomes across different studies12. In addition, quantitative hypothesis-testing studies more frequently assess the impact of their interventions using pre-post comparisons8. However, similar to large-scale changes observed in other industries13, an EHR implementation is a complex, ongoing process that introduces sociotechnical changes that iteratively evolve over time14, exposing end-users to a learning curve of up to two years15. Previous research suggests that when an intervention has a longitudinal effect – which is the case for EHR implementations – interrupted time-series design is the most suitable design to avoid biases caused by time-sensitive variations not detected.
by simple pre-post statistical comparisons. However, an effective interrupted time-series design requires specific components. As demonstrated by Zhang et al., to achieve 80% power with an effect size = 0.5, interrupted time-series studies must have at least 24 time periods for equal pre-post time periods, and at least 30 time periods if the post-intervention period is smaller than pre-intervention. Other studies suggest the use of a control site whenever possible, to overcome the confounding effect of other events not detected by assessing isolated intervention sites. Despite the recommendations, a recent systematic review by Jones et al. reported that only 27 (11%) of 236 health IT adoption studies used a time-series design; out of those, only 8 include 24 data instances or more, and only 2 have control sites. Therefore, a more robust methodology is necessary to increase our understanding of the full impact of health IT interventions. The method should use a robust longitudinal analysis to more effectively monitor the impact of health IT interventions and to identify unexpected effects introduced both during the transition and after the new system has been stabilized, seasonal effects, and time to recover to baseline performance. In addition to improved design, studies should include a compressive set of outcome measurements, covering quality, productivity and safety.

**Potential Solution: Systematic Methodology for Near Real-Time Monitoring of EHR Implementations.** We have previously developed an inventory of measures with potential to detect the impact of EHR implementations in near real-time using data that are routinely captured in electronic format. These measures provide a comprehensive coverage of quality, productivity and safety processes likely impacted by EHR implementations. Measures were identified through semi-structured interviews with health care leaders, and input from informatics experts. By combining these measures with other measures commonly reported in the literature (as detected by our previous study), our final inventory included 102 outcome measures, and a taxonomy to classify these outcomes. In the present study, we use a subset of measures from the larger inventory to detect time-sensitive changes in a group of health care settings implementing a commercial EHR system using an interrupted time-series design with multiple control sites. Our aim is to verify if our proposed methodology detects and quantifies what changes are introduced to the performance of the care delivery organization while it is transitioning from long-used and stable homegrown systems to a commercial EHR.

**Methods**

**Setting and Study Design.** We performed this study at a medium-size (140 beds) non-academic hospital and five ambulatory care clinics implementing a commercial EHR system, and compared them with a medium-size (243 beds) non-academic hospital and five ambulatory care clinics that had not implemented the new EHR at the time of this study. All settings are part of Intermountain Healthcare, a not-for-profit integrated care delivery system of 22 hospitals and over 185 ambulatory care clinics covering the entire state of Utah and southern Idaho. We used an interrupted time-series design, analyzing monthly data for the period of February 1st, 2013 to January 31st, 2017. The baseline period is represented by data instances prior to the new EHR go live, and was compared against the intervention period, which includes data after go live. Intermountain Healthcare’s institutional review board approved the study under protocol 1040351.

**Description of intervention.** Intermountain Healthcare has extensive experience developing and operating EHR systems, including the Health Evaluation through Logical Processing (HELP) system, first introduced at the LDS Hospital in Salt Lake City in 1975. An enterprise, longitudinal EHR was later developed and first deployed in 1994. Intermountain is replacing its legacy systems with the commercial, multifunctional Millennium EHR developed by Cerner Corporation, Kansas City, MO, U.S. Given the size of the Intermountain care delivery system, the implementation of the new EHR follows a staggered schedule with multiple phases, each phase comprising a group of hospitals and clinics from the same geographical area. While the enterprise implementation will be phased, the introduction of the new EHR in each region will use a “big bang” strategy, replacing all legacy systems at once within that region. Such a staggered approach
allowed for the inclusion of one hospital and five ambulatory care clinics from the first region of the implementation, which started using the new EHR in February 2015, and one hospital and five ambulatory care clinics from another region that has not started its implementation as a comparison control.

**Outcome Measures.** We collected data for 22 measures (Tables 1 and 2) of quality, productivity and safety outcomes. These measures were extracted from a rigorous and comprehensive inventory of outcome measures likely impacted by EHR implementations, combining measures from the literature\(^1\)\(^2\) and subject-matter experts’ suggestions\(^3\)\(^4\). Data were collected from existing Intermountain analytics reports and from Intermountain’s Enterprise Data Warehouse (EDW). To test the ability of our methodology to detect various performance changes during the new EHR implementation, we collected data for all measures that were available before and after the Cerner EHR go live for both the implementation and control sites. We were not able to include more measures due to incomplete mapping between Millennium’s database and Intermountain’s EDW. The number of data instances before and after go live varied by measure, but all measures had at least 20 instances of data in each phase. All patients eligible for one or more measures were included; no individual patient health information was accessed for this study.

**Data analysis.** To test the ability of our methodology to detect performance changes during the new EHR implementation, we calculate the effect immediately after the intervention and the pre-post effect over time on the outcome measures. The immediate effect after intervention is the difference between the last predicted value before the introduction of the intervention and the first predicted value after its introduction. Predicted values are automatically generated by the statistical model described below. To calculate the effect over time, we first calculate the monthly change in the period before and in the period after the introduction of the intervention and their difference within each group/setting separately; and then calculate the difference between intervention and control sites on these pre-to-post differences. We combined the five clinics of each region by calculating the arithmetic average of each measure for each month in each group (intervention vs. control). We analyze these monthly data instances using interrupted time series analysis (ITSA) with an ordinary least squares (OLS) model²² with Newey-West standard errors to adjust for autocorrelation, which assumes the error structure to be heteroskedastic and possibly autocorrelated up to some lag²³. After fitting our model, we check if the number of lags included in the model to account for autocorrelation was correctly specified and adjusted accordingly, using the Cumby-Huizenga general test for autocorrelation²⁴. Data analysis was performed using Stata version 14.2 statistical software [College Station, TX: StataCorp LP].

**Results**

From the 22 measures assessed, 17 (77%) measures showed a significant difference in the intervention group when compared to control sites. Nine (41%) measures showed a significant effect immediately after the introduction of the intervention and 14 (61%) measures showed a significant effect over time.

**Ambulatory care measures.** Hemoglobin A1c (Figure 1-A) in the intervention group had a significant immediate effect with a decrease in the proportion of patients under control by 3.03 [95%CI (-4.35, -1.71), p<0.001], and a decrease per month by 0.16 [95%CI (-0.28, -0.05), p=0.006] when compared to the control group. Although the proportion of patients receiving appropriate medication for asthma (Figure 1-B) in the intervention group had a significant immediate effect, decreasing by 25.81 [95%CI (-36.63, -14.99), p<0.001] when compared with control sites, such a difference is attributable to a significant increase in control sites by 28.13 [95%CI (17.65, 38.61), p<0.001].

Both employee movement (Figure 1-C) and employee turnover (Figure 1-D) had a significant effect over time. The proportion of employees transferred to a different department or facility in the intervention group increased per month by 0.11 [95%CI (0.01, 0.21), p<0.05], and the proportion of employees with voluntary turnover increased per month by 0.12 [95%CI (0.34, 0.21), p=0.007] when compared to control sites. Employee movement has an outlier between months 10 and 15 in the pre-intervention period, and although it did not seem to affect the predicted baseline, it may warrant further investigation. Both groups had a
significant immediate effect in the proportion of new patient visits (Figure 1-E) when assessed individually; however, the intervention group decreased by 1.02 more than control sites [95%CI (-1.87, -0.16), p<0.02], and decreased per month by 0.18 more than control sites [95%CI (-0.23, -0.13), p<0.001]. Although the number of patient visits (Figure 1-F) in the intervention group showed a significant immediate effect, increasing by 458.05 [95%CI (364.84, 551.26), p<0.001] when compared to control sites, such a difference is attributable to a significant decrease in the number of visits in control sites by 393.15 [95%CI (-448.22, -338.08), p<0.001]. Both groups had a significant immediate effect in the number of radiology tests completed (Figure 1-G) when assessed individually; however, the intervention group decreased by 61.30 tests more than control sites [95%CI (-99.18, -23.41), p<0.002], and increased per month by 3.45 tests more than control sites [95%CI (0.82, 6.08), p<0.01]. Tables 3 and 4 describe the analysis for immediate effect and pre-post effect over time in ambulatory care settings.

Hospital measures. There was no significant difference between the two hospitals in the proportion of
patients satisfied (Figure 2-A) immediately after the go live; however, there was a significant difference
over time with satisfaction rate in the intervention hospital increasing per month by 0.21 [95% CI (0.06,
0.37), p=0.008] when compared to the control site. Compliance to sepsis bundle (Figure 2-B) significantly
increased over time in the intervention group by 4.08 [95% CI (1.97, 6.20), p=0.008] when compared to
the control site; however, the difference is attributable to a significant decrease per month in the control hospital
by 3.44 [95% CI (-4.76, -2.13), p<0.001]. Sepsis mortality rate (Figure 2-C) significantly decreased per
month in the intervention group by 0.80 [95% CI (-1.31, -0.30), p=0.02] when compared to the control site.

ED length of stay (Figure 2-D) significantly increased in the intervention hospital immediately after the go live by 0.19 hours [95% CI (0.12, 0.27), p<0.001] when compared to the control site; however, this
difference was not observed over time because both sites had a similar significant decrease in the post-
intervention period. ED wait time (Figure 2-E) showed no significant immediate effect when the two
hospitals were compared; on the other hand, it showed a significant effect over time with the intervention
group decreasing per month by 0.32 minutes [95% CI (-0.54, -0.11), p=0.004] when compared to the control
site. Both hospitals had a significant effect over time in the proportion of employees transferred to a
different department or facility (Figure 2-F) when assessed individually, and this effect was significantly
higher in the intervention hospital which decreased per month by 0.43 more than the control hospital
[95%CI (-0.06, -0.02), p=0.001]. Hospitalizations (Figure 2-G) showed a significant effect over time in the
intervention group, decreasing per month by 5.82 admissions [95% CI (-8.83, -2.83), p=0.001] when
compared to the control site. The number of radiology tests completed (Figure 2-H) significantly decreased
in the intervention group immediately after the go live by 259.01 tests [95% CI (-464.28, -53.72), p=0.01],
and significantly increased per month by 18.9 tests [95% CI (1.02, 35.15), p=0.04] when compared to the
control site. Time to complete radiology tests (Figure 2-I) improved with a significant decrease in the
intervention group by 2.75 minutes [95% CI (-3.66, -1.86), p<0.001] immediately after the go live, and a
decrease per month by 0.19 minutes [95%CI (-0.26, -0.12), p<0.001] when compared to the control site.

Although the rate of adverse drug events (Figure 2-J) significantly increased in the intervention group by
1.30 [95% CI (0.33, 2.27), p=0.01] immediately after go live, such an effect may be explained by the
somewhat high variability of the outcome, with rate ranging from 0.80% to 8.90%. In addition, it improved
over time with a significant decrease per month by 0.09 [95%CI (-0.16, -0.02), p=0.02]. Tables 5 and 6
describe the analysis for immediate effect and pre-post effect over time in hospital settings.

### Discussion

We successfully tested a methodology consisting of an interrupted time-series design with multiple control sites and a wide range of outcome measures for monitoring the effect of EHR implementations on quality, productivity and safety outcomes. We detected changes to the performance of several measures over time, seasonal effects, and outcome variability. Such time-sensitive effects would not have been detected by pre-post or short-term time series designs, and demonstrate the importance of long-term studies of health IT evaluations. We also detected different effects on different measures, demonstrating the importance of using a broad set of measures to cover processes likely impacted by EHR adoption. The use of our methodology in future studies will benefit the broader informatics community from knowing what and how to monitor future EHR implementations. Furthermore, it will allow for earlier and potentially more precise detection of unexpected effects introduced by the intervention, and implementation of effective response to mitigate negative impacts, leading to a potentially faster return to, or improvement over, baseline performance.

Our methodology detected seasonal effects that were maintained in control sites in the post-intervention period, whereas the intervention sites seem to have been disrupted and affected for several months following the new EHR go live. While hemoglobin A1c control in the intervention group dropped and had a pattern similar to its initial baseline, ED length of stay and ED wait time stayed above baseline levels for seven months in the post-intervention period. Our methodology also detected specific patterns and outcome variability. Examples include medication for asthma and patient visits that varied even in the control settings; such a variability may have influenced detection of immediate effect in some cases and warrant further investigation of potential indirect effects of the implementation (e.g. organizational resources diverted to implementation regions). Such time-sensitive events would not have been detected if intervention sites were assessed without a control, or in a simple pre-post design, nor would the disruption on ED measures have been detected if data were assessed in a more spaced frequency, e.g. with yearly data collection. Therefore, we suggest future studies focusing on time-sensitive effects, as opposed to conducing
simple pre-post comparisons; we also recommend the use of more comprehensive measurements and more frequent data collection, for at least one year after go live. Otherwise, our understanding of the full impact of health IT adoption will be incomplete, and such evaluations may not be cost-effective. Our analysis included monthly data instances; however, several measures from our larger inventory\(^ {19}\) may be readily available in electronic format allowing for an even nearer real-time assessment (daily or weekly), dependent on the underlying count or frequency of the measurement. In addition, due to the broad coverage of our larger inventory\(^ {19}\), our methodology will be useful for monitoring implementations of new EHRs, upgrading of current EHRs, and other important changes both in the EHR and in the sociotechnical environment.

We also detected interesting improvements. Although patients may have been affected by delayed processes, patient satisfaction increased over time. Other improvements such as faster radiology tests may have contributed to improving patient experience. However, a more complete analysis must be conducted to confirm this hypothesis. As opposed to our previous study\(^ {19}\), where employee measurements were rated by a panel of informaticists as least relevant for monitoring EHR implementations, in the present study, such outcomes were affected over time, although it is difficult to infer how the implementation may have caused such changes. An explanation may be elicited by analyzing the subsequent implementation regions.

Studies evaluating IT adoption in other industries\(^ {25}\) demonstrate that IT adoption rarely produces positive results if not accompanied by complementary changes or investments. In addition, some outcomes assessed, such as ADEs rate, may have been affected by other effects that may or may not have been influenced by the new EHR implementation. Therefore, a more comprehensive analysis is necessary to account for possible confounders or complementary changes that may confirm or discard some of the effects we observed. We are currently evaluating the subsequent implementation regions and expect to report our results in more comprehensive future studies, including a qualitative analysis to identify and classify complementary changes introduced by the new EHR implementation and other potential confounders.

**Limitations.** Our study includes a small number of care settings. Our methodology effectively detected and quantified what changes happened, but not how and why they happened. We expect to improve its ability to detect how and why EHR implementations affect care delivery organizations by expanding our analysis in future studies including other implementation regions, measures, potential confounders, and a qualitative analysis of complementary changes introduced by the new EHR implementation. The two groups are located in different geographical areas and have different patient volume; we mitigated this limitation by comparing each group separately before comparing one against the other. Patients voluntarily answer the satisfaction survey, which could lead to selection bias.

**Conclusions**

We successfully tested a methodology that combines the use of 22 measures of quality, productivity and safety outcomes for monitoring performance changes during EHR implementations. We evaluated a commercial EHR implementation in a medium-size hospital and five ambulatory care clinics with multiple control sites. Nine (41\%) measures had an immediate effect after the go live, and 14 (61\%) measures an effect over time. We detected seasonal effects and outcome variability that would not have been detected by studies using simple measurements or pre-post comparisons. We recommend the use of our methodology in future studies to hopefully increase our understanding of the full impact of health IT interventions. A larger evaluation with the present measures and several others in 6 hospitals and over 50 clinics is underway.

ABSTRACT

Standards to increase consistency of comprehensive pain assessments are important for safety, quality, and analytics activities, including meeting Joint Commission requirements and learning the best management strategies and interventions for the current prescription Opioid epidemic. In this study we describe the development and validation of a Pain Assessment Reference Model ready for implementation on EHR forms and flowsheets. Our process resulted in 5 successive revisions of the reference model, which more than doubled the number of data elements to 47. The organization of the model evolved during validation sessions with panels totaling 48 subject matter experts (SMEs) to include 9 sets of data elements, with one set recommended as a minimal data set. The reference model also evolved when implemented into EHR forms and flowsheets, indicating specifications such as cascading logic that are important to inform secondary use of data.

Introduction

In light of today’s prescription Opioid epidemic, evidence-based and standardized assessment and management of patients’ pain is a high priority from clinical, safety, quality, and regulatory perspective, as discussed in the 2016 Joint Commission Statement on Pain Management. Joint Commission standards emphasize the importance of comprehensive pain assessments consistent with the organization’s scope of care, treatment, and services, as well as with the patient’s age, condition, and ability to understand. Management includes treatment and reassessment of pain, noting that treatment may include pharmacologic and nonpharmacologic approaches, and considering risks and benefits, including potential risk of dependency, addiction, and abuse. Importantly, these standards do not require pain assessment for all patients, but rather based on organizational policy that considers the population served and services delivered. Joint Commission standards also do not require treatment until the pain score reaches zero, but rather emphasizes an individualized patient-centric approach to determine the most appropriate pain goal.

Standardizing pain assessment can support clinician judgment and decision making for individualized patient-centric approaches to pain management by providing consistent and comparative data capture. However, standardization of pain assessment requires acknowledgement that the criteria for what comprises a comprehensive pain assessment may vary across settings, patient populations, and scope of interprofessional practice. Variations in setting, population, and professional practice are a significant challenge for the definition of consistent sets of data elements to represent a comprehensive pain assessment. Moreover, implementation of a comprehensive pain assessment on Electronic Health Record (EHR) artifacts (e.g., forms, flowsheets) results in further variation due to functional differences across EHR tools used in different clinical settings and by different types of health professionals (e.g., nurses, physicians, physical therapists, pharmacists, pain specialists).
Background

A comprehensive pain assessment includes the use of a validated pain severity scale, as well as collection of data to understand the context of the pain experience, such as the type of pain, how it originated, how often it occurs, factors that alleviate or exacerbate pain, and how the pain impacts the patient’s quality of life. As preliminary work, our team performed a literature review of pain assessment data elements that should be captured as part of a comprehensive pain assessment. This review included published standards from Health Level 7 (HL7), Logical Observation Identifiers Names and Codes (LOINC), and the Intermountain Clinical Element Model, among other resources, resulting in a comprehensive reference model for pain assessment subsequently validated by local SMEs. Further, there is a lack of an implementation ready comprehensive reference model for pain assessment that is applicable across clinical settings, patient populations, interprofessional teams of clinicians, and EHR tools.

Such an implementation ready model requires a balance between data constraints and flexible implementation approaches. To achieve this balance, our team adheres to principles for consistent and high quality data capture, while also leveraging and relying on interprofessional clinical subject matter expertise (SME). Here we report results from this process, highlighting the iterative development and validation of an implementation-ready enterprise-wide comprehensive interprofessional pain assessment reference model.

Methods

Our team previously published a 10-step approach for the development, validation, implementation, and evaluation of clinical reference models: 1) identify clinical topics, 2) create draft reference models for clinical topics, 3) identify downstream data needs for clinical topics, 4) prioritize clinical topics, 5) validate reference models for clinical topics, 6) perform gap analysis of EHR data elements compared against reference model, 7) communicate validated reference models across project members, 8) request revisions to EHR data elements based on gap analysis, 9) evaluate usage of reference models across projects, and 10) monitor for new evidence requiring revisions to reference model. Here we report on the application of these steps for the clinical topic of “Pain Assessment,” and the subsequent evolution and refinement of our Pain Assessment Reference Model. Specifically, we report on the reference model evolution at the following points in time: a) initial draft (step 2; model version 1), b) interprofessional SME Validation Delphi Rounds 1 and 2 (step 5; model version 2), c) EHR form implementation (step 6; model version 3), d) specialty SME Validation (step 5; model version 4), and e) EHR flowsheet implementation (step 6; model version 5). Notably, this is an iterative process, hence SME validation in step 5 was repeated when appropriate, e.g. to expand the scope of the model to include pediatric populations, and step 6 was repeated to perform a gap analysis for implementation in flowsheets. In addition, step 5 validation when performed on an initial draft reference model leverages a large group of interprofessional SMEs from across our enterprise and uses a modified Delphi technique with online voting conducted in two rounds to achieve consensus. As we perform follow-up SME validation for refinements to the model, the groups of SMEs are smaller and more targeted, typically requiring a single validation session. Reference model terms were based on standards and SME voting.

Our team has also reported on methodologies for gap analyses of EHR data elements compared against reference model. These methods use the MUC-5 (Fifth Message Understanding Conference) Evaluation Metrics, originally used to express error rates as part of a scoring system for automated information extraction, to compare two sets of structured data elements to determine how well they are aligned. Given the applicability of MUC-5 Evaluation Metrics to compare and quantify variation between sets of information, we used the MUC-5 Evaluation metrics to compare the 5 successive
versions of our reference model. These metrics identify if data elements are a match, a partial match, conflicting, extra, or missing.

In this study we will report the overall iterative process end-result, which includes collaborative sessions with EHR analysts to review results of gap analyses and determine if EHR functionality constraints will require modifications to the reference model in order to support its implementation using current EHR tools.

**Results**

A total of 32 SMEs participated in the initial interprofessional validation sessions, resulting in version 2 of the reference model (see Table 1 and Figure 2). An additional 16 SMEs participated in the specialty sessions focused on the pediatric population, resulting in version 4 of the reference model. These SMEs represented the following roles: physicians, nurse practitioners, registered nurses, pharmacists, physical therapists, occupational therapists, and analysts; these SMEs worked in the following clinical or operational areas: inpatient nursing, ambulatory nursing, inpatient medicine, ambulatory medicine, emergency medicine, acute and chronic pain management, home health, inpatient physical therapy, ambulatory physical therapy, pharmacy, nurse education, oncology, hand therapy, osteopathic medicine, psychology, palliative care, patient safety and quality, and corporate compliance.

*Number of pain scales not counted toward total data elements in reference model; v = version

The Pain Assessment reference model evolved from 21 data elements initially to 47 data elements in its final version (v5) (see Table 1). Throughout these iterative refinements, the data type of 1 data element changed, the names of 8 data elements were revised, and value sets adjusted for 16 data elements.

Figure 1 reports our MUC-5 Evaluation metrics comparing the initial model (v1) to the final model (v5). Figure 2 compares all 5 successive versions of our reference model using the MUC-5 Evaluation metrics. Overtime, 30 data elements total were added to the model and 17 data elements total were modified (Figure 1). Twelve new data elements were added to version 2 during interprofessional SME sessions, and 9 new data elements were added to version 4 during specialty SME sessions. Four new data elements were added to version 3 during implementation as an EHR form, and 5 new data elements were added to version 5 during implementation as a flowsheet (Figure 2).

As the model evolved and was implemented as EHR forms and flowsheets, intuitive sets of data elements emerged. The final model included 9 sets of data elements (see Table 2). The sets included an
average of 5.2 data elements with a range of 2 to 11 data elements each. The first set of data elements includes the recommendation for being “always included” on a documentation artifact (i.e. form or flowsheet). The remaining 8 sets of data elements can be optionally included if relevant to the clinical context of the documentation artifact. The “always include” set is comprised of 9 data elements that SMEs determined capture a minimal set of pain assessment data, namely concepts related to duration, location, quality, temporality, severity, and evaluation of pain relief.

Notably, two of the data elements in the “always include” set were added during our EHR flowsheet implementation step: 1) “Pain episode duration time unit”, and 2) “Pain assessment scale selection for cascade”. The form-based implementation required creation of a separate data element for the end-user to assert the unit of time associated with a numerical data entry for “Pain Duration”, such as minutes, hours, days, or weeks. There are 5 of this type of data element in the model: “Pain episode duration time unit”, “Pain onset time unit”, “Time period for best pain score”, “Time period for worst pain score”, and “Time period for average pain score”. Importantly, a clinical reference model may not require creation of separate data elements to handle units of measure, however, the instantiation of a clinical reference model ready for implementation in an EHR requires this level of specification. The data element ‘Pain assessment scale selection for cascade’ also was added during the last phase of refinement, readiness for Flowsheet Implementation, as a data element necessary to guide end-user to navigation using logic-based cascading within a flowsheet. However, we do recognize that these extensions to the reference model might need to be adjusted depending on the EHR system.

Discussion

Pain assessment documentation is a well-scoped clinical domain, ripe for standardization using a standard reference model. Similar models from HL7, LOINC, and other organizations have informed the development of our initial model. In working closely with SMEs that represent care needs across health professions, including medicine, nursing, and physical therapy, and inpatient and outpatient settings, including chronic pain care clinics, we identified twice as many data elements compared to our initial version. Overall, a larger number of data elements were added to the model for the SME validated versions compared to the EHR implementation versions, indicating that the original reference model was lacking clinical concepts needed for assessing pain in different contexts.

Our experience confirms the need to develop comprehensive clinical topic reference models in stages and with a broad set of interprofessional SMEs that represent the breadth of clinical settings in which that topic is used. We found that the use of online voting, supplemented with targeted and structured group discussion that included guidance and recommendations from informaticians on our team, was successful in driving consensus and resolving disagreements among SMEs. While our team is comprised of informaticians who perform multi-site data science research studies, future work may benefit from inclusion of researchers and data scientists as SMEs, formally representing important consumers of secondary EHR data. We also confirmed that additional sessions with SMEs from relevant specialty areas were beneficial in later stages of model refinement, contributing additional data elements while maintaining the overall structure of the model. We found the overall decreasing rate of change as versions were refined by SMEs to be a positive indicator of reaching a satisfactory level of model completeness. Our team is in the process of replicating these findings using the same methodological steps for other clinical topic reference models. Importantly, continuous reference model optimization is expected and we recommend scheduled updates to incorporate new evidence and models of care, as well as future work to expand model scope to other relevant patient populations and specialty areas.

With the aim of driving adoption of clinical reference models within EHRs, we consider the application of a reference model to at least one EHR instance an important exercise that uncovers the complex decisions required to bridge the inherent gaps between a model and an implementation of that model. In our study we found that both EHR implementations of the model using different types of documentation functionality (e.g., forms versus flowsheets) required a similar number of modifications.
Functionality, user interfaces, and data structures can vary significantly - even within the same EHR system – impacting the ability to standardize implementation-ready clinical reference models.

The types of new data elements added for implementation-ready versions 3 and 5 could be categorized as assisting with end-user workflows and navigation logic, as well as data capture where units of measure are mandatory. We can argue that only SME validation sessions were needed to standardize the capture of important clinical concepts for pain documentation. However, an implementation-ready reference model that reflects decisions made to accommodate end-user workflows and use of cascading logic to support documentation navigation is important to guide subsequent interpretations required for data reporting and analytics. For example, in our work we added a data element “Pain Assessment Severity Scale Selection for Cascade” and a separate data element to capture the Pain Severity Score from whichever pain assessment scale was selected. To simplify our model we did not include each pain severity scale in its entirety, as these are all validated published scales. However, we needed to explicitly include data elements to: 1) support scale selection and use, and 2) capture pain score data in one field for all scores on a scale of 0-10 to support reporting of pain scores across patients, settings, and time.

Our ongoing work also includes mapping our reference model data elements to existing reference terminologies, such as SNOMED CT and LOINC. Importantly, EHR implementation challenges are a barrier to reusing generic data elements, such as anatomical location that is independent of the pain domain. Leveraging generic concepts in our reference terminology mappings is ideal, including post-coordinating when appropriate, however, some EHR data capture and reporting functionality does not support – or is significantly complicated by - duplicate instances of a generic field across multiple contexts. In 2015, Westra and colleagues outlined a number of challenges and lessons learned from a study modeling flowsheet data for quality improvement and research, including the overall need for standards to represent flowsheet data. Our approach identifying an “always Include” set comprised of the minimal data elements available for clinicians to document a pain assessment addresses, at least in part, the challenge of documentation inconsistencies within and across systems. Westra and colleagues identified cascading logic as a critical challenge for secondary use of flowsheet data, leading to ambiguity if data were missing or not applicable for a given patient. EHR flowsheet data comprises a large portion of recorded structured clinical data, particularly for hospitalized patients. As secondary use of these data increases, implementation-ready data element reference models that include relevant implementation specifications, such as cascading logic, will be critically important for reliable and accurate data interpretation. Our work in validating an implementation-ready reference model for pain assessment confirms that “implementation-ready” specifications include variation across EHR forms and flowsheets. Currently, our team is collaborating with the Big Data Science Consortium lead by Westra and colleagues from the University of Minnesota to validate and standardize a flowsheet-based Pain Reference Model across multiple health systems. This final version of our SME validated Pain Assessment Reference Model is being used to inform that multi-site work. This collaboration, in addition to our interprofessional approach and initial model development agnostic to the EHR is intended to minimize silos of EHR data. Future work should include definition and use of metrics to evaluate if the implementation of reference models meets the needs for secondary use of these data for analytic and research activities and incorporation reference models as an EHR standard.

Conclusion

Our work to develop an implementation-ready Pain Assessment Reference Model resulted in a model with 47 data elements organized into 9 data sets. Significant modifications to clinical concepts were made after sessions with interprofessional SMEs, including the addition of data elements and revisions to existing data elements and their value sets. The model further evolved when implemented into EHR forms and flowsheets, adding data elements to support documentation workflows and cascading logic.
Refinements based on SME expertise and EHR functionality are important and complementary in clinical data element reference model development and should be well documented to increase standardization of structured clinical data, while also informing accurate secondary uses of EHR data.

Abstract
Safety reporting systems are improving our current understanding of safety in hospital settings, although mostly from the clinician perspective. Patient Family Relations (PFR) programs provide the opportunity to capture patient/family concerns in the hospital. Descriptive statistics were completed of PFR concern submissions over a 20 month period, as well as a comparison of structured data fields to those of the AHRQ Common Format. We identified statistically significant differences in rates of concern submissions, methods of submission, and role of submitter across patient populations. Overall, the most frequent concerns submitted to PFR were care/treatment and communication concerns. There was very little overlap of the PFR data elements with those of the AHRQ Common Format (overall rate of mismatch approached 80%). These results emphasize both the unique information that PFR data provides, as well as the need for enhancement and continuity of reporting systems for more effective analysis of safety data.

Background/Introduction
Estimates suggest that up to 400,000 preventable deaths may occur each year in the U.S., and consistent vigilance, monitoring, and system improvements are required to improve patient safety. (1–5) Voluntary event reporting systems and patient safety organizations have greatly advanced our understanding of safety from the clinician perspective in the hospital setting. (6–9) However, detailed understandings of the perspective of patients and families who experience a wide range of undocumented safety concerns every day are limited. A recent JAMA study found that patients whose surgeons have large numbers of unsolicited patient concerns and dissatisfaction are more likely to suffer from medical or surgical complications. (10) Patient reported concerns are not limited to individual clinicians, rather they typically capture perceptions of clinical and non-clinical services and processes in a hospital setting that can elucidate systemic weaknesses experienced by patients and families that are not readily clear to staff and administrators.

Root cause analysis (RCA) has recently been criticized for failing to deliver benefits of preventing future harms ‘at-scale’ and oversimplifying based on linear thinking that inappropriately leads to the identification of a single root cause. (11,12) Rather, systems thinking recognizes the multilayered complexity of health services and seeks to solve unrecognized systems issues. (12) In addition, RCA does not typically include the patient and family perspective, and is weakened by hindsight bias and the focus on single incidents which limits opportunity for understanding vulnerability in the context of prevalence of other similar incidents. (11,12) Electronic capture of patient and family reported concerns in data sets that grow overtime could mitigate these weaknesses by enabling real-time analytics aligned with systems thinking frameworks for improvement and evaluation of solutions that consider the patient and family perspective. The National Patient Safety Foundation and Peerally and colleagues recommend the creation
of safety data sets for aggregated analyses at multiple levels (e.g., department, institution, system, state, and national).(11,12)

Hospital-based Patient and Family Relations (PFR) programs provide a mechanism for patients (or their family, friends or staff members on the patients’ behalf) to share any concerns they have while receiving care and serve as a resource to coordinate the resolution of outstanding concerns. These essential programs provide a unique and highly valuable service for patients and families to contact in real-time and at the point of care to resolve clinical and non-clinical concerns. In addition to resolving concerns in real-time, the data captured as part of Patient and Family Relations work is highly valuable from a patient safety perspective to complement existing safety reporting systems. Several data integrity issues exist when capturing safety incidents and near misses/concerns in hospital reporting systems, such as incomplete data in clinician reporting systems.(13) Triangulation of safety data sets from different sources with varied perceptions of care delivered could mitigate the impact of missing data in each data set. Yet, the triangulation of these safety data sets requires standardization of data capture for aggregated and comparative analyses. The AHRQ’s Common Format for capturing safety events provides standards to capture ‘incidents’, ‘near misses’, and unsafe conditions’. (14) An ‘incident’ is defined as a patient safety event that reached the patient, ‘near miss’ as a patient safety event that did not reach the patient, and ‘unsafe condition’ as a circumstance that increases the probability of a patient safety event.

The aims of this study are to: 1) describe reporting trends to Patient and Family Relations across inpatient populations to increase our understanding of patient perceived safety concerns, and 2) compare Patient and Family Relations data set to AHRQ’s Common Format to identify critical gaps that constrain aggregated analyses and learning opportunities of the patient and family perspective and experience in the context of these quality and safety concerns.

Methods
As part of a study focused on hospitalized patient and family perceptions of safety concerns and reporting tools we analyzed a data set of concerns shared with a PFR program at a large academic medical center. These data were de-identified and represented a time period of 20 months (January 2015 - August 2016) for hospital units including the following patient populations: critical care medical and surgical patients, and acute care cardiovascular, medical, surgical, neurology, and oncology patients. The de-identified data set contained the following fields for each submission: clinical unit, date received, resolution date, report submitter, method of submission, description of concern, outcome notes, and up to 4 concern categories and subcategories (selected by PFR staff that entered the reported concern into the system). Method of submission is a structured field, with the following value set: telephone, walk-in, email, letter, and website. Descriptions of concern and outcome notes are free-texts field. The options for report submitter were bucketed into the following values: patient, family/friend, staff, and other.

We performed two sets of analyses: 1) descriptive statistics of role of submitter, method of reporting, and categories of concerns stratified by patient population, and 2) comparison of structured data capture fields from Patient and Family Relations database to AHRQ Common Format. To enable comparative descriptive statistics across patient populations with varying number of patient beds and lengths of stay we utilize counts per 1000 patient days calculated from average nightly census data. This rate was calculated by total number of submissions divided by the total number of patient days multiplied by 1000. We also performed a small sub analysis on the reliability of the structured report submitter field by comparing it to the information recorded in the description of concern field.

We used the MUC-5 (Fifth Message Understanding Conference) Evaluation Metrics to compare PRF data fields to AHRQ Common Format.(15) These metrics are used to express error rates and were originally developed as part of a scoring system for automated information extraction when compared to manual
Results

Descriptive Statistics

A total of 554 concerns were submitted during the 20 months of the study data across all seven inpatient populations: critical care medical and surgical patients, and acute care cardiovascular, medical, surgical, neurology, and oncology patients. Table 1 displays submission rates per 1000 patient days for each patient population along with the range.

1Submission rate calculated by total number of submissions divided by total number of patient days multiplied by 1000

Tests used: ¹Poisson test for equal rates; ²Fishers Exact test
We identified statistically significant differences in rates of concern submissions overall across all patient populations types (Fisher’s Exact Test, p-value <0.0001). We also found statistically significant differences in methods of submission used across patient populations, as well as differences in role of submitter across patient populations (Fisher’s Exact Test p-value 0.0258 and 0.0006, respectively). See Table 1 for the rates and statistical results. Acute care surgical patients had the highest rate of submission per 1000 patient days, followed by acute care neurology patients. The critical care medical patient population had the lowest submission rate across the given time period at 2.25 submissions per 1000 patient days. The telephone was the most used submission method for reporting a concern across all populations, with usage rates for telephone between 62.5% and 84.5%. Acute care oncology and neurology frequency of staff submissions (66.7% and 49.1%, respectively) stand out as an anomaly from the other acute care patient populations, which otherwise have staff submission frequencies at 30%, 34.7%, and 35.2%. The role of submitter that was most frequent varied across the patient populations. As expected due to patient acuity, we found that families and staff submitted concerns on behalf of critical care patients at higher rates than critical care patients submitted themselves. Subsequently, acute care surgical and cardiovascular patients submit more frequently than family and staff for those populations.

A sub analysis was performed on the accuracy of the report submitter field in the PFR data. In about half of all the submissions (278 out of 554) the description of concern field directly stated who contacted PFR about the concern. Out of these 278 submissions, we looked at a random 20% (55) and checked the accuracy of the report submitter structured field against the description of concern. 8 out of these 55 had conflicting documentation on who submitted the particular concern.

The PFR data set included a total of 19 potential concern categories that could be attributed to a concern submission. The 5 most frequently coded categories overall were Care/Treatment, Communication, Coordination and Continuity of Care, Discharge, and Attitude. The top 2-4 categories across each patient population were consistently comprised from these 5 categories, with slight variation in specific ranking (see Table 2).

The breakdown of frequency of concern category used per patient population (normalized across populations by 1000 patient days) can be seen in Figure 1. This shows all the categories and their uses by the various patient populations. It is important to note that up to four categories could be attributed to one submission (i.e., many to one), so the number of categories used does not correlate directly to the number of submissions per patient population.
Figure 2: PFR data elements mapped to AHRQ Common Format data elements

Total primary error represents the number of wrong elements over total elements; undergeneration is the number of elements missing over the number of elements possible; overgeneration is the number of extra elements over number of actual elements. Substitution is defined by incorrect matches and partial matches divided by correct, partial, and incorrect elements.

Mapping to AHRQ Common Formats

The comparison of data elements from the AHRQ Common Formats compared to Patient and Family Relations data elements indicate very little overlap with an overall rate of mismatch of almost 80% (see Figure 2). Interestingly, from our data set of Patient and Family Relations submissions the most frequently selected safety event/concern categories were also the most generic safety event/concern categories from within the categorization schema (see Figure 1). Table 3 below shows the detailed mapping results between PFR data elements compared to the AHRQ Common Formats data elements with shading to note unmatched (missing) data elements.

Following are two examples from our data that demonstrate the implications of the high rate of mismatch between the Patient and Family Relations and AHRQ Common formats data elements. One narrative description from our Patient and Family Relations was: “The care coordinator left a message stating that the patient’s sister is upset that nursing staff did not understand the healthcare proxy documentation policy.” This description was categorized as ‘Care/Treatment’ with a subcategory of ‘Participation in care plan’. While this categorization is arguably insufficient as it does not capture the detailed nature of the submission or indicate its relevance as a healthcare proxy concern, it does categorize the issue at a high level. However, there are no safety event/concern categories from the AHRQ Common formats that would apply to this issue, requiring that it would be coded as ‘other’. It could be argued to be an ‘unsafe condition’ that increases the probability of patient safety event from the perspective that the sister’s ability to act as a patient advocate is being limited in this situation.

A second example is: “Patient is concerned about how to care for her shunt once she is discharged”. In the Patient and Family Relations data this was categorized as: ‘Care/Treatment’ with a subcategory of ‘Outcome of surgery/procedure’. These categorizations are also arguably insufficient, although not wrong. Using the AHRQ Common Formats this could be an ‘unsafe condition’ increasing the probability of complication or infection and a readmission to the hospital. However, we consider the safety event

---

**Shaded boxes indicate no match (missing). *indicates partial match**
categories ‘Healthcare-associated Infection’ and ‘Surgery or Anesthesia (includes invasive procedure)’
tangential, or only slightly connected, and not appropriate to categorize the issue.

Discussion
This data set of patient and family concerns contains a vast amount of information that can be used to
learn more about the patient and family experience and patient-perceived concerns across inpatient
populations. There was interesting variation in patient and family concern reporting across patient
populations. One trend in particular that stands out is the high level of staff submissions seen on the acute
care oncology and neurology units. Perhaps due to the nature of the conditions for these specialty
populations there is a greater need for patient advocates. Oncology care can be very complex and of
significant gravity, difficult to navigate, and there are likely many cognitive issues on neurology, both
making it complicated for the patient to advocate for his or her self. There are also some variations in
reporting method: telephone use is most common across all patient populations, but there is a higher use
of walk-ins for acute and critical care medical populations than, for example, acute and critical care
surgical populations. Communication, care/treatment, coordination and continuity of care, attitude, and
discharge are the most commonly reported categories of concern, with good consistency across the patient
populations looked at in this study.

The discrepancies found in the sub analysis on accuracy of the report submitter field highlight the need to
review the structured field definitions to confirm if they meet the needs of the data set and the individual
entering the data, either through usability analysis or detailed interviews to better understand the
workflow of Patient and Family relations and barriers to this data entry. Patient concerns are often
complex and not straightforward, and may include multiple parties. The addition of a structured field
indicating who is concerned, or who is followed up with after the initial contact could give a better picture
of the situation, e.g. the nurse calls at the request of the family and then the family talks to PFR to
describe the details of the concern. Since these situations are not always as simple as one person
reporting, we need a way to reflect this in the structured data. In the long run that will allow for better
and more accurate data analysis using big data analytics with less need of retrospective qualitative
checking.

Upon detailed analysis, the current categorizations in the PFR data set are too generic to adequately
capture the context and content of concerns. Therefore, aggregated quantitative analyses of these
categories and subcategories provide limited information and utility. In fact, qualitative analyses are
needed to learn relevant trends from this rich data set that could increase our understanding of the patient
experience and inform system improvement. There exists an opportunity for a data-driven categorization
of concerns based on these data sets.

Further, the data elements used by Patient and Family Relations appears tangential to the AHRQ
Common Formats, likely due to variation in the purpose of data collection for these data sets. The
significant differences in concern categories between the AHRQ Common Format and the PFR data show
there is much need for intensive work on providing better and more informative categorization for the
PFR data. It is also clear that there is a large need for the information the PFR data supplies, since it is
not well represented in the AHRQ Common Format. Demonstrated through the descriptive PFR
examples such as ‘Patient is concerned about how to care for her shunt once she is discharged’, we can
see that the AHRQ common format categories are likely more designed to capture near misses and
incidents, which are typically gathered from clinician-type reporting systems. The type of data that PFR
captures can help inform on the “unsafe conditions” incident put forth by the AHRQ Common Format in
providing the unique view of hospital conditions from the patient and family perspective, and differences
and tendencies among patient populations.
Patient and Family Relations does not explicitly have a method to submit anonymously (a phone call or a letter could always be unidentified or a patient/family member could request to stay anonymous, but that is not the main pretense of the system). The AHRQ Common Format does have the option to submit an anonymous concern. A straightforward way to anonymously submit safety concerns through PFR might provide an important view into the group of patients that might not report concerns otherwise. This can be for a number of reasons, but most prominent is the fear of repercussion; in reporting a concern, some patients and family members might worry that his or her care will be compromised or will be treated differently. Our team is leading work to provide patients with an electronic reporting app called MySafeCare on each clinical unit to complement existing hospital-wide reporting methods. MySafeCare is an electronic safety reporting tool that aims to 1) provide patients and families that might otherwise not speak up with an anonymous way to address concerns they have about their hospital stay, and 2) create a quick and easy to use method of reporting that can facilitate real-time capture of worrisome or concerning events. (16,17) This tool is helping to add to the pool of patient-generated data that is becoming more recognized as important and useful in patient care. The structured Patient and Family Relations data is extremely beneficial to learn from because it already established as an operational system in the hospital. Initiatives like MySafeCare aim to target areas of need, i.e. the patients that wouldn’t otherwise report a concern because they do not want to do it in person or identified. We can leverage analysis of PFR data to learn about areas of need and effective methods to implementing these new types of tools. Current development work is also being done with MySafeCare to enable data exports using AHRQ Common Formats, further aligning data for ease of analysis.

Table 5 below gives a summary of the recommendations for patient reporting systems and their potential benefits based on the analysis completed for this paper. A robust and comprehensive patient and family reporting system will greatly improve our knowledge of patient perspectives in the hospital setting.

**Conclusion**

Patient and family generated safety concern data can be utilized to help systemically improve patient care and satisfaction at both a unit and hospital-wide level. We can learn, among other things, which types of concerns are most prevalent on different clinical units, which patient populations are in the most need for patient advocates, and the best methods for increasing communication of these issues. Development and enhancement of reporting systems that capture concerns from the patient and family perspective are needed to improve on the quality and accuracy of data capture, so we can learn important reporting.
patterns across patient populations in a standardized manner. This information can complement data from clinician-reported events and offer critical insight into safety and the patient experience in the hospital.

Calibration Drift Among Regression and Machine Learning Models for Hospital Mortality

Sharon E. Davis, MStat1, Thomas A. Lasko, MD, PhD,1 Guanhua Chen, PhD,1 Michael E. Matheny, MD, MS, MPH1 2

Abstract

Advanced regression and machine learning models can provide personalized risk predictions to support clinical decision-making. We aimed to understand whether modeling methods impact the tendency of calibration to deteriorate as patient populations shift over time, with the goal of informing model updating practices. We developed models for 30-day hospital mortality using seven common regression and machine learning methods. Models were developed on 2006 admissions to Department of Veterans Affairs hospitals and validated on admissions in 2007-2013. All models maintained discrimination. Calibration was stable for the neural network model and declined for all other models. The L-2 penalized logistic regression and random forest models experienced smaller magnitudes of calibration drift than the other regression models. Calibration drift was linked with a changing case mix rather than shifts in predictor-outcome associations or outcome rate. Model updating protocols will need to be tailored to variations in calibration drift across methods.

Introduction

Risk prediction models are developed across clinical domains1-6 to support patient and provider decision-making, adjust quality metrics for acuity, and augment enrollment strategies for clinical trials1,5. Although model validations have traditionally focused on discrimination, calibration is increasingly recognized as an essential aspect of model accuracy, particularly when models support individual-level patient decision-making1, 7, 8. With the adoption of electronic health records and use of advanced modeling methods, the role of clinical prediction models and our understanding of the challenges presented by the incorporation of predictive analytics into clinical care are rapidly evolving1, 9-11. One such challenge is deterioration of model calibration as characteristics of patient populations shift over time6,12-15. Limited evidence is available regarding how such calibration drift may vary across advanced regression and machine learning models, and how modeling methods may impact the need for routine model updating.

Mortality within 30-days of hospital admission, a key metric of hospital quality and patient safety, is assessed and tracked by the Centers for Medicare and Medicaid Services (CMS) to both inform the public and, since 2013, to adjust reimbursements16. CMS quality metrics rely on prediction models to standardize mortality rates by adjusting for the case mix of each hospital’s patient population16. In addition to quality benchmarking, prediction models for hospital mortality may be used to support decision-making particularly in the critical care setting. Numerous prediction models for hospital mortality have been presented in the literature2, and external validations have documented deteriorating calibration over time for many of these models13,14,17-19. While advanced regression and machine learning methods have been implemented for mortality prediction20-22, studies of calibration drift have primarily focused on logistic regression models and crude measures of average calibration. We sought to extend this existing literature through consideration of additional modeling methods, more stringent assessments of calibration, and systematic quantitative evaluations of the population data shifts driving performance changes.

Methods

We accessed data on eight years (2006-2013) of admissions to Department of Veterans Affairs hospitals nationwide with corresponding pre-admission data from 2002 for admitted patients, and randomly selected 50% of the sites within each Veterans Integrated Service Network for inclusion in this analysis. We modeled 30-day all-cause mortality after hospital admission using a predictor set developed through review of previously published risk models2, 23-25. Predictors were extracted from the national Corporate Data Warehouse26 and included demographics, vital signs during the first 48 hours of admission, laboratory values during the first 48 hours of admission, and diagnoses codes, medications, and care utilization prior to admission. Admissions were excluded if the patient was under 18 years of age, discharged to hospice care, admitted for less than 48 hours, or lacked 30-days of available follow-up (i.e., admitted in the last 30 days of 2013).
Admissions beginning in 2006 served as our training set and admissions beginning in 2007-2013 served as our validation set. Using the common training data and predictors set, we developed seven parallel models for hospital mortality based on logistic regression (LR), L-1 penalized logistic regression (L1; i.e., lasso), L-2 penalized logistic regression (L2; i.e. ridge), L-1/L-2 penalized logistic regression (L1-L2; i.e., elastic net), random forest (RF), neural networks (NN), and naïve Bayes (NB)\textsuperscript{27}. For those models requiring tuning (i.e., L1-L2, NN, RF), hyperparameters were selected with 5-fold cross-validation. Each model was internally validated with the bootstrap (B=200) using only admissions in the training set (2006 admissions). We divided the 7-year validation set into consecutive 3-month periods (n=28) and assessed performance of the models within each. Discrimination was measured with the area under the receiver operating characteristics curve (AUC)\textsuperscript{28}. Calibration was measured with observed to expected outcome ratios (O:E), the Cox logistic recalibration model’s intercept and slope, and flexible calibration curves\textsuperscript{29, 30}. The most stringent measure of calibration in this study, flexible calibration curves assess calibration across the range of probabilities by fitting a logistic model for the observed outcome based on predicted probabilities fit with a restricted cubic spline\textsuperscript{29}. We summarized these calibration curves with the estimated calibration index (ECI; the mean squared difference between predicted probabilities and estimated observed probabilities from the flexible calibration curves)\textsuperscript{29} and by regions of predicted probability where the model was calibrated, overpredicted, or underpredicted (i.e., ranges of probability over which the confidence interval of the flexible calibrations curve captured the 45° line of perfect agreement, was below the line, or was above the line were labeled as regions of calibration, overprediction and underprediction, respectively). In addition, we calculated within-region ECIs and rescaled each region by the volume of observations with predictions in its range. This proportional regional volume assessment emphasized calibration status based on data density and ranges of probability most relevant to the observed data.

We also characterized data shifts in the patient population to link any changes with model performance over time. We documented shifts in the mortality rate and in the distribution of each predictor across the study period. Case mix changes were further assessed by fitting membership models in each 3-month validation period. Membership models are prediction models aimed at discriminating between validation and development observations using the outcome and predictor set from our original model to determine whether case mix shift is present and identify variables contributing to such shift\textsuperscript{31}. We refit the LR, L1, and RF models in each 3-month validation period to explore shifts...
in the strength of associations between predictors and 30-day mortality. Any changes in association were documented as changes in LR odds ratios, L1 variable selection patterns, and RF variable importance ranks.

All analyses were conducted in R 3.2. This study was approved by the Institutional Review Board and the Research and Development committee of the Tennessee Valley Healthcare System VA.

Results

Nationwide, 3,467,142 admissions to VA facilities met all eligibility criteria for our 30-day all-cause mortality models. Restricting to admissions from the randomly selected sites, our analysis set included 1,893,284 admissions (54.6% of all eligible admissions), 235,548 in the 2006 development set and 1,657,736 in the 7-year validation set. The final validation set (i.e., 2013-Q4) was smaller than the other validation set (n=37,442) as it was restricted to admissions beginning on or before December 1, 2013 to allow for sufficient follow-up time for outcome ascertainment. The remaining 27 validation sets consisted of 60,011 admissions on average (range 57,367 – 62,139). A brief summary of the patient population at select points across the study period is presented in Table 1. Admitted patients were primarily male (95.0%), white (72.1%), in their early 60s (mean age: 63.4; standard deviation: 14.0), and diagnosed with at least one chronic medical condition (93.9% diagnosed with one condition, 86.8% diagnosed with multiple conditions). Overall, the 30-day all-cause mortality rate after admission was 4.9%.

Initial performance of each of the seven models is presented in Table 2. Due to large sample sizes, the confidence intervals are narrow for all measures. Discrimination was generally good, with AUCs ranging from 0.768 to 0.847. The NN and NB models had slightly lower AUCs than the regression and RF models. The regression models and the NN model were calibrated based on both O:E ratios and ECIs. The RF model, with an O:E ratio of 0.929 (95% CI: 0.927, 0.931), slightly overpredicted on average. The NB model lacked calibration due to strong overfitting.

Model Performance Over Time

We observed stable discrimination for all models over the 7-year validation period (Bonferroni adjusted p<0.001; Figure 1). The regression and RF models had comparable AUCs and maintained higher discrimination than the NB and NN models, which exhibited similar levels of discrimination.

We observed calibration drift over time for all models, with the magnitude and pattern of drift varying by modeling method and calibration metric (Figure 2). The NB model substantially underperformed all other models in terms of calibration due to extreme predictions, and thus the calibration of this model is not considered further.

The O:E ratio (ideal value: 1) declined immediately after development and across the study period for all models, indicating increasing average overprediction. At the first 3-month validation period, O:E ratios included the ideal values of 1.0 for only the NN and LR models. These two models achieved calibration according to the O:E ratio at two to four additional time points, however, overpredicted on average for most of the validation period. The trajectory of the O:E ratio was similar for most models, with the exception of the NN model which did not exhibit a significant slope in the O:E ratio over time (Bonferroni adjusted p<0.001). The NN model demonstrated significantly less overprediction than the RF and regression models, particularly in the last three years of the validation period. In
addition to the overall drift, a seasonal pattern was apparent in the O:E ratios. In the first and fourth quarters of most validation years, O:E ratios peaked for all models.

The Cox logistic recalibration intercept (ideal value: 0) and slope (ideal value: 1) also noted different patterns of drift across modeling methods. The Cox intercept declined across the validation period for each of the regression models, indicating increasing overprediction, while remaining stable for the RF and NN models (Bonferroni adjusted p<0.001). The L2 model exhibited a smaller decline in the Cox intercept over time than the other regressions. The RF model did not systematically over or underpredict in most (24 of 28) validation periods, and the NN model systematically overpredicted to a stable degree for the entire study period. Additionally, we observed a seasonal pattern in the Cox intercept similar to that of the O:E ratio, although to a lesser degree. Cox slopes were stable over time (Bonferroni adjusted p<0.001). No significant overfitting was observed for the LR, L1, and L1-L2 regression models. The L2 regression and RF models exhibited some underfitting (i.e., Cox slope>1.0). This underfitting was consistent over time for the L2 regression model and demonstrated a nonsignificant tendency toward increasing for the RF model. The NN model had Cox slopes less than 1, indicating overfitting; however, there was no significant change over time.
Measuring calibration more stringently with flexible calibration curves, we observed drift among the regression and RF models, and stable overall calibration with some seasonal variation for the NN model. ECIs (ideal value: 0) of the regression and RF models increased across the validation period (Bonferroni adjusted p<0.001), indicating declining calibration, and exhibited no changes in the trajectory or rate of ECI drift during the seven validation years. The L2 regression model experienced a smaller magnitude of drift in the ECI compared to the other regression models and a similar magnitude of drift to the RF model. Compared to the L2 regression and RF models, the rate of change in ECI was 50% higher for the LR model (0.006 [95% CI: 0.005, 0.008] vs 0.004 [95% CI: 0.003, 0.005] and 0.004 [95% CI: 0.002, 0.005] for the LR vs L2 and RF, respectively) and 75% higher for the L1 and L1-L2 models (0.007 [95% CI: 0.006, 0.009] for both). For each model, seasonal corrections of the ECI were generally observed in the first and fourth quarters of each year. ECI was stable over time for the NN model (Bonferroni adjusted p<0.001). Although not significantly different from the surrounding time periods, in most validation years, the ECI of the NN model was markedly lower (i.e., closer to the ideal value of 0) during the first and fourth quarters of most years.

The ranges of predicted probabilities and proportion of admissions over which each model was calibrated also changed over time and varied by modeling method (see Figure 3). With the exception of the NB model, which strongly overpredicted for most predicted probabilities, each model moved in and out of regions of calibration, overprediction,
Figure 4. Model calibration over time, measured by regions of calibration scaled by proportion of observations in each region and shaded by the magnitude of the within region ECI.

and underprediction across the range of predicted probabilities. The RF model was the only model with a large range of probabilities over which it strongly underpredicted. During the first half of the validation period, the L2 regression model tended to be calibrated for predictions in the 50% to 90% ranges. The remaining models and the L2 regression model during the second half of the validation period tended to strongly overpredict for predicted probabilities starting at approximately 20%. For each regression model, across the validation period the proportional volume assessment (Figure 4) indicated that nearly half of admissions were in regions of overprediction, with the proportion increasing slowly over time. The majority of these admissions were minimally overpredicted, falling in areas with regional ECI values near the ideal value of 0, as highlighted by the lightest blue shades in Figure 4. For example, in the LR model, a low risk region of overprediction captured at least 40% of admissions in each 3-month validation period and had a mean ECI of 0.005 (range: 0.002 – 0.009). Each of the regression models also experienced growth in an overpredicted region with a larger magnitude of miscalibration among higher predicted probabilities. For the L1 and L1-L2 regression models, the vast majority of admissions were strongly overpredicted in the last year of the study period. The overpredicted region of the RF model captured a growing proportion of admissions over time and increased modestly in the magnitude of overprediction across the validation period. The proportional volume analysis highlighted a seasonal pattern in the calibration of the NN model for admissions with predicted probabilities under
3%. On average, 61.3% of all admissions were in this low risk region for which the NN model was calibrated during the first and fourth quarters of most years and minimally overpredicted during the second and third quarters.

Data Shifts in the Patient Population Over Time

Over the 7-year validation period, there was a statistically significant decline in the 30-day mortality rate (Bonferroni adjusted p<0.0003); however, this change was small, declining from 5.0% in the 2006 development year to 4.8% in the final validation period. Seasonal fluctuations within each validation year were three times larger than the overall change in the mortality rate (mean within year change: 0.6%; overall change: 0.2%). Compared to predictor variables, the outcome was relatively unimportant in RF membership models aimed at distinguishing validation and development observations. The variable importance rank of 30-day mortality declined from 59 to 63 out of 67 over the first validation year and was stable at a mean of 63 (range: 52 – 64) over the next 6 years.

We observed case mix shift across the validation period. Distributions of predicted probabilities generally indicated increasing severity and heterogeneity of risk in the patient population over time (Bonferroni adjusted p<0.002). Membership models also noted the presence of case mix shift, with the logistic membership models increasingly discriminating between admissions from the development and each sequential validation set as the AUC increased from 0.616 (95% CI: 0.613, 0.618) to 0.836 (95% CI: 0.834, 0.839) over the seven validation years. We observed changes in the distributions of 94.5% of predictors during the study period (Bonferroni adjusted p<0.0003). The proportion of admissions to black patients, that were planned, and that were unplanned but not readmissions did not change over time. In addition, the mean of the most recent blood urea nitrogen level was constant over. Changes in vital signs, laboratory values, and body mass index were generally small in magnitude. The forms of these changes were variable, with some having an inflection points at three to four years after model development. The largest changes were observed among the health history variables. With the exception of HIV, which declined by less than 0.5%, the proportion of admissions involving patients with each health condition increased across the validation period. The rates of these increases were generally constant over time. Among health history variables, the largest changes over time occurred for dyslipidemia (41.8% to 66.8%), fluid and electrolyte disorders (19.0% to 38.9%), and depression (20.1% to 39.9%), while the smallest change was observed for lymphoma (1.2% to 1.6%).

Changes in the structure of associations between predictors and 30-day mortality were measured by changes in the confidence intervals of the odds ratio from the original model based on 2006 data. However, a few variables exhibited a non-significant tendency toward strengthening or weakening associations. For some laboratory values, such as chloride and sodium levels during admission, odds ratios were less stable, moving in and out of significance in both directions of association. In L1 regression models refit over time, we observed significant temporal changes in selection patterns for two predictors (Bonferroni adjusted p<0.0004): history of liver disease and mean corpuscular hemoglobin concentration during the admission window. The frequency of selection for inclusion in L1 regression models began to decline starting approximately two years after development for both predictors. The magnitude of decline in selection frequency was larger for liver disease, which was selected in 98.0% of bootstrapped models at development and in 44.5% of models in the final validation period. Refitting RF models in each 3-month validation period revealed temporal changes in variable importance ranking for three predictors (Bonferroni adjusted p<0.0004): history of depression, history of dyslipidemia, and serum creatinine during the admission window. Ranks increased from 51 to 43 for depression and 29 to 17 for creatinine. The variable importance rank of dyslipidemia was steady through the first five years and then declined from 39 to 50 over the last two years of the validation period.

Discussion

In repeated validations over seven years, we observed varying patterns of performance among regression and machine learning models for 30-day all-cause mortality after hospital admission. Among all models, discrimination was stable over time. With the exception of the NN model, calibration drifted across the entire validation period as well as the other overpredicted risk. Seasonal changes in the mortality rate were correlated with cyclical fluctuations in the calibration of all models, including the NN model despite its maintaining stable calibration overall. Case mix shift dominated temporal changes in the patient population. Taken together with the observed calibration drift, the data shift assessments highlight robustness of the NN model, moderate susceptibility of the RF and L2 regression models, and high susceptibility of the other regression models to case mix shift.

Our findings of stable discrimination and increasing overprediction over time are consistent with previous studies of performance drift in logistic hospital mortality models [13, 14, 15-19]. While most prior work focused on logistic regression...
models, Minne et al\textsuperscript{14, 32} provide a comparison of calibration drift between corresponding logistic regression and tree-based rSAPS-II models for mortality among elderly ICU patients. Based on O:E ratios, the logistic rSAPS-II experienced increasing levels of overprediction within four years of development, while the tree-based rSAPS-II demonstrated stable calibration\textsuperscript{14, 32}. Although we did not observe differences in calibration drift between our logistic and RF models based on the O:E ratios, our RF model did experience a smaller magnitude of deterioration in the more stringent ECI metric compared to our logistic regression model.

Performance drift is driven by changes in the prevalence of an outcome, patient case mix, and associations between predictors and outcomes\textsuperscript{3, 5, 6, 13, 15, 31}. In our cohort, we detect limited evidence of predictor-outcome association shifts and observed primarily seasonal changes in the mortality rate. Seasonal event rate shift was correlated with a cyclical pattern in calibration. However, with the exception of the NN model, our models experienced calibration drift across the validation period that could not be explained by the seasonal variation in the mortality rate alone and is likely, therefore, associated with the documented changes in patient case mix. The stability of calibration of the NN model suggests this method is robust to case mix changes, at least to the extent seen in our cohort. The Cox recalibration model and flexible calibration curves indicated less deterioration in calibration over time for the L2 regression and RF models compared to the LR, L1, and L1-L2 regression models. The basic logistic regression and penalized regression methods that include variable selection, therefore, appear to be the most susceptible methods to calibration drift in the presence of case mix shift, while the L2 regression and RF models appear to be moderately susceptible, falling between the other regression approaches and the NN model. Additionally, we note that case mix shifts leading to changes in the variability of risk in the patient population have been previously noted to be of particular concern for discrimination drift, as patients become more difficult to distinguish or more easily separable as they become more homogenous or more heterogeneous, respectively\textsuperscript{31}. Although we observed increased heterogeneity of risk among admissions over time, we did not observe drifting discrimination. This may indicate that the degree of change in the variability of the risk in this cohort was not sufficient to trigger discrimination drift.

An important limitation in interpretation of modeling performance over time in real-world data is that different patterns of data shifts could result in differential model performance. We previously executed a separate study in which we explored calibration drift and data shifts in the clinical domain of hospital-acquired acute kidney injury\textsuperscript{33}. Diverging patterns of calibration drift between regression and machine learning methods were observed in both studies. Our current study extends and complements our previous findings by revealing disparate patterns of calibration drift across modeling methods in the presence of distinctive combinations of data shifts. For both clinical domains, the calibration of all models was susceptible to shifting event rates. While we did not observe predictor-outcome association shifts in our 30-day mortality cohort, association shifts in the acute kidney injury population temporally coincided with diverging patterns of calibration drift between regression and machine learning models. While case mix shift was observed in both study populations, the dominance of this form of data shift in our 30-day mortality population allows us to link case mix shift with differences in calibration drift between across modeling methods. Synthesizing findings across both studies, we found RF and NN models are generally less susceptible to case mix and association shifts than regression models, with the exception of the L2 regression model in the presence of case mix shift. Our findings in this work inform which methods may be most useful for modeling hospital mortality in changing environments and highlight both the variable updating needs of different modeling approaches and the influence of particular combinations of data shifts on our understanding of model susceptibility to deteriorating performance. As model performance patterns emerge among different data, understanding similarities in the assessed domains and a future domain of interest can assist in calibration maintenance.

Our findings have important implications for the integration of prediction models into clinical decision support tools and the design of model updating protocols. With the exception of the NN model, calibration drift impacted all models and began shortly after model development. Miscalibration of risk predictions can be harmful, potentially leading to inappropriate changes in treatment selection, anxiety, over-confidence, or inefficient allocation of limited clinical resources\textsuperscript{3, 7, 8, 13}. Lack of calibration may also mislead benchmarking assessments of facility quality\textsuperscript{14}. Calibration drift must, therefore, be addressed with routine model updating through recalibration, full model revision (i.e., refitting), or even model extension with the incorporation of new predictors\textsuperscript{3, 6, 34}. The form of population data shifts and performance drift should drive the timing and approach to model updating. We recommend implementation of active surveillance tools to track model performance and characterize changes in patient populations over time in order to trigger model updating and inform updating approaches. As our findings highlight, models based on different methods will have different updating requirements. We thus further recommend that the updating protocols built into such surveillance systems be tailored to modeling methodologies and support flexibility in timing of updates rather than being restricted to regularly scheduled intervals.
There were some limitations in this work. In this analysis, we consider model performance under a particular combination of data shifts; however, other combinations of data shifts in patient populations, including different forms and extents of shift, may expose other performance drift patterns. This was highlighted by the different combinations of data shifts observed in this study and prior work with AKI models\textsuperscript{33}. Studies in additional populations with diverse data shift scenarios or in simulated populations with defined forms and extents of data shift would provide a more nuanced understanding of the susceptibilities of various modeling methods. Additionally, we focused on a limited number of common modeling methods, and assessment of additional modeling techniques may reveal more patterns of performance drift. Finally, while we observed significant deterioration in the calibration of most models, we note that statistically significant miscalibration may not translate to clinically relevant changes in performance. Explorations of drift across methods using clinical utility metrics or extensions of calibration metrics to incorporate clinically acceptable margins of error would be particularly informative.

Conclusion

Predictive analytics providing tailored predictions at the individual-patient level are becoming increasingly feasible and commonplace. As we continue to identify and pursue opportunities to incorporate predictive analytics into clinical decision-making, we will require well-calibrated models that consistently deliver highly accurate predictions. In this study, we explore a set of methodologies that can be implemented as an ensemble for active surveillance of clinical prediction models in order to understand potential impacts in the choice of which modeling method to use and how trends in changes in clinical data impact calibration over time in order to make decisions about periodic modeling updating. For our models of 30-day all-cause mortality after hospital admission, case mix shift had little impact on the neural network model, moderate impact on the random forest and L-2 penalized logistic regression models, and a significant impact on most variations of logistic regression. In order to maintain the utility of and user-confidence in model predictions, routine maintenance of implemented clinical prediction models will be essential moving forward. We emphasize the importance of considering the long-term performance implications of modeling methods when developing, implementing, and updating clinical prediction tools. As best practice guidelines for model updating are developed, modeling methods must be a central consideration in order to promote efficient and effective strategies.

Abstract

Clinical dashboards that display targets compared to performance metrics are increasingly used by healthcare organizations in their quality improvement efforts. However, few studies have evaluated the extent to which healthcare professionals can readily understand and interpret these data. This study explored associations between measures of graph literacy and numeracy in home care nurses from two agencies (N=195) with comprehension of quality targets presented in a graphical dashboard format. Data were collected using an online survey. Results from linear regression models indicated that nurses’ levels of graph literacy and numeracy were positively associated with comprehension of quality targets. Nurses with low levels of both graph literacy and numeracy tended to have the lowest target comprehension scores compared to those who had high levels of both graph literacy and numeracy. Nurses with low graph literacy and high numeracy also had significantly lower scores for comprehension of quality targets compared to those with high graph literacy and numeracy. These findings suggest that developers of clinical dashboards that incorporate quality target information need to evaluate users’ ability to understand the information displayed in graphs and tables before they release the product for general use in healthcare settings.

Introduction

Clinical dashboards are a form of Health Information Technology (HIT) that use data visualization techniques to provide feedback to healthcare professionals on their performance compared to quality metrics (1). Dashboards are increasingly used by healthcare providers to enhance clinical productivity and track performance on quality improvement efforts. Most clinical dashboards aim to provide timely information to care providers in a succinct visual format. One feature that is often incorporated is the presentation of performance relative to quality targets or benchmarks. In the context of home healthcare services, quality targets might present clinical performance against outcome metrics like hospital readmission and emergent wound infections, which clinicians can use to benchmark their current performance against organization goals (2).

Despite the widespread use of dashboards in clinical settings, researchers have yet to explore the extent to which healthcare professionals can understand and interpret quality targets presented in a dashboard format. Two factors that may influence comprehension of quality targets include numeracy and graph literacy. Numeracy is defined as the ability to understand basic probability and math concepts (2). Graph literacy represents the ability to comprehend information displayed in graph formats (3). Few studies have explored numeracy and graph literacy among health care professionals in general or nursing specifically (3, 4). Those studies that have explored the impact of graph literacy with either the general population or patients have highlighted that individuals with high graph literacy have greater comprehension of information presented in a graphical format, and individuals with low graph literacy have greater understanding if the same information is presented in a number format (5-7). Studies exploring graph literacy and numeracy in physicians and nurses suggest that the type of graph used to display data interacts with graph literacy to impact data comprehension (3, 4). The present study builds upon earlier research by examining how numeracy and graph literacy skills are related to comprehension of quality targets presented in a graphical format among nurses sampled from two large regional home care agencies. We hypothesized that home care nurses with lower levels of graph literacy and numeracy would be less likely to comprehend graphical data presented to them about clinical quality targets.

Method

The study employed data collected via an on-line survey. Eligibility criteria included: 1) Registered Nurses (RN) who were currently employed at a Certified Home Health Agency (CHHA), and 2) visiting patients once or more per week. Nurses were recruited from two large, not-for-profit home health agencies located in the North East Region of the United States. All potential participants were sent an email invitation describing the purpose of the study and
containing a link to the survey website. Reminders to complete the survey were sent to all non-responders two, three and four weeks after the initial email. Participants first completed screening questions to ensure their eligibility to participate in the study, and if eligible they were directed to a demographic questionnaire followed by both the numeracy scale and graph literacy scale. The survey then randomized participants into one of four groups; each group received information in different graph formats (the results of this experimental study have been reported elsewhere). Finally all participants completed the questions related to comprehension of quality target information (the results reported in this paper). On completion of the survey nurses could provide their contact details (separate from survey responses) to receive a $20 gift voucher in recognition of their time. All study procedures were approved by the institutional review boards at Columbia University Medical Center and the Visiting Nurse Service of New York.

**Study Measures**

**Numeracy**

Numeracy was measured using the expanded numeracy scale developed by Lipkus et al (8). This is an 11-item scale that evaluates numerical skills such as familiarity with probability, the ability to convert percentages into proportions and risk magnitude. It is widely used as a method for assessing objective numerical competence, with high reliability (Cronbach α ranging from 0.7 – 0.75). The median numeracy score was used to categorize respondents with lower (<8) and higher numeracy levels (≥8).

**Graph Literacy**

Graph literacy was measured using a scale developed by Galesic and Garcia-Retamero (9) specifically for the health domain, to measure both basic and advanced graph reading skills and comprehension across different types of graphs (9). The scale consists of 13 items and measures 3 levels of graph comprehension: i) the ability to read the data (to find relationships in the data); and iii) the ability to read beyond the data (e.g., to be able to predict a future trend from a line chart). The scale was originally tested in two samples from Germany and the US, with high internal consistency (α = 0.74 and 0.79 respectively), and has been used previously to evaluate the graph literacy of nurses (9). The median graph literacy score was used to categorize respondents with lower (<9) and higher graph literacy levels (≥9).

**Comprehension of Quality Targets**

Comprehension of quality targets was assessed with four questions that asked nurses to interpret data presented in a table and graph relative to a quality target. The four questions assessing comprehension of quality targets were chosen based on their importance for home health nursing practice. Questions were developed to assess comprehension of quality targets related to the completion of a home health plan of care, visiting high risk home health patients within 24 hours of admission, assessment of hospitalization risk, and tracking the signs and symptoms of patients with chronic illness. An example of one quality target graph and corresponding comprehension question is shown in Figure 1. Binary variables were created to code correct responses and then summed to create a single measure of quality target comprehension that ranged from 0 (no correct responses) to 4 (all correct responses).

**Figure 1.** Example of Graph Displaying Quality Target and Corresponding Question Measuring Comprehension.
Demographic Characteristics

Nurse responders were asked about their demographic characteristics at the start of the survey. These characteristics included sex, age, race/ethnicity, education and nurse training level, number of years in a nursing role, number of years working at the agency from which they were sampled, and full-time or part-time status.

Data Analysis

Descriptive statistics were used to examine the demographic characteristics of the sample population, and chi-square or t-test were used to compare these characteristics between the two agencies. Linear regression models were used to estimate bivariate relationships of quality target comprehension with 1) graph literacy, 2) numeracy, and 3) a four-category interactive variable specifying combinations of graph literacy and numeracy. All data were analyzed using R (version 3.1.3).

Results

The survey was conducted between February 16th and May 26th 2016. Email invitations were sent to 1,052 nurses across the two agencies. 322 individuals accessed the survey (30.6 % response rate); of these 125 failed to complete all of the survey questions. Of the 125 respondents who did not complete the entire survey, 23 participants were disqualified because they did not meet all study inclusion criteria and 102 participants gave partial responses before dropping out of the survey. Of those with partial responses, 44 completed screening and/or demographic questions, 8 dropped out before completing the graph literacy scale, 38 dropped out before completing the numeracy scale, and 12 dropped out before completing the data comprehension questions. Overall we received a total of 195 completed responses (129 from Agency 1 and 66 from Agency 2). Reliability of the numeracy scale for our sample was α= 0.68 and for the graph literacy scale α=0.76. Similar to previous studies (9), the numeracy and graph literacy scales were strongly correlated (r=0.56; p<0.001), but with enough variance to indicate that they were measuring different concepts.

The characteristics of nurses who participated in the study are displayed in Table 1. Most nurses were female (89.7%), with an average age of 49 years (SD=11.0). The majority of nurses held a Bachelor’s (52.3%) or Post-Graduate degree (18.5%). Further, most nurses had a Bachelor’s (52.8%) or Post-Graduate nursing degree (11.8%). Nurse respondents differed in their average tenure at their respective agencies, with nurses surveyed at Agency 1 being employed for significantly (<0.001) longer on average (M=12.0; SD=7.7) compared to those surveyed at Agency 2 (M=5.5;
SD=6.9). Further nurses surveyed at Agency 1 tended to have higher levels of education compared to those at Agency 2 (<0.001).

There was no difference in mean numeracy or graph literacy between nurses at the two agencies; the mean numeracy score for the total sample was 8.4 (SD 2.0) and graph literacy was 9.7 (SD 2.4). The average quality target comprehension score was 3.4 (SD=0.8) out of 4 possible points; this score also did not differ between the two agencies.

</table>

In bivariate and multivariate analyses mean graph literacy did not differ by sex, age, race (white vs. non-white), education level, nurse training level, whether the nurse was staff or per-diem, agency, experience (years as a nurse), or agency tenure. Mean numeracy was slightly and inversely associated with years as a nurse (each year of additional nursing experience was associated with a 0.03 lower numeracy score (p=0.014) in bivariate analyses. After adjusting for all demographic characteristics in multivariate analyses, years as a nurse was no longer a significant predictor of numeracy level (p=0.08).

We categorized nurses as having either high (score ≥ 8; N=147, 75%) or low (score < 8; N=48, 25%) numeracy and high (score ≥ 9; N=146, 75%) or low graph literacy (score < 9; N=49, 25%). Nurses were then further categorized into four groups based on their level of numeracy and graph literacy: 1) low numeracy and low graph literacy (n=24; 12%), 2) high numeracy and low graph literacy (n=24; 12%), 3) low numeracy and high graph literacy (n=25; 13%) and 4) high numeracy and high graph literacy (n=122; 63%).

Table 2 presents the results of three linear regression models examining associations between graph literacy and numeracy with comprehension of quality targets presented in a graphical format. Findings from Models 1 and 2 suggest that both high graph literacy and high numeracy, respectively, are positively and significantly associated with level of quality target comprehension. Model 3 explores the relationship of a categorical variable representing the interaction between graph literacy and numeracy with level of quality target comprehension. Results from this model suggest that, compared with nurses who scored as having both low graph literacy and low numeracy, greater comprehension of quality targets is associated with the combination of low graph literacy and high numeracy, high graph literacy and low numeracy, and high graph literacy and high numeracy.

Conclusion

This study identifies the importance of numeracy and graph literacy levels among home care nurses for their comprehension of quality targets presented in graphical displays—a format that is increasingly used by healthcare organizations to share performance feedback with staff. We found variation in both numeracy and graph literacy in our sample population. Our sample of nurses had higher average numeracy and graph literacy skills than that identified in the wider US population (9). Compared to previous studies of nurses, respondents in our study scored higher on measures of numeracy and graph literacy (10). The findings also highlight the importance of considering numeracy and graph literacy when evaluating data presentation formats. Our results suggest that individuals with low numeracy and low graph literacy are less likely to comprehend quality targets compared with those who have high numeracy and high graph literacy. These findings may help to clarify prior research on the impact of clinical dashboards on patient outcomes, by raising the possibility that comprehension of quality targets is an additional factor that may be related to clinical practice (11). Individuals who have low numeracy and graph literacy may have difficulty effectively comprehending quality targets and other data presented in dashboards, potentially influencing their ability to make decisions related to patient care.

The findings of our study have important implications for the design of clinical dashboards that include quality targets. In general, there is an assumption that the presentation of data in a visualized format will improve data comprehension, through reduction in cognitive workload associated with processing that information (12, 13). However, our findings would suggest that consideration also needs to be given to individual variation in clinicians’ ability to understand that information. Although individuals with high graph literacy and numeracy may be able to comprehend quality targets presented in graphical formats, those with low graph literacy or numeracy may not. One unexpected finding was the lack of any significant relationships between demographic characteristics and graph literacy or numeracy level.

Strengths of our study include a large home care nurse sample recruited from two health care agencies, with variation in age, experience, and race/ethnicity, the use of a validated objective measure of numeracy rather than subjective measures used in prior research (4, 10), and a validated measure of graph literacy. Study limitations included that the sample was self-selected by choosing to respond to the survey invite. This sample excludes individuals who started but did not complete the survey. Analysis of partial responses to the survey revealed that those who did not complete the full survey tended to have significantly lower scores on the graph literacy scale, suggesting that they may have been more challenged by the questionnaire and decided not to continue with the survey.

As healthcare organizations expand use of complex data presentations for key performance indicators, the ability of end-users to comprehend that data will represent an important linchpin in efforts to improve healthcare quality. Further research is needed to explore numeracy and graph literacy in nursing populations across health care settings and to investigate the influence of these factors on clinical practice and patient outcomes. In addition, future research should investigate how best to provide support to clinicians to enable them to comprehend dashboards that include data visualizations such as quality targets. Researchers may also seek to examine whether providers in

Abstract

Over 15% of young people with autism spectrum disorders (ASD) will contemplate or attempt suicide during adolescence. Yet, there is limited evidence concerning risk factors for suicidality in childhood ASD. Electronic health records (EHRs) can be used to create retrospective clinical cohort data for large samples of children with ASD. However, systems to accurately extract suicidality-related concepts need to be developed so that putative models of suicide risk in ASD can be explored. We present a systematic approach to 1) adapt Natural Language Processing (NLP) solutions to screen with high sensitivity for reference to suicidal constructs in a large clinical ASD EHR corpus (230,465 documents), and 2) evaluate within a screened subset of 500 patients, the performance of an NLP classification tool for positive and negated suicidal mentions within clinical text. When evaluated, the NLP classification tool showed high system performance for positive suicidality with precision, recall, and F1 scores all > 0.85 at a document and patient level. The application therefore provides accurate output for epidemiological research into the factors contributing to the onset and recurrence of suicidality, and potential utility within clinical settings as an automated surveillance or risk prediction tool for specialist ASD services.

Introduction

Over 1 in 6 young people with autism spectrum disorders (ASD) will contemplate or attempt suicide during childhood, making them 30 times more at risk than typically developing children.1,2 Why children with ASD have higher rates of suicidal behaviours is unclear. It is possible that risk factors for childhood suicidal behaviour found in typically developing children, such as depression or being bullied, are more prevalent or potentially have a greater negative impact in children with ASD.1 However, very little work has been conducted in ASD cohorts, and findings derived from non-ASD samples cannot be assumed to generalise to children with ASD.1 A growing number of studies have shown that putative risk factors (both environmental and genetic) for psychiatric outcomes can have different effects in children with neurodevelopmental disorders.4,5 Therefore individuals with ASD may express and manifest suicidal tendencies and behaviours in ways that differ from those observed in typical development.9

Given the widespread adoption of Electronic Health Records (EHRs) in primary and hospital care systems and the rapid growth of health informatics capabilities, longitudinal data from large samples of children with ASD can be used to develop and test new models of suicide risk behaviour. There is considerable potential to adapt EHR research methodologies used in recent epidemiological and risk factor studies1 and apply these approaches to address the evidence gap in ASD and other vulnerable adolescent groups. Although to capitalise on these developments for suicide research, accurate EHR data extraction systems need to be developed to capture data on those young people with ASD who present to public health services with suicidal thoughts or behaviours.
Information about suicidality in clinical documents is predominantly written in free-text. Haerian et al. showed that using only ICD-9 E-codes to detect patient-level suicide and suicide ideation from clinical text had the lowest positive predictive value (PPV): 0.55, while a combination of codes and Natural Language Processing (NLP) had the highest: 0.97, when applied on EHRs from the New York Presbyterian Hospital/Columbia University Medical Center. They used MedLEE (Medical Language Extraction and Encoding System) to generate Concept Unique Identifiers (CUIs) related to suicidality, and to filter out negated mentions as well as mentions not related to the patient. Anderson et al. applied a rule-based NLP approach to identify positive or negated mentions related to suicidality in the History of Present Illness (HPI) section of EHRs from a distributed health network of primary care organizations in the US, and found that suicidality information was predominantly recorded in free-text.

Because suicidality is routinely assessed in mental health care, the absence or negation of suicidal behaviour is also documented in EHRs. An NLP tool developed specifically for detecting negated mentions of suicide in mental health records using syntactic tree information has been developed in our group with high accuracy (91.9%) when evaluated on 6,000 sentences from mental health EHRs. The tool classifies each target mention (e.g. suicid*) as negated or positive using a set of negation terms and rules applied on the information provided from a syntactic representation (constituency-based parse tree) of the sentence in which the target term is found, using the Stanford Core NLP toolkit for preprocessing and syntactic representation.

The aim of this study was to extend, further develop and robustly evaluate an NLP approach which could accurately identify suicidality in ASD-patients’ clinical records, with the future goal that it may provide data to enable improved risk prediction for related major adverse events, such as suicide attempts. Using EHR documents, such as progress notes, risk assessments and medical correspondence, we examined whether negation detection methods could be used to accurately identify references to suicidality in the EHRs of adolescents with ASD presenting to clinical mental health services. We defined suicidality as either the reporting of the intention to engage in a potentially lethal act towards oneself, or undertaking such acts themselves. To achieve the study aim, we developed coding rules using expert consensus, to define explicit suicidality-related mentions for adolescents with ASD seen in specialist mental health clinics (inpatient and ambulatory). Based on these rules we extended our NLP tool to 1) identify documents containing suicide-related (SR) information (i.e. NLP tool to screen documents) and 2) identify positive and negated references of suicidality on a document and patient level (i.e. NLP to classify SR documents and patients as positive, SR-Pos, or negative, SR-Neg) across a large number of EHRs. We then compared the performance of the NLP tool against expert human-rater case note reviews.

Materials and Methods

Data resources

This study used data extracted from the anonymised, electronic clinical records of a sample of adolescents with ASD referred to South London and Maudsley NHS Foundation Trust (SlaM). This sample and clinical setting has been described elsewhere, but in brief SlaM provides specialist inpatient and outpatient ASD assessment and treatment services for young people from across the UK. Children and adolescents in this study were referred from primary care, child health, and educational and social care services, and typically underwent a multidisciplinary assessment by Child and Adolescent Mental Health Service (CAMHS) clinicians. Primary and secondary psychiatric disorders were diagnosed by CAMHS using the International Classification of Diseases, 10th Revision (ICD-10) multi-axial classification system.

The Clinical Record Interactive Search (CRIS) system was used to produce an anonymised EHR dataset to search on structured data and free text fields for all ASD patients. CRIS was established in 2008 to allow searching and retrieval of full but de-identified clinical information for research purposes with a permission of secondary data analysis, approved by the Oxfordshire Research Ethics Committee C (reference 08/H0606/71+5). The patients were part of an open clinical cohort (entering and leaving the study at different time points) and included children aged 3–17 years with a diagnosis of ASD (ICD-10 F84.0, F84.1, F84.5, F84.9) recorded between 1 January 2008 and 31 December 2013. Free text entries, correspondence and reports were available for this sample from their initial assessment until June 2016. The resulting cohort contained 3,642 unique patients (complete age range). For the purposes of this study, we selected the sample of adolescents who had at least one contact with CAMHS (i.e one free text document in CRIS) between the ages 14 and 18 years, totalling 1,906 patients.
Overall workflow

Figure 1 outlines the overall workflow of our study. There were three main phases. The first phase related to the definition of classification rules to identify suicidality-related information in EHR documents for adolescents with ASD (step 1 below). These rules were then applied in the second phase where a manual review of documents (step 2) was used to inform the development and evaluation of our NLP approach to screen for suicidality-related (SR) mentions in documents and filtering out documents with no mentions related to suicidality (NSR) – step 3 below. The NLP approach was then used to extract SR documents for the third phase (step 4). In the third phase, a manual review of documents was performed to annotate mentions of suicidality in SR documents as positive (SR-Pos), negative (SR-Neg) or uncertain (SR-U), step 5. Finally, the NLP approach was evaluated for its ability to correctly classify SR-Pos or SR-Neg in these documents and patients, step 6.

Step 1: Development of a set of classification rules to identify suicidality in adolescents with ASD.

Senior clinicians with expertise in the clinical management of neurodevelopmental disorders (JD) and suicidality assessment (RD) developed a set of rules to classify explicit mentions of suicidality in every document as either positive, negated or unknown. Positive mentions included text that referred to previous attempts, the presence of current or past plans of suicidal acts, command hallucinations related to carrying out a suicide attempt, a desire to be dead, researching methods, having ideas or describing plans of how to end their life or, a clinical opinion of the young person being at an elevated risk of attempting suicide. Negated terms included clinical opinions of the young person not being at elevated risk of suicide, recorded denial of suicidality by the young person (either directly or via third person report). Mentions were classified as uncertain, when aspects of suicidality were referred to, but did not appear to relate to risk of the young person being suicidal, for example references to dreams of being dead, or joking about death, or when references to suicidality were about other people (e.g. family members or friends).

Figure 1. Overall workflow of the study.

Step 2: Manual review of suicidality-related (SR) information and NLP screening tool development.

A randomly extracted subset of 100 patients and their corresponding documents were allocated to a training corpus, and another random selection of 100 patients was allocated to the test corpus. To generate a subset of patients with a
reasonable amount of documentation for manual review, the random sample was extracted based on documentation prevalence: each included patient had at least 7 documents (1st quartile) and at most 50 (3rd quartile), yielding a total of 2,445 (training set) and 2,433 (test set) documents in total. One clinically trained annotator (HD) was given these documents grouped for each patient. The annotator reviewed all documents for each patient, marked suicidality-related (SR) expressions, and labelled each SR-expression as either positive, negated or uncertain, according to the rules developed in step 1. However, for this phase, only annotations for SR information (regardless of polarity) were used for analysis.

**Step 3**: Extension and provisional assessment of the NLP approach for SR screening.

Results from the manual review were used to extend the NLP approach with the addition of new explicit SR expressions. Given the low frequency of the positive or negated SR mentions within the training set, we used the test set to assess precision, recall and F1-score of the tool detecting any SR content (regardless of polarity). Because the end goal is to address overall suicidality risk behaviour, the approach was evaluated on a document and patient level rather than on the mention level.

**Step 4**: NLP tool deployed to screen for SR documents

The NLP tool was then deployed to filter out documents without any SR mentions (positive or negative) from the original cohort (excluding the already annotated 200 patients). From 1706 patients (225,577 documents), 890 (52.2%) patients had at least one SR document, resulting in a total of 10,749 documents.

**Step 5**: Manual review of SR subset for identification of positive (SR-Pos) and negative (SR-Neg) suicidality mentions

Two manual coders (RH and MK) were randomly assigned 500 (56.2%) patients from the SR subset. Each annotator was given all documents (for each patient) that were detected by the NLP tool as containing a SR mention. The annotators were not given the NLP system output, but instead were asked to annotate explicit mentions of suicidality (same as above) and label these as positive (SR-Pos), negated (SR-Neg) or uncertain (SR-U). The documents were given to the annotators on a per-patient basis, and each patient was reviewed by one annotator. A subset (n=100) of randomly extracted documents was also used to calculate inter-rater agreement (measured with Cohen's κ and F1-score) on a document-level.

A majority rule was applied when evaluating document-level agreement: all mention-level annotations in each document were first counted, then, if the number of annotations labelled as positive for suicidality outnumbered or equalled the number of annotations labelled as negated, the document-level label was assigned “Positive for suicidality” – SR-Pos, otherwise it was designated “Negated for suicidality” – SR-Neg. To evaluate patient-level performance, priority was given to document-level outcomes: if the patient had at least one document labelled as SR-Pos using the majority rule, the patient-level label was assigned SR-Pos, irrespective of the number of previous or subsequent documents labelled as SR-Neg, i.e. each patient only required a single ‘positive suicidality’ document to be labelled SR-Pos.

**Step 6**: Final, comprehensive evaluation: NLP SR-Pos/SR-Neg classification

As a final step, the NLP approach was evaluated with precision, recall and F1-score against the manual annotations of the larger, filtered set of documents/patients with SR-Pos and SR-Neg labels, using the same heuristics for document- and patient-level classification assignments as above. Note that the evaluation is only performed on these two labels, i.e. SR-U annotations are not mapped to SR-Pos or SR-Neg. Thus, a false positive or false negative from the NLP approach could be due to an annotation marked as SR-U. A manual error analysis on cases of disagreements between the NLP tool and human annotation labels was also performed to gain a deeper understanding of the results.

**Results**

Table 1 shows the distribution of SR and non-SR (NSR) documentation and the individual level prevalence amongst the 100 adolescent patients with ASD in the final training set and the 100 patients in the test set. Manual review of both training and test documents revealed that only a small proportion of the corpus contained any SR information: <3% at the document level and around 22% at the patient level, with a similar distribution in the training and test.
set. Precision, recall, and F1 scores showed high system performance (> 0.8) for both SR and NSR in the test set (table 1).

The lexical markers of suicidality that were added to the NLP tool included *kill himself/herself/themselves/myself, end his/her/their life, take his/her/their own life, want to die, were dead*. Note that the NLP tool relies on lemmatised forms in both target expressions and document surface forms in order to achieve a more robust matching, e.g. different verb inflections of *want* will be matched with this approach.

**Table 1.** Confusion matrix: Screening for suicidality (SR) or non-suicidality (NSR), NLP tool compared to human annotation (A).

Table 2 shows the distribution of negated and positive suicidality-related information (SR-Pos/SR-Neg) using our majority rule criteria in 4,911 pre-screened documents derived from 500 patients. Evaluation of the NLP tool (table 2) showed high system performance for SR-Pos with precision, recall, and F1 scores all > 0.83 at a document and patient level. SR-Neg performance measures were lower, especially in recall (0.75 on document level, 0.62 on patient level), but overall good levels of classification were produced (F1 = 0.79 on document level, 0.72 on patient level).

A manual error analysis on a random sample of ten documents where the NLP tool classified a document as positive (SR-Pos) but the human annotator as negated (SR-Neg) was performed to gain a deeper understanding of the reasons behind the lower recall results. The main themes involved:

1) classification of documents with only one suicide-related mention (annotator SR-Neg count = 1, NLP SR-Pos count = 1) due to missing negation term, e.g. ‘*Nil suicidal*’ or error in syntactic parsing due to e.g. badly formatted sentences.

2) cases where the majority heuristic is problematic and negation detection scope is erroneous, e.g. one document annotated with SR-Neg = 2, while the NLP output was: SR-Neg = 1, SR-Pos = 3 contained the following: ‘*XXX denied any recent sleep difficulties, excessive fatigue or guilt, changes in appetite or morbid or suicidal ideation*’, ‘*The risk of suicide is low, XXX denies suicidal ideation.*’

3) co-reference in combination with majority heuristics (annotator SR-Neg = 3, SR-Pos = 2, NLP SR-Neg = 1, SR-Pos = 2): ‘*XXX reported that XXX has had suicidal thoughts in the past but has no current plans on acting on them, co-reference*’ (sentence repeated twice in document), ‘*[clinician reporting] further stated that no evidence of psychosis, self-harming behaviour, suicidal thoughts, sleep or appetite …*’

4) clinically challenging cases and complex information given in the document. Three examples are:
Annotator: SR-U = 4, SR-Neg = 3, SR-Pos = 1; NLP tool output: SR-Neg = 1, SR-Pos = 2. ‘... reported fleeting suicidal thoughts... but strongly denied that XXX could act on these...’, ‘presenting for serious OD without suicidal...’, ‘firm denial of suicidal...’, ‘overdose’ marked as uncertain by annotator.

Annotator: SR-U = 2, SR-Neg = 1, NLP tool output: SR-Neg = 2, SR-Pos = 3 included sentences with information reported by external authorities such as the health care team and the school, references to the past, and includes a conclusive statement towards the end of the document: ‘we could not assess negated suicidal ideation as XXX left the room’, ‘unable to assess negated suicidal ideation’; ‘historically past has threatened self harm and disclosed suicidal ideation...’, ‘concerns from school about suicidal ideation’; ‘no suicidal ideation expressed’.

Annotator: SR-U = 2, SR-Neg = 1, NLP tool output: SR-Pos = 2: ‘I tried to assess XXX’s suicidal risk - XXX does not know if XXX wants to kill self’, ‘XXX does not have any specific plan’

Table 2. Confusion Matrix: Classification of positive and negative SR, document- and patient level assessments. SR-Neg = Suicidality-related (SR) mention is negated (Neg), SR-Pos = Suicidality-related mention is positive (Pos).

Discussion and Conclusion

This is the first study to demonstrate that an NLP tool can be used to accurately capture a clinical construct as complex as suicidality within health records of young people with ASD. Our NLP tool identified suicidality-related (SR) mentions with high degrees of precision and recall from clinical free text held within EHRs. This NLP application provides powerful opportunities for surveillance work in adolescent ASD and in other clinical samples, with the potential to improve risk prediction for major adverse events, such as suicide attempts.

The development of this high performance NLP tool was achieved in several steps. First, owing to the potentially distinctive characteristics of the ASD clinical population, and their specialist mental health service provision, we began by building a suicidality terminology from a detailed note review of over 2000 random sets of clinical entries in 100 children with ASD, combined with expert clinical consensus. Because of the limited literature on suicidal terminology in ASD, we used a randomly extracted training and test set from all potential ASD EHR source data, rather than an enriched set filtered by restricted terms (e.g. “suicid” or ICD coding classifications). The rationale for this was to reduce selection bias and loss of sensitivity through the use of training and test data derived using restricted terms or coding classifications.

Random selection from the whole potential corpus also provided us with a better understanding of the overall distribution of suicidality-related information in documents and allowed us to refine and advise on additional terminology. During the training phases, it became clear that there was a low frequency of SR terms (less than 3% of all documents). A much larger corpus was required to conduct an adequate test of the NLP tool’s classification performance in discerning positive and negated SR mentions within the documents. We therefore configured the NLP tool to provide a SR screening step and identify a smaller, more feasible volume of suicidality-related documents for human annotation from the whole ASD corpus of c. 220,000 documents. We then tested the positive predictive value (precision) and sensitivity (recall) of the NLP screening tool against the EHR of another 100 children (approximately 2000 human rated documents) which were annotated for any references to suicidality. Finally, we began a comprehensive test of the accuracy of the tool against positive (SR-Pos) or negated (SR-Neg) mentions of suicide within the screened suicide related documents.

The abstraction of mention-level annotations and NLP system predictions to document- and patient-level assessments using simple heuristics (majority rule for document level and SR-Pos priority on patient level) showed that promising results can be obtained even though the NLP tool relies only on a relatively small number of suicidality-related and negation terms. This finding also shows that even though suicidality behaviour is documented with a variety of expressions (e.g. ‘took an excessive amount of pills’, ‘threw him/herself in front of a train’), indicative terms (mainly suicide in different forms) are typically also used at some point in the documentation and will thus be detected automatically.

Our motivation for applying a majority rule on document level assessments was based on the finding that the main source for false positive errors in our negation detection approach stemmed from cases of question forms (e.g. ‘I asked him if he feels suicidal’), references to the past, etc. Applying this rule was a way of smoothing this error rate. However, the error analysis showed that this approach might be a limitation. In future studies, we aim to compare results with NLP approaches such as ConText where variables relating to the past (‘historicity’) and subject (‘experiencer’) are encoded with target terms. We also aim to experiment with other abstraction heuristics, e.g. instead of majority rule, applying a priority hierarchy. In keeping with prior work, another alternative could be to define the annotation task on a document level. Longer term, we aim to compare the predictive validity of different heuristics within our NLP tool, and across other NLP approaches, for later adverse outcomes (i.e. significant suicide attempts or death by suicide), and seek external validity through replication in other EHR systems. Without these further steps, it is difficult to assess the potential clinical impact of differences in precision or recall across NLP tools.

The annotators expressed that it was sometimes challenging to assess suicidality risk based on one document at a time; single documents did not provide sufficient context in all cases. At the same time, given the rare prevalence of suicide-related content in all patient documents, defining a patient-level annotation task using this type of abundant clinical documentation would be very time-consuming. We plan to explore different ways of addressing this issue, one being a nested case-control study design similar to the one presented in Metzger et al.
A strength of this study is that we have not assumed that clinical terms used in more typically developing children or adults generalize to ASD populations. Assessing suicidality in adolescents with ASD often requires a different approach to other patient groups, which in our clinical experience was likely to be reflected in the clinical notes. Young people with ASD presenting to mental health services commonly have severe difficulties with interpersonal interactions, making for a more complex clinical assessment. Clinicians are likely to deliberate within the clinical notes on whether potential behaviours are driven by suicidal ideation. They may have a greater reliance on third person report – i.e. caregivers voicing concerns regarding the young person’s suicidality rather than direct accounts from the young person. Also, where a first person account is provided, clinicians will often write verbatim statements (i.e. He told me “I just want to end it”, and he “went to the car park to get it done”), providing more atypical clinical terminology for describing suicidality, and increasing the chance of NLP misclassification.

In addition, young people with ASD may not present with suicidality as a principle complaint, but through a behavioural change such as school refusal, with suicidal behaviour emerging through later clinician screening. This may change the emphasis and position within the patient’s clinical record relative to other populations where suicidal behaviour is the principle trigger during the first presentation to services. Testing these clinical assumptions empirically using an non-ASD control sample was beyond the scope of the current study, however future work is underway to examine the variability of the NLP tool’s accuracy across non-ASD child populations seen in mental health services. NLP applications are commonly validated using randomly extracted documents from EHRs covering a broad range of clinical contexts, seldom rarer clinical populations, such as young people with ASD. As mental health assessment and management needs to be tailored to the developmental needs of the young people in clinic, so should the validation of NLP data extraction tools.

The suicidality outcome data provided by this NLP extraction tool permits analyses of the complex interplay of ASD-specific traits on factors contributing to the onset and recurrence of suicidality. ASD specific mental health services are becoming increasingly available for child and adolescent populations in high-income countries. Although there is more work to be done before clinical application, we believe the NLP tool described provides a step forward in enhancing suicidality surveillance, risk prediction and treatment selection for children with ASD.

Abstract Electronic medical records (EMRs) are critical, highly sensitive private information in healthcare, and need to be frequently shared among peers. Blockchain provides a shared, immutable and transparent history of all the transactions to build applications with trust, accountability and transparency. This provides a unique opportunity to develop a secure and trustable EMR data management and sharing system using blockchain. In this paper, we present our perspectives on blockchain based healthcare data management, in particular, for EMR data sharing between healthcare providers and for research studies. We propose a framework on managing and sharing EMR data for cancer patient care. In collaboration with Stony Brook University Hospital, we implemented our framework in a prototype that ensures privacy, security, availability, and fine-grained access control over EMR data. The proposed work can significantly reduce the turnaround time for EMR sharing, improve decision making for medical care, and reduce the overall cost.

Introduction

Electronic medical records (EMRs) are critical but highly sensitive private information for diagnosis and treatment in healthcare, which need to be frequently distributed and shared among peers such as healthcare providers, insurance companies, pharmacies, researchers, patients families, among others. This poses a major challenge on keeping a patient’s medical history up-to-date. Storing and sharing data between multiple entities, maintaining access control through numerous consents only complicate the process of a patient’s treatment. A patient, suffering from a serious medical condition such as cancer, or HIV, has to maintain the long history of the treatment process and post-treatment rehabilitation and monitoring. Having access to a complete history may be crucial for his treatment: for instance, knowing the delivered radiation doses or laboratory results is necessary for continuing the treatment.

A patient may visit multiple medical institutions for a consultation, or may be transferred from one hospital to another. According to the legislation1–4, a patient is given a right over his health information and may set rules and limits on who can look at and receive his health information. If a patient needs to share his clinical data for the research purposes, or transfer them from one hospital to another, he may be required to sign a consent that specifies what type of data will be shared, the information about the recipient, and the period during which the data can be accessed by the recipient. This may be extremely difficult to coordinate, especially when a patient is moving to another city, region, or country and may not know in advance the caregiver or hospital where he will be receiving care later on.

Even if the consent is provided, the process of transferring the data is time consuming, especially if sending them by post. Sending the patients’ data via email over the Internet is not considered in most hospitals as this could impose security risk while the patient’s healthcare records are in transit1. Ecosystems for health information exchange (HIE) such as CommonWell Health Alliance aim to ensure that the data form patient electronic health record are securely, efficiently and accurately shared nationwide in US. This implies that once providers receives an access to the patient’s health information it is difficult to guarantee that a patient could receive independent opinions from different healthcare providers. Moreover, such ecosystems do not address the requirements in case of transferring data from one country to another.

Data aggregation for research purposes also requires the consent unless the data are anonymized. However, it has been shown that independent release of locally anonymized medical data corresponding to the same patient and originated from different sources (e.g., several healthcare institutions visited by the patient) could cause de-identification of the patient, and, therefore, violation of privacy31,32.

Relying on centralized entity that would store and manage the patients’ data and access control policies means having
single point of failure and a bottleneck of the whole framework. It also requires either conducting all the operations (such as search, or anonymization) over encrypted data, or choosing a fully trusted entity that will have access to sensitive information about the patients. The former still requires management of large amounts of memory and is not suitable for hospital environment. The latter was proven to be very difficult to put in practice. An example of GoogleHealth wallet has shown that patients are concerned about their privacy and aware of the potential risk that their sensitive data might be misused.

Having access to a ledger - shared, immutable, and transparent history of all the actions that have happened to all the participants of the network (such as a patient modifying permissions, a doctor, accessing or uploading new data, or sharing them for research) overcome the issues presented above. By providing the tool to achieve consensus among distributed entities without relying on a single trusted party, blockchain technology will guarantee data security, control over sensitive data, and will facilitate healthcare data management for the patient and different actors in medical domain. In the healthcare settings we can define a transaction as a process of creating, uploading or transferring EMR data that is performed within the connected peers. A set of transactions grouped at certain time is added to the ledger that records all the transaction and therefore represents the state of the network. The key benefits of applying the blockchain technology in healthcare are the following: verifiable and immutable transactions; tamper resistance, transparency, and integrity of distributed sensitive medical data. This is mainly achieved by employing consensus protocol and cryptographic primitives such as hashing and digital signatures.

The possibility of using blockchain for healthcare data management has recently raised a lot of attention in both industry and academia. However, only one functioning prototype of a system that uses blockchain for medical data management has been proposed. In our work, we focus on a practical implementation of a system that uses blockchain technology and can be integrated in clinical practice. We employ permissioned blockchain technology to maintain metadata and access control policy and a cloud service to store encrypted patients’ data. Combining these technologies allows us to guarantee data security and privacy as well as availability with respect to the access control policy defined by the patient.

The contribution of the paper is twofold. First, we propose multiple scenarios of blockchain applications in healthcare and analyze existing technology implementations that could be used to put the scenarios in practice. Second, we present a framework for blockchain based data sharing for primary care of oncology patients under cancer treatment. We developed a prototype in collaboration with the Department of Radiation Oncology in a major US hospital. Therefore, the functionality of the prototype is expected to meet the requirements from medical practice perspective.

1 Background on Blockchain

Blockchain is a peer-to-peer distributed ledger technology that was initially used in the financial industry. Based on how the identity of a user is defined within a network, one could distinguish between permissioned and permissionless blockchain systems. A permissionless system is one in which the identities of participants are either pseudonymous or even anonymous and every user may append a new block to the ledger. In contrast, in case of a permissioned blockchain, the identity of a user is controlled by an identity provider. The identity provider is trusted to maintain access control within the network and the user’s rights to participate in the consensus, or validate a new block. Next we introduce two most well-known implementations of the blockchain technology: Ethereum and Hyperledger.

1.1 Permissionless Blockchain Implementation

Ethereum is an implementation of a permissionless programmable blockchain that allows any user to create and execute the code of arbitrary algorithmic complexity on the Ethereum platform: Ethereum Virtual Machine (EVM). “Accounts” of two types could be created on EVM. Externally owned account (EOA) is an account controlled by a private key of a user. Contract account is the second type of accounts that can be seen as an autonomous agent that lives in the Ethereum execution environment and is controlled by its contract code: smart contract. Smart contract is used to encode arbitrary state transition functions, allowing users to create systems with different functionalities by transforming the logic of the system into the code.

Code execution in Ethereum must be paid. The transaction price limits the number of computational steps for the code execution in order to prevent infinite loops or other computational wastage. Users could participate in a consensus
process to obtain the tokens to be paid for transaction execution. In Ethereum, the consensus is achieved by using a proof-of-work (PoW) mechanism. PoW is based on “mining”: finding a nonce input to the algorithm so that the resulting hash of a new valid block satisfies certain requirements. These requirements set the difficulty threshold for the process of finding the nonce. The difficulty threshold impacts the amount of energy to be spent to find such nonce. For example, the amount of energy used by Bitcoin mining is comparable to the Irish national energy consumption. Existing PoW blockchains can achieve throughput of not more than 60 transactions per second without significantly affecting the blockchain’s security. These two findings show that PoW can negatively impact the system scalability and overall throughput.

Proof-of-Stake (PoS) and Proof-of-Burn (PoB), or virtual mining mechanisms, have been recently proposed as alternatives to PoW. Instead of having participants mine by exchanging their wealth for computational resources (which are then exchanged for mining rewards), in virtual mining, participants could exchange their wealth directly for the ability to append a new block to the ledger. For example, in PoS, selection of a participant that will create a new block is based on the amount of tokens owned by the participant, in PoB – based on the amount of tokens “burnt” (sent to an unspendable address). However, providing a rigorous argument for or against the stability of virtual mining remains an open problem.

1.2 Permissioned Blockchain Implementation

In the case of a permissioned system, users do not have an incentive to cheat as their identity is revealed to the identity server. Moreover, participation in consensus management is restricted to a predefined set of users. This opens a possibility to use a state machine replication algorithm (such as PBFT) as a consensus mechanism. Hyperledger – an implementation of a permissioned blockchain – is an open source blockchain initiative hosted by the Linux Foundation. Hyperledger has a modular architecture that allows plugging in different consensus mechanisms, including PBFT. Hyperledger services could be logically grouped in three categories: Membership services, Blockchain services, and Chaincode services.

Membership services manage identity, privacy, and confidentiality on the network. A user is assigned a username and a password that will be used to issue the Enrollment certificate (ECert) to identify every registered user. It is possible to use different Transaction certificates (TCert) associated with the same ECert for every transaction to ensure their unlinkability (a mapping between TCert and ECert are only known to the membership service). Blockchain services manage the distributed ledger through a peer-to-peer protocol built on HTTP/2. In Hyperledger, smart contracts are implemented by the chaincode. Chaincode services provide a secure way to execute smart contracts on validating nodes.

In Hyperledger, smart contracts are implemented by chaincode that consist of Logic and associated World State (State). Logic of the chaincode is a set of rules that define how transactions will be executed and how State will change. State is a database that stores the information in a form of keys and values that are arbitrary byte arrays. The State also contains the block number to which it corresponds. Ledger manages blockchain by including an efficiently cryptographic hash of the State when appending a block. This allows efficient synchronization if a node was temporary off-line, minimizing the amount of stored data at the node.

2 Potential Blockchain Applications in Healthcare

Blockchain provides a unique opportunity to support healthcare. In this section, we propose three scenarios: primary patient care, medical research, and connected health. Figure 1 shows a graphical representation of the combination of the aforementioned scenarios.

Scenario 1: Primary Patient Care. Using blockchain technology for primary patient care can help to address the following problems of the current healthcare systems:

- A patient often visits multiple disconnected hospitals. He has to keep the history of all his data and maintain the updates. This leads to the situation when required information may not be available.
- Due to the unavailability of the data, patient may have to repeat some tests for laboratory results. This is common when the results are stored in another hospital and can not be immediately accessed.
The healthcare data are sensitive and their management is cumbersome. Yet, there is no privacy-preserving system in clinical practice that allows patients to maintain access control policy in an efficient manner.

- Sharing data between different healthcare providers may require major effort and could be time consuming.

Next, we propose two approaches that can be implemented separately or combined to improve patient care.

- **Institution-based**: The network would be formed by the trusted peers: healthcare institutions or general practitioners (caregivers). The peers will run consensus protocol and maintain a distributed ledger. The patient (or his relatives) will be able to access and manage his data through an application at any node where his information is stored. If a peer is off-line, a patient could access the data through any other online node. The key management process and the access control policy will be encoded in a chaincode, thus, ensuring data security and patient’s privacy.

- **Case specific** (serious medical conditions, examination, elderly care): During a patient’s stay in a hospital for treatment, rehabilitation, examination, or surgery, a case-specific ledger could be created. The network would connect doctors, nurses, and family to achieve efficiency and transparency of the treatment. This will help to eliminate human-made mistakes, to ensure consensus in case of a debate about certain stage of the treatment.

**Scenario 2: Data Aggregation for Research Purposes.** It is highly important to ensure that the sources of the data are trusted medical institutions and, therefore, the data are authentic. Using shared distributed ledger will provide traceability and will guarantee patients’ privacy as well as the transparency of the data aggregation process. Due to the current lack of appropriate mechanisms, patients are often unwilling to participate in data sharing. Using blockchain technology within a network of researchers, biobanks, and healthcare institutions will facilitate the process of collecting patients’ data for research purposes.

**Scenario 3: Connecting Different Healthcare Players for Better Patient Care.** Connected health is a model for healthcare delivery that aims to maximize healthcare resources and provide opportunities for consumers to engage with caregiver and improve self-management of a health condition. Sharing the ledger (using the permission-based approach) among entities (such as insurance companies and pharmacies) will facilitate medication and cost management for a patient, especially in case of chronic disease management. Providing pharmacies with accurately updated data about prescriptions will improve the logistics. Access to a common ledger would allow the transparency in the whole process of the treatment, from monitoring if a patient follows correctly the prescribed treatment, to facilitating communication with an insurance company regarding the costs of the treatment and medications.

**Implementing the Scenarios.** In order to implement the three healthcare scenarios presented above, we must choose
between a permissionless and a permissioned blockchain implementations. Below we present the facts that favor a permissioned system implementation.

- The anonymity of users and impossibility to verify the identity of account holders (as in case of permissionless blockchain) could cause impersonalization and data misuse.
- Patients’ healthcare data are of high sensitive nature. Even monitoring communication between a patient and a specific clinician may reveal some sensitive data about the patient, therefore violating the privacy.
- Fast response of a system is required as any update of the information about a patient’s treatment could be crucial for the patient.
- The need to pay for transaction execution, for example, updating permissions for a medical doctor to access a piece of healthcare information or sharing some data for research could limit the usability of the system.

3 Application in Radiation Oncology: Sharing Clinical Data between Healthcare Providers

In this section, we present a prototype design and implementation of a system to support electronic medical record sharing for primary patient care (Scenario 1). More precisely, we focus on patients that are receiving a cancer treatment via ionizing radiation, which is usually performed in the Department of Radiation Oncology of a hospital. First, we describe a specific use-case scenario and the benefits of the system. Second, we present the architecture of the system and describe the data structure and functionality of the system. Finally, we discuss how privacy, security, and scalability are ensured within the proposed framework.

3.1 Use Case Scenario

Cancer is a serious medical condition that may require a long-lasting treatment and a life-time monitoring of a patient. Therefore, it is crucial for the patient to maintain his medical history and to be able to access or share his medical data during the treatment and post-treatment monitoring. Due to the mobility of a patient, the management of the data generated during every patient’s visit can be cumbersome especially given the sensitive nature of healthcare data. How to guarantee that the patient’s data are complete, stored securely, and can be accessed only according to the patient consent in a fast and convenient manner?

We tackle this problem by applying the blockchain technology to create a prototype of an oncology-specific clinical data sharing system. To present our solution, we take as an example an oncology information system, ARIA, which is widely used to facilitate oncology-specific comprehensive information and images management. ARIA combines radiation, medical and surgical oncology information and can assist clinicians to manage different kinds of medical data, develop oncology-specific care plans, and monitor radiation dose of patients. Different types of data stored in this system can be structured depending on the clinician’s request and exported in PDF format. The documents that contain the data such as history and physical exams, laboratory results, and delivered radiation doses are of the high importance for the clinicians and are most commonly used during the treatment.

Currently, if any of these data have to be transferred from Hospital 1 to Hospital 2, the following procedure takes place. First, the patient (or his official representative) has to sign a consent – a document that specifies the data to be transferred and contains the information about the recipient of the data (Hospital 2). Then, the information has to be printed and mailed to the recipient. Consent management and data transfer in this case can become complicated and inconvenient: the patient may need to contact the caregiver and sign a consent in the hospital from which he is not receiving care anymore. Data transfer can take time, and on receiving the hard copy of the patient data, a clinician will have to introduce them into the system again. Moreover, with this approach, it is very difficult for the patient to maintain any access control of his data and to have a complete view of the data.

By employing blockchain technology, our solution allows to facilitate the consent management and speed up data transfer. We developed a chaincode that allows a patient to easily impose fine-grained access control policy for his data and enables efficient data sharing among clinicians.

3.2 System Architecture

Figure 2 presents the architecture of our framework for the oncology-specific data management. The framework consists of the Membership service, Databases for storing healthcare data off-chain, Nodes managing consensus process,
and APIs for different user’s roles. Currently, we focus on Doctor and Patient, but the roles and their functionality could be extended depending on the scenario.

The main functionality of the Membership service is to register users with different roles (currently Doctor and Patient). The roles define the functionality of the chaincode that is available to the user. During the registration of a user as a Doctor, it is important to ensure that it is not a potential malicious user, but a qualified medical doctor. To verify this, the National Practitioner Data Bank could be consulted by the membership service. The membership service is also hosting a certification authority involved in the generation of a key pair for signing ($SK_{SU}$, $PK_{SU}$) and encryption key pair ($SK_{EU}$, $PK_{EU}$) for every user ($U$).

Patient ($P$) also generates a symmetric encryption key ($SK_{AESP}$) that will be used to encrypt/decrypt the data corresponding to the patient, $P$. This key will also be used to generate pseudonyms so that only authorized users could verify whether the ledger stores any information about the patient. When a patient ($P$) needs to share his data with a doctor ($D$), the patient could share this key, $SK_{AESP}$, using the encryption public key of the corresponding clinician ($PK_{ED}$). If the symmetric key $SK_{AESP}$ is compromised, the patient could generate a new one, run a proxy re-encryption algorithm$^{26}$ on the data stored in the cloud and then share a new key with the clinicians according to the desired access control policy.

The patient’s data are stored off-chain in the following Databases. First, a local database management system in the hospital that stores the oncology-related data (for example, ARIA in our use case). Second, a cloud based platform (Varian Cloud) that stores patient’s data organized based on the data category (for instance, according to the sensitivity level of the data, or their semantics), and encrypted with corresponding patient key, $SK_{AESP}$. A registered clinician could assess or upload the data in the cloud repository based on the access control policy defined by the patient and implemented in the chaincode Logic.

A custom chaincode is deployed on every Node that acts as a Hyperledger validating peer. Nodes receive all transactions submitted by the users through a role-based APIs. The Node, selected as a leader, organizes transactions in a block and initiates the PBFT consensus protocol. Transactions are executed by all nodes according to the implemented chaincode Logic. The State stores the information about patients in a key-value pair format. A Key – a Patient Id in the system – is a pseudonym of the patient that is generated as a hash of the concatenation of the symmetric key $SK_{AESP}$ and a Uniquely Identifiable Information of the patient ($UII_P$): $H(SK_{AESP} || UII_P)$. Combination of SSN (if applicable), date of birth, given names, and a ZIP code of the patient could be used as $UII_P$. A Value is a patient record stored as a byte array. Next we describe the data structure in detail.
3.3 Data Structure and System Functionality

Figure 3 shows how the patient’s data and metadata are organized: the patients’ data are stored off-chain: locally (in the clinician database) and in the cloud as presented in Figure 3 (a) based on their categories. Currently we use three categories in our prototype: History and physical exams, Laboratory results, and Delivered radiation doses. In the future, we plan to define categories based on both the semantics and the sensitivity level of the data. Data files related to the patient and uploaded by different clinicians are stored within the corresponding category. A patient could optionally store some private data or notes encrypted with the patient public key, $\mathcal{PK}^S_p$.

Figure 3 (b) presents the structure of the patient’s metadata that consists of the following blocks: Permissions, Clinical Metadata, and Patient Private Data (optional). Permissions block is organized as follows: every Permission corresponds to a Doctor Id, with which a clinician is registered in the system. Every permission specifies the timeframe (From: To:) during which a clinician has a Right to read the patient’s data that fall into a specific Data Category, upload them to the cloud repository (write), or share the patient’s data within a framework of a specific research study, Study Id. For the latter the patient could also use Anonymity tag to specify if the data must be anonymized before sharing or could be shared as they are. Timestamp makes every permission unique and allows a patient to update and track access control changes corresponding to the same Doctor Id.

Clinical Metadata are a block that contains information about all the data files uploaded to the cloud by different clinicians. The Metadata Items are categorized based on the semantics of the corresponding data files. Every Item contains an Id of the clinician that uploaded the data (Doctor Id), a pointer to the file that is stored in the cloud, Path to File, the Hash of the Data File, Hash(File), to ensure unforgeability of the data stored in the cloud, and the Timestamp of the event when the Data File was uploaded. Similarly to the Patient Private Data stored on the cloud, some private data could be added by a patient to be stored in the State associated with the chaincode (CC). The metadata are stored as a “value” part of a CC State. It can be accessed and modified using the functions that can be invoked on a CC.

To ensure a correct functioning of the developed chaincode we built a network that consists of a Membership service and four Nodes capable of running PBFT consensus protocol. Four is the minimum number of nodes needed to run the PBFT consensus protocol. We deployed CC on every node and issued a set of the “invoke” transactions (that trigger creation of a new patient metadata record, adding a permission, and uploading the metadata item), and “query” transactions to access the information from the State. Currently, a patient is able to create a metadata record on the chaincode, add permissions, and retrieve his up-to-date metadata record, and, thus, his data that are stored on the cloud. A user registered with a Doctor role is able to upload, access and share for research purposes the data in the cloud based on the permissions specified by the patient.

Verification of the access control rights (currently read, write or share) is done via Logic of a chaincode written in Go programming language\cite{27}. For instance, every time a clinician would try to add new data on the cloud repository,
a permission corresponding to this clinician has to be retrieved from the patient’s metadata record. Then, the validity of the permission with respect to the data category and timeframe is controlled. Similarly, sharing patient data for the research purposes can not be performed by clinician without patient’s agreement. This is guaranteed by the chaincode implementation. Interfacing our system with the existing clinical database management systems and conducting more experiments with the data of the real patients are next steps of our work.

4 Discussion

Next we discuss the privacy, security, and scalability of the proposed framework.

Privacy. A patient’s privacy is ensured by providing the patient with a possibility to specify fine-grained access control over his data via permissions. Permissions are enforced by chaincode logic and, therefore, can not be violated by any user, unless the consensus protocols fails. The latter could happen only if a fraction of the verifying nodes intentionally tries to damage network operations. Centralized membership service already protects against Sybil attacks. Moreover, in the permissioned network, the nodes identities are known, therefore, there is no incentive for malicious behavior. In the case if a node still behaves maliciously, access to the network could be promptly restricted for this node. Membership service also controls the identity of the users. Before registering a clinician, his identity is verified in the National Practitioner Data Bank. A patient is registered with his UII, but all his data are linked to the pseudonym generated using his secret key, SKAES. Therefore, Membership service does not have an access to the patient’s clinical data, yet guarantees authenticity of the users (via digital signature verification). If SKAES is compromised or lost, access to the network will be recovered using UII of a patient, a new key will be generated, and proxy reencryption will be used.

Security. Clinical data stored in the cloud repository are encrypted with a patient secret key, SKAES, to provide data confidentiality. Only the patient can share encryption key and set up the access control policy via permissions. Shared data from the cloud registry are hashed and signed with a secret key of a user (SKSU), before the data are uploaded. The hashes are stored as a part of a corresponding metadata item in the State. Transactions are also digitally signed, thus the data integrity is ensured.

Availability of the shared data is guaranteed by providing a cloud platform to store the data. Role-based APIs can be used at any node registered in the network to invoke or query the chaincode. As already mentioned, if a patient loses his credentials, access to the data stored on- and off-chain could still be recovered.

Scalability. Clinical data sharing requires scalability of the system in terms of both the number of users and the number of nodes. PBFT consensus protocol provides excellent scalability in terms of the number of users, but have not been well explored in terms of the number of Nodes (verified only up to few tens of Nodes). Possible scalability issues could be addressed by using hierarchical BFT protocols. Frequency of creating a block or number of transactions in a block (batch size) could be adjusted. System load is already minimized by storing patient’s clinical records off-chain. We plan to evaluate the system performance and scalability in clinical settings in future work.

5 Related Work

The potential of the applications built on top of the blockchain technology for healthcare data management has been recently discussed. Yue et al. claim to be the first to import blockchain into the design of a healthcare system. They presented the architecture of a healthcare data gateway application for easy and secure control and sharing of medical data between different entities that may use patient data. However, the system has not been implemented nor tested yet. A possibility of sharing the data for research purposes is only sketched in the paper, without any security or privacy evaluation. Jenkins et al. proposed to use blockchain technology for a multifactor authentication in a specific research scenario (medical large data analysis with functional biomarkers) that involves biometric and biomedical data.

MedRec is the first and the only functioning prototype that have been proposed until now. The authors presented a system based on Ethereum smart contracts for an intelligent representations of existing medical records that are stored within individual nodes on the network. Two incentivizing models for “mining” are also proposed in. Our prototype significantly differs from the framework in. First, MedRec is based on permissionless blockchain implementation.
and PoW, thus involves transaction fees, and requires involvement into “mining” and account management processes. In contrast, we have chosen permissioned blockchain implementation based on the requirements from the medical perspective. We justified our choice in Section 3.4. Second, in the patients data are stored locally at every node. We decided to use a cloud-based storage, and employ encryption and key-sharing to ensure availability of the data even if the hospital node is temporary off-line.

Conclusion and Future Work

In this paper, we proposed scenarios of blockchain technology application in different healthcare settings: primary care, medical data research, and connected health. We discussed how maintaining an immutable and transparent ledger, which keeps track of all the events happened across the network, could improve and facilitate the management of medical data.

Based on the constrains related to the healthcare context, we justified the choice of the permissioned blockchain technology for the implementation of the proposed scenarios. We also presented an architecture of the framework for the specific needs in case of radiation oncology data sharing and implemented a prototype that ensures privacy, security, availability, and fine-grained access control over highly sensitive patients’ data.

As part of future work, we would like to extend the structure of a patient record and its metadata, using the semantics of healthcare data, including the possibility of sharing radiology images, which is much more challenging. Since we work in collaboration with a hospital, we plan to test our system with the data of the real patients. Our long term goal is to explore other scenarios proposed in the paper (such as connected health and medical data research) and apply them in practice to enhance the current healthcare data management.

Abstract

Objective: Secondary use of electronic health record (EHR) data is enabled by accurate and complete retrieval of the relevant patient cohort, which requires searching both structured and unstructured data. Clinical text poses difficulties to searching, although chart notes incorporate structure that may facilitate accurate retrieval. Methods: We developed rules identifying clinical document sections, which can be indexed in search engines that allow faceted searches, such as Lucene or Essie, an NLM search engine. We developed 22 clinical cohorts and two queries for each cohort, one utilizing section headings and the other searching the whole document. We manually evaluated a subset of retrieved documents to compare query performance. Results: Querying by section had lower recall than whole-document queries (0.83 vs 0.95), higher precision (0.73 vs 0.54), and higher F1 (0.78 vs 0.69). Conclusion: This evaluation suggests that searching specific sections may improve precision under certain conditions and often with loss of recall.

Introduction

The use of electronic health records (EHR) in inpatient and outpatient clinical facilities has increased rapidly over recent years. Incorporating EHRs has facilitated clinical practice, resulting in widespread access to patient information and potentially better care. Because of the quantity of data in an EHR and the number of patients in a typical health-care system, using this data for secondary purposes can be of enormous benefit both to the local health care system and nationally.

EHRs are used primarily for direct patient care and for billing purposes, and they are designed to maximize the ability to provide these functions. However, in this process, the EHR becomes a repository of a vast amount of clinical data, both structured and text. This data can be used for many purposes beyond clinical care and billing: research, quality measures, disease surveillance, operational improvement, and administrative applications. All of these uses of EHR data require the ability to find desired information with a high degree of accuracy. In many cases, this means that we need to be able to identify specific patient cohorts. For example, researchers may want to look at records for all patients with a particular disease or all patients who received a specific treatment. For accurate disease surveillance, we must be able to identify patients who had that disease, either by locating specific diagnosis codes or mentions of the disease, or by locating surrogate indicators such as treatments or symptoms. Alternatively, hospital administrators may want to count the number of patients who received a particular treatment, or the number of procedures performed in a clinic. In some cases, conditions or symptoms may be documented only in clinical notes, and only available through a text search.

The way data is stored in an EHR determines how we need to search for specific patients. Some of the data is stored in structured fields, which are relatively easy to access. This data is recorded in consistent ways as specific codes, including international classification of disease (ICD) or other codes, or as predetermined phrases. Although structured data is relatively easy to search, several studies suggest that a search relying solely on structured data will not retrieve all patients relevant to the topic1,2,3,4, and other studies suggest that combining structured and unstructured data will improve cohort retrieval5. A great deal of EHR data, however, is stored as unstructured text in clinical notes, history and physical exam notes, and reports. This unstructured text is very difficult to access on a large scale. Medical text contains several features that compound this difficulty, including frequent use of abbreviations, lack of standardization of abbreviations, context-dependent differences in word meanings and abbreviations, negation of symptoms or diseases, and documentation of history not directly related to the current visit. Because of the difficulty in accurately extracting data from text, most non-research use of EHR data utilizes structured data only. Clinical notes contain highly valuable information not found in structured fields, and they
document clinical thinking and decision making. Further, relying solely on structured data for analytic functions results in a greater data-entry burden on providers. Because of these factors, improving retrieval accuracy from text would have great value.

The National Institute of Standards and Technology (NIST) has sponsored challenges to evaluate and improve the ability to accurately retrieve patient data from medical text for secondary uses. In NIST's 2011 and 2012 Text Retrieval Conference Medical Records Track (TRECMed), participants were given a list of clinical topics and a set of de-identified textual medical records. Participants developed search systems and algorithms to retrieve records relevant to each topic. Retrieved visits were then judged for relevance to the topic. An analysis of incorrectly retrieved visits identified several key problems in accurate retrieval of patient cohorts6. Factors in retrieving non-relevant visits included terminology similarities, negation of the desired term, and mention of the desired term as a past or future occurrence. Relevant visits were overlooked when the chart notes used different terminology or described rather than named the condition.

The Electronic Medical Records and Genomics Network (eMERGE) Consortium has also evaluated the ability to retrieve specific patient cohorts from EHRs7. In this study, EHR data from five different sites were used to identify patients with at least one of five diseases (dementia, cataracts, peripheral arterial disease, type 2 diabetes, and cardiac conduction defects). Patients were identified with a high level of accuracy when the data were stored in structured fields; however, in some cases, target information was stored only in clinical text. The use of natural language processing (NLP) tools increased retrieval significantly—129% more cases were identified by including the use of NLP tools rather than through using structured data and string matching alone. In evaluating results from one site, use of the same terms to mean different things within one document was an issue in correct retrieval of patients; for example, 'potassium' can be a medication or the name of a lab value, and a drug name can be listed as an allergy or as a prescribed medication8.

Several approaches may be utilized to overcome these issues and facilitate the retrieval process: the query can be constructed to yield a more accurate response, and the original text can be manipulated to make it more searchable. Clinicians are trained to write medical records in a highly structured fashion. Physicians' chart notes are also divided into sections that indicate the source and purpose of the information, in a structure referred to as SOAP (Subjective-Objective-Assessment-Plan). Within these sections, a typical chart note for a first encounter with a patient includes the chief complaint, a history of the present illness, a review of systems, past medical history, family history, and social history. Manipulating and searching the text according to these sections would allow the construction of searches targeted to the appropriate section, avoiding or minimizing some of the issues found in previous work. Several tools and strategies9,10,11,12,13,14 have been documented that segment clinical records. Although the effectiveness of each segmentation strategy has been evaluated, no studies could be located that demonstrate whether segmenting improves the performance of searching clinical text.

Temporality is an information retrieval (IR) issue that is particularly relevant to medical text, which often documents the current illness as well as previous illnesses. Clues to temporality can be found in identifying the section of the medical record: a description of the chief complaint is likely the current issue, whereas a condition listed in the past medical history is something that has resolved or is not the focus of the current visit.

Subject identification can also complicate retrieval of medical information. Chart notes may document illnesses of other family members as well as those of the patient. Identifying who has the disease improves accuracy of recall by avoiding retrieval based on someone else's disease status. The ability to separate sections of the medical record may facilitate retrieval accuracy by identifying the family history section and allowing that section to be searched only when applicable.

The hypothesis of this study is that searching for patient cohorts by looking in specific, relevant sections of clinical text will improve retrieval accuracy.

**Methods**

**Data** This project used de-identified clinical records developed by the Massachusetts Institute of Technology (MIT), Philips Medical Systems, and Beth Israel Deaconess Medical Center15. The Multiparameter Intelligent Monitoring in Intensive Care (MIMIC-II) data is a publicly available dataset containing more than 30,000 intensive-care unit (ICU) patients. The MIMIC-II data is stored in a relational database containing structured data and unstructured
textual discharge summaries, MD notes, radiology reports, and nursing notes. This project used all four types of text
documents for the search corpus.

**Search Engine** Queries for this project were run using the Essie 4 search engine developed by the National Library
of Medicine. Essie 4 maps terms to the UMLS and allows differential weighting of terms to alter the order of
documents retrieved. Mapping terms to the UMLS allows comparison of different but equivalent terms; for example,
'myocardial infarction' and 'heart attack' refer to the same concept using different words. Because Essie 4 maps to
the UMLS, equivalent terms are found without being listed explicitly, allowing the queries to focus on detecting the
difference in retrieval when using sections, rather than including an exhaustive list of all possible synonyms.

When a query is run, Essie 4 returns a list of documents retrieved for that query. Because of term weighting, each
document is assigned a rank that indicates the relative likelihood that it is relevant to the query. Weights are given
values greater than 0 and less than 1.

**Segmentation** To segment the documents, we examined a subset of each type of document to identify the most
common section headings, recording all terminology, spelling, and punctuation variations. We then created a text
file containing these heading variations and the corresponding XML heading tags for the new sections. Table 1
shows examples of the headings inserted for the indicator text listed.

<table>
<thead>
<tr>
<th>Inserted Heading</th>
<th>Indicator Text</th>
</tr>
</thead>
<tbody>
<tr>
<td>AssessmentAndPlan</td>
<td>disposition/plan treatment/plan: overall assessment and plan:</td>
</tr>
<tr>
<td>Course</td>
<td>clinical course in the emergency department: ed course: institution course:</td>
</tr>
<tr>
<td>CDCDisposition</td>
<td>transferred to: dispo:</td>
</tr>
<tr>
<td>LabRadResults</td>
<td>cta chest: important diagnostics and labs: radiographs-</td>
</tr>
<tr>
<td>FinalDiagnosis</td>
<td>diagnoses at the time of discharge: final discharge diagnosis: diagnosis on transfer:</td>
</tr>
</tbody>
</table>

The documents were searched for exact matches to the heading variations listed in the text file, and the appropriate
heading tags were inserted at those locations. Two tags were inserted for each heading, one at the start of the section
and the other at the end. When a new heading was located, an opening tag was inserted for that heading, and an
ending tag for the previous heading was inserted just before it. Tags were set up in XML format; for example,<AdmissionDiagnosis> at the start of the section and </AdmissionDiagnosis> at the end of the section.

Prior to having the section tags inserted, the original documents contained a single block of text surrounded by
opening and closing tags, as shown in this example:

```xml
<text>
DATE: [**3305-8-7**] 1:51 PM
CHEST (PORTABLE AP)
Reason: CHECK ETT TUBE PLACEMENT
?PNA, CHF
REASON FOR THIS EXAMINATION:
CHECK ETT TUBE PLACEMENT
?PNA
CHF
UNDERLYING MEDICAL CONDITION:
85 y/o male s/p acute mi and catheterization now
</text>
```
in ccu with cardiogenic shock.

FINAL REPORT

Comparison is made to previous study of one day earlier. An endotracheal tube is present, in satisfactory position. A Swan-Ganz catheter terminates in the proximal left pulmonary artery and has been withdrawn in the interval. An intraaortic balloon pump terminates about 3.3 cm below the superior aspect of the aortic knob, and a nasogastric tube terminates in the region of the gastroduodenal junction.

Cardiac and mediastinal contour are stable in the interval and pulmonary vascularity is within normal limits for technique. There has been improvement in the left retrocardiac opacity and there remains a patchy right basilar opacification which is slightly increased. A small amount of fluid is seen in the minor fissure.

IMPRESSION:
1) Lines and tubes in satisfactory position, as detailed above, with no evidence of pneumothorax.
2) Improved left retrocardiac opacity and worsened right lower lobe opacity likely due to atelectasis.

After segmenting this text, the document is broken into blocks, with the preamble, indication, condition, procedure details, and study impression separated by XML tags:

The segmented documents were indexed in Essie 4. Search queries utilized the XML tags to locate text in specific sections of the documents.

Queries A set of clinical topics to be retrieved from the text were developed from topics in TREC Med 2012, a project which used a set of de-identified clinical records for hospital and emergency-department patients. This set contains fifty clinical topics drawn from the Institute of Medicine's clinical comparative effectiveness priorities (16 topics), meaningful use clinical quality measures (12 topics), and the OHSUMED literature retrieval test collection (22 topics). Because the original query topics were developed for a wider range of patients, not all topics were relevant to ICU patients. A subset of 22 topics was used, modified as necessary to fit the current clinic population.
Queries were developed in an iterative fashion, refining the search details to maximize the number of relevant visits returned. An initial query was run against the data. The text of a subset of the returned visits was examined to determine if any new terms or operators needed to be added to the query, or if any query components needed to be removed. Although information from the returned visits was used to guide query development, details that appeared to be site-specific were not used. Once a set of queries was developed, they were run on the data, and the retrieved visits were recorded. The queries were then revised to utilize the sections, and visits retrieved with the revised queries were recorded. Below are examples of two clinical topics and the two queries for each topic:

**Topic: Patients with esophageal cancer who develop pericardial effusion**
Base Query: \textit{esophageal cancer AND "pericardial effusion"}
Query by sections: \textit{esophageal cancer AND [AREA][FinalDiagnosis] "pericardial effusion" OR AREA[Course] "pericardial effusion" OR AREA[LabRadResults] "pericardial effusion" OR AREA[AssessmentAndPlan] "pericardial effusion"}

**Topic: Adults with Alzheimer's disease with pressure ulcers discharged to nursing homes**
Base Query: \textit{alzheimers AND EXPAND[concept] (bed sore OR pressure ulcer) AND (NOT home OR facility OR "nursing home" OR "extended care" OR "assisted living") AND NOT expired}
Query by sections: \textit{alzheimers AND EXPAND[concept] (bed sore OR pressure ulcer) AND AREA[DCDisposition] (NOT home OR facility OR nursing OR extended) AND AREA[DCDisposition] NOT expired}

**Query Analysis** A subset of retrieved documents was examined to understand the effect of segmenting on retrieval performance. Three sets of documents were examined; two of these sets were the ten highest ranked documents retrieved only with the base query or only with the query by sections. The third set compared results when both queries retrieved the same document; the difference in rank assigned to those documents by each query was used to decide which to examine. The difference was calculated by subtracting the rank assigned by the query by sections from the rank assigned by the base query. When this value was highly positive, the base query had assigned a much greater rank than the query by sections; ie, the document was placed much lower in the list of ranked retrieved results. When this value was highly negative, the query by section had assigned a much greater rank than the base query. The ten documents with the largest positive difference in rank and the ten documents with the largest negative difference in rank were examined. Because the queries retrieved different numbers of documents, the actual number analyzed for each topic was usually lower than 40. Table 2 below shows the topics and the number of documents analyzed for each topic.

**Table 2. Query topics and number of documents analyzed.**

For each document, several observations were recorded. Retrieved documents were evaluated for relevance to the topic. Non-relevant documents were examined to determine the reason for retrieval; specifically, the documents were examined to identify occurrences of the search terms. We assessed the reason for performance differences between the two queries, and the reason for performance difference when querying by sections. Codes to reflect these assessments were developed in an iterative fashion, with new codes added as necessary to capture new reasons.

**Results**
A total of 574 documents were examined. Of those, 344 were relevant to the given topic. Both queries retrieved 247 of these documents, querying by sections retrieved an additional 20 documents, and querying the whole document retrieved an additional 77 documents. The remaining 230 non-relevant documents included 146 that were not at all relevant, 53 that were relevant to portions of the topic but not the entire topic, and 18 that were possibly relevant.

Eighty-one non-relevant documents were retrieved by both queries, querying by sections retrieved an additional six documents, and querying the whole document retrieved an additional 143 documents. Figure 1 illustrates the comparative retrieval rates for queries of specific sections versus querying the whole document.

</tbody>
</table>

Examination of the documents revealed that not all sections were identified correctly. This was not surprising, given our method of section identification. Because sections were ended only when new ones were identified, unidentified
sections were erroneously included in the previous section. Our identification rules specified text patterns that
signified new sections, so sections that were implicitly identified by extra spaces or changes in wording or content
were overlooked. In all, we identified 44 documents in which relevant sections were not correctly tagged, factoring
into incorrect retrieval. Eleven of these were relevant documents not retrieved when querying by section; accurate
segmenting would have enabled retrieval of this set.

Of the relevant documents, 77 were retrieved by the base query only, and 20 were retrieved only by the query by
section. The remaining 247 were retrieved by both queries. Querying by section returned 78% of the relevant
documents examined, and the base query returned 94%. Designing queries to examine only specific sections of the
text led to overlooking a number of relevant documents: fifty-two relevant documents were not retrieved because of
overly restrictive queries of specific sections of the document.

Looking at the 20 documents retrieved when querying by section revealed two topics these queries handled
especially well. One topic was "Patients with low-back pain who had imaging studies." The query for this topic
included the word *lumbar* as a synonym for *low back*. Adding this term resulted in retrieving a number of
documents in which patients had lumbar punctures, so the base query was adapted to eliminate documents with any
mention of that procedure. Querying by section eliminated documents that mentioned lumbar puncture only in the
lab and radiology results, allowing this query to place additional relevant documents higher in the ranked list. The
other topic handled well by querying by section was "Patients taking atypical antipsychotics without a diagnosis of
schizophrenia or bipolar depression." The base query looked for documents without these diagnoses, leading to
omission of documents in which non-relevant mention was made in the family or social history. The other query was
able to specify the absence of these in sections of the chart pertaining to the patient, while ignoring sections
mentioning diagnoses of relatives or other family members.

Queries of specific sections returned only 38% of the non-relevant documents examined, whereas the base queries
returned more than 97%. Only six non-relevant documents were retrieved only by querying specific sections, and
143 were retrieved by whole-document queries only. The remaining 81 were retrieved by both queries. Reasons for
returning non-relevant documents included mention of conditions that had been denied or ruled out, past conditions
or medications, future or possible conditions, non-relevant references to conditions (for example, in the family
history, or one word with multiple meanings), and, in one case, a procedure that was aborted prior to completion.
Because of their ability to search in specified sections of the chart, these queries were able to avoid retrieval of many
non-relevant documents.

Matthews correlation coefficient (MCC) was used to evaluate performance of individual queries. MCC is used in
machine learning as a measure of the quality of binary classifications. It was chosen for this project because it yields
reliable results with small samples and can measure both increases and decreases in performance. To calculate
MCC, retrieval results were first classified as true and false positives and negatives, indicating relevance to the topic
and score differential. Table 4, below, illustrates the classification of documents according to these criteria.

<table>
<thead>
<tr>
<th>Document relevant</th>
<th>Querying by section has higher score than querying whole document</th>
<th>Querying by section has lower score than querying whole document</th>
</tr>
</thead>
<tbody>
<tr>
<td>True Positive</td>
<td>False Negative</td>
<td>False Negative</td>
</tr>
<tr>
<td>False Positive</td>
<td>True Negative</td>
<td>False Positive</td>
</tr>
</tbody>
</table>

In some cases, only one type of query retrieved a document. For example, a document may be retrieved by the base
query but not the query of specific sections. In this case, the score assigned by the base query was used, and a score
of zero was used for the section query. Because of this, the MCC values do not reflect a difference between
documents that were retrieved and documents that were not retrieved. Possible values for MCC range from -1 to 1.
If querying by sections produces an overall performance decrease, MCC will be less than zero. A score of -1
indicates that querying by sections yields only false positive and false negative results. If querying by sections
increases performance, MCC will be greater than zero. An MCC of 1 indicates that querying by sections yielded
only true positive results. MCC was calculated for each topic as follows (scores listed in Table 5):
MCC could not be calculated for six topics because the sum of true negative and false negative or the sum of true positive and false positive was zero, resulting in a denominator of zero. The average of all MCC values was 0.422, which is significant at \( p<0.01 \). Although there was great variability in the values of MCC, the queries using sections for eight topics performed very well, showing statistical improvement over the base queries using Fisher’s exact test for significance, and no topics had statistically significant decreased performance. The queries of sections for Patients who had a carotid endarterectomy during this admission and Patients with diabetes mellitus who also have thrombocytosis performed very well with MCCs of 0.905 (\( p<0.001 \)). The sectioned query for Patients who develop thrombocytopenia in pregnancy had an MCC of 0.853 (\( p<0.001 \)). Other high performers were Patients with acute vision loss (MCC=0.756, \( p<0.001 \)), Patients who received pneumonia vaccination during this admission (MCC=0.734, \( p<0.01 \)), and Patients who have gluten intolerance or celiac disease (MCC=0.666, \( p<0.001 \)).

</table>
Discussion
In the documents examined, searching for information in specific sections of the document did provide some improvement. Overall, queries of specific sections retrieved only about half the number of non-relevant documents as compared to the base queries. However, they also retrieved only about 80% of the relevant documents. This suggests that querying specific sections will not retrieve as large a set of relevant documents, but it is more likely to avoid retrieving non-relevant documents.

Expanding the queries to look at more sections for the desired information would result in retrieval of more documents, both relevant and non-relevant. Because Essie returns documents that match the search criteria, queries developed for this project were designed to retrieve documents that were most likely to be relevant. The queries utilizing the section headings were written to look only in the relevant section, resulting in two different queries for each topic. Some NLP search engines will identify each relevant item of information as well as the document section in which it was found. While the methodology in the present project may reflect real-world practice, using an NLP tool like this would allow the use of one set of queries and an evaluation that could focus more closely on the use of looking in specific sections. Improving retrieval of relevant documents could also be achieved through greater accuracy in labeling section headers. In the sample of documents validated for this project, better section detection may have allowed retrieval of 13 additional relevant documents, about 16% of the overlooked relevant documents.

Although these methods may improve the chance of retrieving relevant documents, it is important to keep in mind that the documents themselves are not perfect. Clinical text is a tool used to communicate medical information, and is often created in high-stress situations. The current examination found several cases where information was documented in non-typical sections. For example, one document noted the patient's Alzheimer's disease only in the social history when describing the living condition. Additionally, the sections themselves may vary slightly between institutions or clinicians. The current data set contained problem lists in some documents, while other documents listed ongoing problems only in the past medical history.

For some topics, the query must look for documents that do not reference a specific condition or medication, as in the topic "Patients taking atypical antipsychotics without a diagnosis of schizophrenia or bipolar depression." Searching for documents that do not reference these eliminates those that mention the conditions in other people. Being able to search specific sections improves recall in this situation by avoiding sections likely to contain false positives.

Future work should take several approaches. First, a formal evaluation of the section identification in these documents would provide a baseline to help interpret the results of the query evaluation. An alternative approach would be the use of a validated sectioning algorithm, which may provide greater accuracy in labeling section headings. The tool chosen should have the ability to identify section changes that are not explicitly identified by headings. Using regular expressions or other pattern matching algorithms would improve section detection and accuracy, which would improve overall performance.

Second, some of the common retrieval issues in medical text, such as negation, should be identified using a published tool. Next, a set of queries can be run, and a quantitative analysis of the results can be done to provide greater insight into the effectiveness of segmenting documents on retrieval.

Another avenue of future work is to develop algorithms that combine the two search types to predict document relevance. Because of the differences in recall and precision between the two types of searches, knowing which documents are retrieved by both searches provides a clue to predict relevance. Future work in this area would develop prediction models based on retrieval results.

The queries used in this project contained multiple components. Breaking down the cohort criteria into individual concepts would allow a more focused evaluation. For example, in the search for patients who have cerebral palsy and depression, one set of queries could look for cerebral palsy and another set for depression. This would allow an assessment of which individual concepts may be more accurately identified in specific sections of the document, and which can be accurately identified when searching the whole document.

Because of the high value of clinical text and the documentation burden on clinicians, pursuing further work in this area would provide great value to providers, healthcare organizations, and patients. Identifying and searching
specific sections of clinical text significantly improves precision with only modest decreases in recall, resulting in greater usability of this data source.

Abstract

The Echocardiography Appropriate Use Criteria (EAUC) are a set of indications for transthoracic echocardiography (TTE) developed to guide physician decision making around ordering of TTE. In this study, an automated rule-based method for processing “indications” listed within TTE reports and classification into one of the major EAUC categories was developed and validated against a clinician-annotated reference standard. The system performed at a comparable level to trained physicians allowing for the automated classification of more than 30,000 TTE indications from a public database in less than ten minutes. The most common indication for TTE was Valvular assessment closely followed by General, Hypertension/Heart Failure/Cardiomyopathy, Acute, and Cardiac Structure assessment each contributed more than ten percent within this patient population. These results suggest potential for automated approaches for tracking appropriate use of TTE, as well as guide the development of systems for prospectively identifying when TTE use is recommended.

Introduction

Medicare alone spends more than $1B annually on transthoracic echocardiography (TTE) and the per capita growth rate in the performance of TTE increased steadily by 8% per year from the mid 1990s to early 2000s, a rate that exceeded any plausible increase in commensurate clinical value1,2. TTE is a powerful, non-invasive, low-cost imaging tool for evaluating cardiac structure and function. Trends towards evidence-based, targeted diagnostic testing highlight the potential for optimization of transthoracic echocardiography utilization. In response to this trend, a joint task force published a set of consensus echocardiography appropriate use criteria (EAUC) to define indications for TTE in 2007 and revised criteria were published in 20113. In the years since the EAUC were revised their use has been a component of echocardiography laboratory accreditation, necessary for insurance reimbursement, and also a way to promote quality improvement. However, the guidelines for how EAUC should be used are non-specific, only requiring that labs be aware of the EAUC, have access to them, and make concerted effort to improve the rates of appropriate testing while maintaining the caveat that the EAUC are “expert opinion” that are non-exhaustive in scope4. Changes to prior authorization requirements implemented with the Affordable Care Act were in part responsible for a 17% decline in spending between 2009 and 2013, however there is little evidence that this decline resulted in a higher rate of appropriate testing and there still exists an 8.5 fold variation in testing rates by geographic region in the United States5,6. All of this suggests the need to characterize physician TTE ordering practices for improving rates of appropriate clinical testing.

There have been concerted efforts to characterize TTE ordering behavior using the EAUC since they were published7. These studies have revealed insights into the rates of inappropriate testing and variability across centers, as well as the relative effectiveness of different interventional methods for impacting physician behavior and reducing rates of inappropriate testing. However, these studies have been limited by the need for manual classification of TTE appropriateness. This is a labor intensive process which is time consuming and limits the sample size available for analysis. The largest appropriate use TTE study consisted of approximately 3,000 TTEs classified in a manual fashion8.

To date, TTE appropriate use studies have relied on manual annotation of patient medical records to determine EAUC classifications; however, natural language processing (NLP) has been successfully applied to extract information from the medical record in other related ways. For example, one study analyzed the medical record for
necessary information required to calculate the Framingham Risk Score\textsuperscript{9}. Others have developed methods to extract clinical findings from echocardiogram reports\textsuperscript{10,11}. Tools like these have been shown to be able to be applied across health systems demonstrating their broad utility beyond the electronic health record system within which they were developed\textsuperscript{12}. Applying such technology to the study of the appropriate use of TTE could have far reaching implications as it would allow for classification of TTEs on a much larger scale and provide the opportunity to more readily study clinical practice patterns and the impact of educational and other interventions.

This study aimed to develop an automated rule-based method for processing the “indication” listed in a TTE report and classifying it into one of the broad, major EAUC categories. The technique was evaluated relative to a manually annotated reference standard derived from a publicly available dataset.

**Method**

TTE indications were extracted from a publically available dataset. The indication text was processed and then matched against a thesaurus of terms to determine the EAUC indication category for the TTE. This method was validated on a sample of expertly adjudicated indication categorizations and then applied to the entire dataset. Most of the processing was implemented using the Julia (v.0.5) programming language, with statistical calculations done using R (v.3.3.1).

![Image](image.png)

**Figure 1. Overview of Study**

**MIMIC-III Database**

The Medical Information Mart for Intensive Care III (MIMIC-III) is a publicly available de-identified database of critical care unit patient health information from a tertiary care hospital\textsuperscript{13}. MIMIC-III data range from provider notes and charts to imaging reports and survival information on approximately 60,000 critical care unit admissions at Beth Israel Deaconess Medical Center from 2001 to 2012. This study focused on patients who had at least one transthoracic echocardiogram report available in the “noteevents” table and associated demographic information from the “patients” table. TTEs were identified using the “category” column from “noteevents” where values containing “Echo” AND either the phrase “TTE (Complete)” OR “TTE(Complete)” were selected for analysis. Free text indications for performing each TTE were extracted from the reports as the text between the standardized header “Indication:” and special character marking the end of the line “\n.”

**Manual Classification of TTEs**

A reference standard was developed to evaluate the performance of the automated classification program. Using the EAUC and specific annotation guidelines (shown in Table 1), two cardiology fellows with prior experience researching TTE ordering practices performed independent classification of a random sample of TTE indications. Three overlapping training rounds were used to ensure consistency between reviewers. Discrepancies were discussed and adjudicated by a cardiology attending physician, and the annotation guidelines were updated after each training round to reflect consensus categorization and a Cohen’s Kappa statistic was calculated. Once the training rounds were performed, each reviewer independently categorized 450 TTEs to complete the reference set (n = 1200).

**Automated Classification of TTEs**

A rule-based computer program was developed in the Julia programming language to automatically classify TTEs into the categories outlined in the EAUC for echocardiography. Phrases and acronyms likely to indicate TTE ordering reason were generated using a combination of sampling MIMIC-III TTE indications (different from the reference set), consulting clinical experts, and SNOMED-CT concepts. These phrases were then associated with
EAUC indication categories and collectively make up a “TTE thesaurus” of 355 phrase-category associations, which were mapped to 179 clinical concepts. TTE indications were pre-processed and compared to each phrase in the thesaurus using a string matching algorithm, which were consequently mapped to one of the clinical concepts contained in the thesaurus.

Pre-processing prior to string matching consisted of converting text to lowercase and removing non-alphabetic characters (except for hyphens, which are commonly used in clinical text). Finally, “stop words” (common indefinite articles and prepositions such as “the”, “at”, or “on”) were also removed.

Processed TTE indications were then compared against the TTE thesaurus to determine likely matches (demonstrated in Table 2). For each processed TTE indication string, the matching algorithm employed a moving window of \( m \) words, where \( m \) is the number of words in the thesaurus phrase string (note that for the purposes of this study, an abbreviation is considered a “word”). The window was moved across the TTE indication phrase to compare the potential thesaurus phrases against substrings of the TTE indication. Comparisons of processed TTE strings to thesaurus substrings were done using Damerau-Levenshtein distance to evaluate the similarity of strings. The similarity threshold for declaring a match was dependent on the length of the strings being compared, with shorter strings requiring near-perfect similarly and longer strings allowing for some disagreement. A constraint was also imposed such that a match could not be declared unless the first character of each word in one string matched that of its positional counterpart in the other.

*Typographical errors are highlighted*

TTE indication matches were then reduced to distinct clinical concepts using the TTE thesaurus and frequency of concept-category matches for each TTE indication were tabulated. TTE indications were then assigned an EAUC associated category based on the highest number of matches with the following exceptions. The General category was only chosen when no more precise category matches were found and due to the specificity of valvular indications, any mention of valve disease or endocarditis were annotated as “Valvular.” The automated rule-based method for classifying TTE indications according the EAUC was evaluated compared to the expert derived reference set. Level of agreement was quantified using Cohen’s Kappa. Precision, recall, and F-measure were all
calculated for each classification category. The program was then used to categorize all 30,320 TTE reports in MIMIC-III database.

Comparison Against a Machine Learning Classifier

The rule-based classification approach was compared to a random forest classifier. The target variable was the human-generated, adjudicated TTE classifications. The features were engineered using a bag-of-words approach on individual words from the indication text after the removal of "stop words" (same "stop words" as above). Term frequency–inverse document frequency (TF*IDF) was used for normalization. This yielded 603 sparse features. The 1200 adjudicated TTE classifications were split into training and test sets (80% and 20%, respectively). Five-fold cross validation was used to select the following meta-parameters: number of features to sample at each node, proportion of training set to be sampled for each tree. All trials used 1000 trees.

Results

Data for 30,320 TTEs from 18,487 different patients were analyzed with a mean of 1.6 (95% CI: [1-2]) TTEs per patient. Less than half (38%) of the TTEs were performed inpatient. Patients had a mean age of 68 years (95% CI: [56-79]), 56% were female, with a mean height of 67 inches (95% CI: [64-70]), weighing 170 lbs (95% CI: [144-201]). Mean patient BMI was 26.8 (95% CI: [23.4 - 31.3]).

Classification validation results are reported in Table 3. Two physicians classified a sample of TTE indications according to the EAUC across three training rounds in order to ensure consistency between them. Once consistency was achieved they each independently classification an additional 450 TTE indications. Collectively, 1200 expertly classified TTE indications comprise a reference set. The automated method was then tested against a small sample of the expertly adjudicated classifications before being applied to the balance of the reference set. Physician v. automated categorization validation round discrepancies are shown in Table 4. Precision, recall, and f-measure were calculated for each category and are reported in Table 5.

</tbody>
</table>

A random forest classifier was generated to benchmark the rule-based method. The final model used 1000 trees, randomly sampled 250 features for splitting at each node, had a maximum of five observations in leaf nodes, and drew bootstrap samples from 70% of the training set for each tree. This model achieved a classification weighted Cohen’s Kappa of 0.89 (0.83 - 0.95).

After the automated classification program was validated against the reference set, it was applied to the entire MIMIC-III database. Frequency of each TTE category is reported in Table 6, showing that more than half of the TTEs were ordered for General (27%) or Valvular (30%) reasons. HTN, HF, or CM (17%), Acute (15%), and Cardiac Structure (10%) accounted for most of the remaining TTEs with Aortic Disease and ACHD at less than 1% combined. Less than 1% of the TTE indications could not be categorized automatically.

To assess the effect of accepting fuzzy matches in the algorithm, the program was rerun to only accept exact matches. Out of the entire dataset of 30,320 TTE indications, there were 4,511 with missed thesaurus phrase matches when fuzzy matching was not implemented. This resulted in 364 changes to classification categories, indicating redundancy in the information available in the TTE indication despite typographical errors.

Discussion

An automated rule-based method was developed in this study for classifying TTEs into one of seven categories outlined by the EAUC for echocardiography. The most common indication for TTE was Valvular assessment closely followed by General, HTN/HF/CM, Acute, and Cardiac Structure assessment each contributed more than ten percent within this patient population. The system performed at a comparable level as trained physicians, allowing the classification of more than 30,000 TTE indications from a public database in less than ten minutes. This task would have taken the same physicians more than 45 hours.

Validation testing elucidated that areas of disagreement between the computer program and reference set established by trained physicians were mostly limited to four out of 56 possible discrepancy types, accounting for more than 65% of discrepancies. Two of these included the computer selecting the more specific categories of Acute or HTN/HF/CM, whereas a trained physician selected the General category. The remaining common discrepancy areas included the computer selecting Acute or Valvular where the trained physician classified them as HTN/HF/CM. The tight clustering of discrepancies demonstrates known overlaps in the EAUC categories. For example, determining whether the assessment of ventricular function belongs in the General or HTN/HF/CM depends on whether or not there is associated clinical suspicion of heart failure. This information is not always available from the TTE report indication and therefore would require additional associated clinical data to make this classification with certainty.

It was found that a machine learning classifier (built using Random Forests) performed comparably to the rule-based method. However, machine learning approaches may be difficult to fully interpret and may therefore be viewed as being less transparent (i.e., the rules for a particular classification are not readily discernable). In addition, rule-based approaches may be more computationally efficient than machine learning approaches, which often require large training sets. For example, the Random Forest approach used in this study required 80% of the adjudicated data set for training. The success of the rule-based approach demonstrated in this study, suggests the potential scalability to development of similar methods for use in other clinical contexts.

Categorization of TTE indications according to the EAUC have previously involved relatively small sample sizes largely due to the time required for manual classification. Research to date has utilized the EAUC in order to track rates of appropriate testing or as an outcome measure for quality improvement. These studies have reported that a significant number (15-25%) of TTEs are ordered inappropriately, with the majority of rarely appropriate TTEs being ordered in the outpatient setting. Randomized control trials of various combinations of educational intervention, clinical decision support, and audit/feedback mechanisms have demonstrated the ability to improve rates of appropriate use with limited sustained effect. Applying an automated tool such as the one developed in the current study would allow for the evaluation of appropriate use of TTE to occur on a much larger scale. This would
likely have several important clinical implications, including more accurate characterization of current practice patterns in various settings (e.g., academic, community, and inpatient/outpatient) and determining the impact of educational and other interventions.

Generalizability of the breakdown of TTE ordering indications reported in this study are limited by the patient population. All TTE data within the MIMIC-III database were either obtained during or subsequent to a hospitalization in which the patient received care in an ICU. Other limitations to this study are a function of the data being used and how the EAUC are written. TTE indications are brief notes that lack clinical context provided by access to a complete medical record. Accurately distinguishing between some overlapping indications would require this additional information when TTE indications are non-specific.

Future research will use this classification algorithm to guide automated EAUC classification using additional clinical data including physician notes, discharge summaries, and lab testing results to determine appropriateness. The development of a system to automatically determine TTE appropriateness according to the EAUC will enable sustainable audit/feedback intervention that can be applied to any electronic medical record system at the point of care. Finally, an automated tool may facilitate appropriate use tracking for individual laboratories and improve the ability to comply with standards set by accrediting bodies.

Conclusion

More than 30,000 TTEs were classified according to the EAUC for echocardiography using a computer program that was validated against trained physicians. The promising results suggest that there is potential for an automated approach to track appropriate use of TTE, as well as guide the development of systems for prospectively identifying when TTE use is recommended. Automated assessment of EAUC adherence may enable effective and sustainable intervention to improve appropriate use rates and efficiency in the application of diagnostic echocardiography in the care of patients.

Abstract

Social networks, such as Twitter, have become important sources for active monitoring of user-reported adverse drug reactions (ADRs). Automatic extraction of ADR information can be crucial for healthcare providers, drug manufacturers, and consumers. However, because of the non-standard nature of social media language, automatically extracted ADR mentions need to be mapped to standard forms before they can be used by operational pharmacovigilance systems. We propose a modular natural language processing pipeline for mapping (normalizing) colloquial mentions of ADRs to their corresponding standardized identifiers. We seek to accomplish this task and enable customization of the pipeline so that distinct unlabeled free text resources can be incorporated to use the system for other normalization tasks. Our approach, which we call Hybrid Semantic Analysis (HSA), sequentially employs rule-based and semantic matching algorithms for mapping user-generated mentions to concept IDs in the Unified Medical Language System vocabulary. The semantic matching component of HSA is adaptive in nature and uses a regression model to combine various measures of semantic relatedness and resources to optimize normalization performance on the selected data source. On a publicly available corpus, our normalization method achieves 0.502 recall and 0.823 precision (F-measure: 0.624). Our proposed method outperforms a baseline based on latent semantic analysis and another that uses MetaMap.

Introduction

Pharmacovigilance is defined as “the science and activities relating to the detection, assessment, understanding and prevention of adverse effects or any other possible drug-related problems”.1 The primary focus of pharmacovigilance is the monitoring of adverse drug reactions (ADRs). Due to the various limitations of pre-approval clinical trials, it is not possible to assess all the consequences of the use of a particular drug before it is released.2 Therefore, ADRs caused by prescription drugs is currently considered to be a major public health problem and various ADR monitoring mechanisms are currently in place, such as voluntary reporting systems, electronic health records, and, relatively recently, social media.3

Social media has emerged as an important source of information for various public health monitoring tasks. The increasing interest in social media is largely because of the abundance of data in the multitude of social networks—data that is directly generated by a vast number of consumers. It is estimated that about 75% of all U.S. adults have a social network account and about 50% worldwide. Data from social networks have been used in the past for a variety of tasks such as studying smoking cessation patterns on Facebook,4 identifying user social circles with common medical experiences (like drug abuse),5 and monitoring malpractice.6 In addition, recent research has utilized social media for the monitoring of ADRs from prescribed medications.7 From the perspective of pharmacovigilance, social media could be a platform of paramount importance, since it has been shown in past research that users discuss their health-related experiences, including use of prescription drugs, side effects and treatments on a regular basis. Users are known to share their personal experiences over social media sources, and as such, a large amount of health-related knowledge is generated within the realm of social media.7 However, while significant progress have been made in ADR text classification, and ADR mention extraction,7,8 the normalizing of user posted ADR mentions into a predefined set of concepts is still a largely unaddressed problem.

In this paper, we address the task of normalizing distinct ADR mentions to standardized concepts. This is an essential task given that the same ADR concept may have multiple lexical variants (e.g., “high blood pressure”, and “hypertension”). Therefore, following automatic ADR extraction approaches, automatic normalization techniques
must be applied to obtain realistic estimates for the occurrences of ADRs. For social media data, this is particularly important because users often tend to express their problems using non-standard terms. For example, consider the following user posts:

"<DRUG NAME> makes me having the sleeping schedule of a vampire.",
"<DRUG NAME> evidently doesn't care about my bed time",
"...wired! Not sleeping tonight. #<DRUG NAME>"

In the above examples, all the posts are referring to sleeplessness caused by the intake of a specific medication. Each expression is unique and non-standard, although referring to the same ADR concept. In the corpus that we use, each ADR concept is encoded using the Unified Medical Language System (UMLS) concept IDs. All standard and non-standard lexical variants of an ADR are mapped to the most appropriate UMLS entry. The target of our approach, formally, is to predict the UMLS concept ID of a text-based ADR mention.

**Concept normalization**

The task of normalization of ADRs involves assigning unique identifiers to distinct ADR mentions, with different lexical variants of the same concept. The IDs are derived from any lexicon or knowledge base with sufficient coverage. In the case of our research, we use the UMLS concept identifiers to uniquely specify each ADR concept. The UMLS provides a vast vocabulary of medical concepts and the semantic groups into which the concepts can be classified. Each UMLS concept is assigned a unique ID, which represents all the lexical variants of the concept. From the previously mentioned example, all synonyms of the concept hypertension (e.g., hypertensive disorder, high blood pressure, high bp and so on) are assigned the ID c0020538. The UMLS Metathesaurus, due to its comprehensive coverage of medical terminologies, has been used to build corpora specialized for normalization in the past.9–11

The task of medical concept normalization can be regarded as a sub-field of biomedical named entity recognition (NER). Due to the abundance of text based medical data available, NER and concept normalization have seen growing research in the medical domain primarily through challenges such as BioCreative,12 BioNLP,13 TREC,14 and i2b2.15 Building on from these initiatives, the problem of concept normalization has seen substantial work for genes and proteins. Majority of the research on concept normalization relies on some variants of dictionary lookup techniques and string matching algorithms. Machine learning techniques have recently been employed, but mostly in the form of filtering techniques to choose the right candidates for normalization.16 A number of approaches17 rely on the use of tools/lexicons such as MetaMap18 as a first step for the detection of concepts. Due to the advances in machine learning techniques and also the increasing availability of annotated data, recent approaches tend to apply learning based algorithms to improve on banal dictionary lookup techniques. Very recently, Leaman et al.19 applied pairwise learning from a specialized disease corpus for disease name normalization. Prior works have involved list-wise learning, which learn the best list of objects associated with a concept and return the list rather than a single object, for tasks such as gene name normalization,19,20 graph-based normalization,21 conditional random fields,22 regression based methods,23 and semantic similarity based techniques.24 Semantic similarity or relatedness is a measure that shows how similar two concepts are. Such measures are often used for word sense disambiguation,25 where the term and its context information are utilized to assign a meaning to it. A number of techniques for computing semantic relatedness among medical entities have been proposed and compared in the past,26 some of which are mentioned in the next section. However, to the best of our knowledge, measures of semantic relatedness have not been previously used for normalizing ADR mentions.

**Social media text normalization**

While the task of normalization of medical concepts is itself quite challenging, in our case, the problem is exacerbated by the fact that our data originate from social media. Social media data is notoriously noisy.27 And while this hampers the performance of natural language processing (NLP) techniques, it is also the primary motivation behind the implementation of techniques for automatic correction and normalization of medical concepts in this type of text. Typos, ad hoc abbreviations, phonetic substitutions, use of colloquial language, ungrammatical structures and even the use of emoticons make social media text significantly different from texts from other sources.27
Past work on normalization of social media text focused at the lexical level, and has similarities to spell checking techniques with the primary difference that out of vocabulary terms in social media text are often intentionally generated. Text messages have been used as input data for normalization models, and various error models have been proposed, such as Hidden Markov Models and noisy channel models. Similar approaches targeted purely towards lexical normalization have been attempted on social media texts as well. For the research task we describe in this paper, although the primary goal is to perform concept level normalization, we apply several preprocessing techniques to perform lexical normalization before the application of our concept normalization pipeline.

Methods

The goal of this normalization task is to find the UMLS concept ID related to a text segment in a tweet that is pre-tagged as an ADR. For example, in the tweet: "had 2 quit job: tendons in lots of pain," the phrase "tendons in lots of pain" is tagged as an ADR. The goal of our system is to normalize the annotated text to a concept in UMLS, which in this example is "c0231529-tenalgia". Figure 1 shows the overall pipeline of the proposed normalization system. The system consists of syntactic and semantic matchers, synonym normalization and evaluation components. The pipeline is sequential, and so, as soon as a matching module finds a match between a lexical component and a UMLS concept, the remaining matchers in the pipeline are skipped and the flow goes to the synonym normalization and evaluation components.

For evaluation, we use a publicly available, annotated corpus of 2008 tweets mentioning drugs and adverse reactions. The corpus was generated by using Twitter API to search for tweets that contain the names of selected drugs. The dataset includes 1544 annotations using 345 unique concepts, of which 1272 are ADRs, 239 are indications/symptoms and 32 are medications. The annotations were performed by two trained biomedical informatics annotators, and all disagreements were resolved and the final corpus was validated by a pharmacology expert. In this work, we did not differentiate between annotation types (e.g., ADR vs. indication) and attempted to normalize all types using the same pipeline. More information about the corpus and annotations can be found in the publication associated with this dataset.

Figure 1. Overall architecture of the Hybrid Semantic Analysis technique.
**Syntactic match**

The first step in our normalization pipeline involves syntactic or lexical matching with concept names in UMLS. This part of the pipeline involves two steps: *exact match* and *definition match*. An exact match happens when an ADR mention in a user post exactly matches a UMLS concept name (i.e., when the user uses a standard lexical expression for a concept). This simple matching technique can detect many easy matches as standard terminologies are often used by the users. However, in many cases in informal text, ADR mentions are misspelled, and exact matches are not possible. Some of these misspellings can be caught by simple pre-processing techniques. For example, unnecessary character repetition can be removed, as in the tweet "I feel siiiiiiiiiiiiick", "siiiiiiiiiiiiick" is matched with UMLS concept "c0231218-sick".

The next step in syntactic matching utilizes the formal definitions of UMLS concepts. The UMLS metathesaurus provides one or more definitions for each concept. The definition is a passage that describes the concept in plain English. We use this information, in the semantic similarity component later in the pipeline, to create semantic vectors and calculate the similarity values. In the syntactic matching module, we check if the mention appears in the definition of a single concept only in UMLS. If it does, the mention is normalized to the concept. In most of the cases, a phrase appears in the definition of many concepts and no conclusion can be made.

**Semantic match**

ADR concepts that are not normalized by the syntactic matching components are passed on for semantic matching. The primary task of this component is to compute the similarities of potential ADR concepts with the UMLS concepts. We experiment with two Measures of Semantic Relatedness (MSR) methods. MSR methods or kernels are functions that accept a pair of phrases/words as input, and return a numeric value representing the relatedness score of the inputs. In this module, an MSR method is used to find semantic similarity of a mention and a subset of concepts in UMLS. The most similar concept, with a similarity above a specified threshold, will be chosen as the concept of the mention. We evaluated Latent Semantic Analysis (LSA), and our proposed hybrid method. In the semantic matching modules, only the UMLS concepts that are used in the annotations are considered for the prediction.

**Latent semantic analysis**

Latent Semantic Analysis (LSA) uses a term-document frequency matrix to estimate semantic similarity of two segments of text. LSA then harvests the matrix using Singular Value Decomposition (SVD), by selecting the $k$ best SVD values. More details about LSA technique and various weighting techniques can be found in past publications. In our system, for the first step, the term vector space is generated from a corpus of plain text documents. Then this vector space is used to find a representative vector for each UMLS concept. The UMLS concept names are used to search for term vectors in the vector space. We evaluate some of the corpora, which are listed in Table 1 for creating the representative vectors for the UMLS concepts. After finding a representative vector for each UMLS concept, we search for a representative vector for each annotated text in the same vector space. The cosine similarity of each concept's vector and the annotated text’s vector is computed. The concept with the highest similarity to the ADR is chosen as the normalized concept if the cosine similarity is above a certain threshold ($\geq 0.8$).

**HSA**

HSA uses machine learning to find the optimal combination of semantic relatedness function scores for each context, based on a set of calculated features. Using different free text sources, semantic representations for the concepts are learned, and then the different MSR scores are computed for the social media based lexical representations and the standard lexical representations of the concepts. Since different resources can be used, each MSR can return different values when applied to different resources. For example, we can apply PMI, and distinct resources like PMI-GENIA and PMI-I2B2ClinicalNotes. Each MSR method returns different scores when trained on different resources, and these scores are combined in a regression function as features.

For each pair of words/phrases, the Feature Calculator component of the system computes feature scores, which are the returned values from each MSR consisting of different corpora combinations. For example, one feature can be semantic relatedness returned for a pair by LSA-I2B2ClinicalNotes. After feature calculation, the regression model (SVM) is trained, and the model is evaluated against the test set.
Since the MSR and information resources are dynamic, and can be added or removed from the system, the feature set for the regression function is also dynamic and can be varied depending on the task. The output of regression function is a semantic relatedness score of two concepts in the given context, and the regression function is optimized using the labeled training data. The method is designed to easily adapt to new knowledge sources or corpora and adjust parameters accordingly. Also, it can be trained for a new text type or entity type.

For training the regression model, we prepared the training set from a subset of annotation (50% of the annotation). For each annotated text we created training examples for the annotated text and the UMLS concept names of the assigned concept with expected similarity of 100. For each annotation we generated 10 negative examples from the annotated text to random concepts in UMLS with expected similarity of 0. Figure 2 shows an example how HSA training examples are generated.

The ratio of negative to positive examples can affect how the HSA regression model is trained. We used SVM with a linear kernel as the regression model, and trained HSA with the resources listed in Table 1 and LSA as the only MSR. SVM (SVMLight) was used to create the regression model but other models such as neural network can be used and explored. We refrained from adding additional MSR methods as the intent of this experiment to study the effect of using the regression model with a single MSR and various additional resources. These resources are described in the next section.

After HSA is trained, the regression model is used to calculate the similarity of annotated phrases as ADR (which are the input to our system) to UMLS concept names. First, testing instances between the phrase and a set of selected UMLS concepts names are created. To limit the search space, UMLS concepts appeared in the training set annotations with frequencies of three or more are used for creating the test instances for HSA. Following that, for each example, the features are calculated. The features are all possible MSR and resource combinations defined in the system setup (e.g., LSA with PubMed). Next, the regression model is run on the test instances to calculate the similarity of the annotated text and each UMLS concept. The concept with the highest similarity and above a certain threshold (\(\geq 90\)), note that the maximum and minimum similarities in the training set are 0 and 100) is chosen as the normalized concept. Since the method has to calculate several semantic similarities for normalizing each annotated text, the process is slower than using a single MSR. The output of the trained regression is not normalized to any boundary and can be any real value.

**Corpora**

The two semantic matching techniques discussed above require data from suitable corpora to generate their models. We used three textual corpora generated from three different queries on PubMed (provided as special queries: http://www.nlm.nih.gov/bsd/special_queries.html): Dental Journals (PubMed query: “(jsubsetd[text]))”, Nursing Journals (PubMed query: “(jsubsetn[text])”) and Systematic Reviews. We filtered out articles that do not have publicly available abstracts. Table 1 shows the number of documents in each corpus. We are also interested in evaluating additional corpora instead of only those generated from PubMed. HSA uses all of the corpora matched with LSA as features to train the hybrid model. When using LSA independently for evaluation, without HSA, only one corpus is used for each run.

For the semantic similarity match step, we evaluate the following different settings:

1. Most similar concept returned by LSA using each of the corpora listed in Table 1.
2. Most similar concept returned by HSA
Evaluation criteria

For strict evaluation, we consider a prediction correct when the predicted concept is exactly the same as the expected concept. In contrast, in the relaxed evaluation mode, before calculating the evaluation metrics, we change the predicted class to the expected class if the predicted class has any of these relationships in the UMLS: "synonym", "is-a", "mapped-to" relations with the expected class. This means that if the system predicts a concept which is, for example, the synonym, child or parent of the expected concept, we consider it as a true positive. Considering the size of UMLS graph, we only do this normalization by distance of 2—meaning that if a concept “A” has an ‘is-a’ relation with a concept “B”, and the concept “B” has a “mapped-to” relation with a concept “C”, the concept “A” and “C” would be considered the same for the evaluation purpose. The following list shows some other examples of match in the relaxed evaluation:

- A –(is-a)→ B –(is-a)→ C: A will match with C
- A –(is-a)→ B –(mapped-to)→ C: A will match with C
- A –(mapped-to)→ B –(mapped-to)→ C: A will match with C
- A –(mapped-to)→ B –(synonym)→ C: A will match with C

Results

From the perspective of evaluation, each UMLS concept is considered to be a class. We compute the final precision, recall, and F-measure as the micro-average of all the classes. For each class true positive (TP), false positive (FP), true negative (TN) and false negative (FN) are defined as below: TP is when the expected class is equal to the predicted class and the evaluated class. FP is when the predicted class is equal to the evaluated class but not equal to the expected class. FN is when the expected class is equal to the evaluated class but the predicted class is not equal to the expected class.
class. TN is when both predicted and expected classes are not equal to the evaluated class. The following table illustrates an example for the evaluation strategy. The micro-averaged precision and recall are calculated using the following formula:

\[
\text{Precision} = \frac{\sum_{c \in \text{Classes}} TP_c}{\sum_{c \in \text{Classes}} (TP_c + FP_c)}
\]

\[
\text{Recall} = \frac{\sum_{c \in \text{Classes}} TP_c}{\sum_{c \in \text{Classes}} (TP_c + FN_c)}
\]

\[
F\text{—}measure = \frac{2 \times \text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}}
\]

Table 2. Illustration of the evaluation technique.

Table 3 shows the results for syntactic matcher, LSA using different corpora and the proposed hybrid model. HSA yielded the best F-measure of 62.37 and the best recall of 50.20. The next best precision after syntactic match is achieved by LSA with UMLS definitions corpus. Among LSA with various corpus, ADR-Tweets resulted in the best F-measure. In the investigated normalization problem, the ADR-Tweets corpus yielded the best performance for LSA method. Syntactic matcher has the highest precision, which was expected. Adding LSA-ADR-Tweets matcher on top of syntactical matcher decreases the precision but increases the recall resulting in a higher F-measure. Using HSA instead of LSA decreases the precision slightly more than LSA but the gain on recall is higher and results in a higher F-measure. MetaMap, which is designed for public medical literature data, suffers from very poor recall and therefore overall F-measure. We used the relaxed evaluation method in all of the reported results.

Table 3. Results obtained by our system using the proposed pipeline and the relaxed evaluation technique.

Discussion

Figure 3 shows the sources of false positives and true positives. Semantic match generates most of false positives followed by exact match. Exact match returns majority of true positives followed by semantic match. As expected, when only the syntactic matching module is employed, we obtain high precision but very low recall. Searching for exact match in definition helps to find alternative representation of the concept. For example, “urge to vomit” is normalized correctly to “c0027497-Nausea” when we search the definition of “c0027497”: “unpleasant sensation in the stomach usually accompanied by the urge to vomit”. Exact match fails when the words in a phrase are expressed
in complex orders and another concept matches exactly with the annotated phrase. For example, in the following tweet: "dreams have taken a terrifying turn.", "dreams" is annotated as "c0857051-bad dreams" but exact match matches the phrase with "c0028084-dreams".

![Figure 3. Sources of correct and incorrect predictions.](image)

In contrast to syntactic matching, semantic methods are designed to compute estimates of similarity, and match concepts that are not necessarily the same, but are similar. As such, they are expected to have high recall. In our experiments, the semantic matchers LSA and HSA have the higher numbers of false positives but yield higher recalls than syntactic match. This was expected since most of the hard to normalize concepts reach the semantic matchers modules. Most of the errors are caused by concepts with very similar meanings. For example, "anti-depressant" in a tweet is tagged as "c0011570-mental depression," but LSA returns "c0005586-manic depression" as the most similar concept.

Table 4 shows examples of correct and incorrect predictions by HSA. The hybrid model is very good at normalizing when the same word is represented in a different variation ("antidepressant" vs. “depression”) or match similar words which appear frequently in corpora (“fewer” vs. “loss”, “increase” vs. “gain”). In contrast, HSA performance is limited to the information in the provided resources and MSR technique. Since in this experiment we only used LSA, HSA would perform solely based on co-occurrences of terms in the resources. If there are not enough numbers of co-occurrences of two terms in the provided resources, we expect to have a very low similarity of the terms. In addition to using larger corpora, adding more diverse techniques that can leverage other resource types (such as graph-based techniques) can significantly boost this limit.

**Conclusion**

In this work, we proposed a natural language processing pipeline for the problem of normalizing extracted mentions of ADRs from colloquial texts to UMLS concepts. We compared two semantic similarity techniques: LSA and a proposed hybrid approach (HSA). The hybrid approach shows improvement over a single similarity technique (LSA). The proposed hybrid approach is supervised and benefits from training data while LSA is unsupervised and does not have any training. Tweets, like other informal texts, required heavy pre-processing and cleaning. The errors of the system could be reduced by applying more advanced pre-processing like spelling correction. This is the first effort towards the ADR normalization from social media or other noisy text sources, and can provide a baseline for future work.

In the future, we will utilize our tool to perform normalization on a larger set of mentions. We will also incorporate more complex NLP preprocessing techniques, such as negation detection, and perform comparisons of our approach with a larger number of semantic similarity measurement approaches. In the recent past, approaches using distributed representations of words have become very popular, and the use of such representations along with deep neural networks have outperformed past benchmark systems in a variety of natural language processing tasks. Therefore, we will attempt to utilize annotated data to develop and evaluate such neural network based systems.
against ours. Because of the modular implementation of our system, if such methods provide promising results, we
will incorporate them as a module in our concept normalization pipeline.

Word-of-Mouth Innovation: Hypothesis Generation for Supplement Repurposing based on Consumer Reviews

Jung-wei Fan, PhD1,2, Yves A. Lussier, MD1,2,3
1Department of Medicine; 2Center for Biomedical Informatics & Biostatistics; 3BIO5 Institute, The University of Arizona, Tucson, Arizona, USA

Abstract

Dietary supplements remain a relatively underexplored source for drug repurposing. A systematic approach to soliciting responses from a large consumer population is desirable to speed up innovation. We tested a workflow that mines unexpected benefits of dietary supplements from massive consumer reviews. A (non-exhaustive) list of regular expressions was used to screen over 2 million reviews on health and personal care products. The matched reviews were manually analyzed, and one supplement-disease pair was linked to biological databases for enriching the hypothesized association. The regular expressions found 169 candidate reviews, of which 45.6% described unexpected benefits of certain dietary supplements. The manual analysis showed some of the supplement-disease associations to be novel or in agreement with evidence published later in the literature. The hypothesis enrichment was able to identify meaningful function similarity between the supplement and the disease. The results demonstrated value of the workflow in identifying candidates for supplement repurposing.

Introduction

For more than a decade, there has been fervent interest in drug repurposing (or repositioning) due to the expensive and time-consuming process of drug development. It was estimated that on average it takes 10 years and at least $1 billion to bring a drug to market. On the other hand, finding a new use for an old drug has advantages such as shortened time in verifying toxicity and higher probability of government approval. Renowned examples include sildenafil for erectile dysfunction and thalidomide for erythema nodosum leprosum. Interestingly, a relatively overlooked territory along this repurposing movement is dietary supplements, which are widely available off the shelf and may offer great variety of functions.

According to a 2015 survey by the Council for Responsible Nutrition (CRN)2, about 68% of Americans use dietary supplements. Among these supplement users, 69% said their doctor talked to them about the benefits of taking supplements. Additionally, most supplement users aged 18-34 (66%) anticipate an increased use over the next 5 years. Dietary supplements come in diverse categories: minerals, vitamins, amino acids, enzymes, herbals and botanicals. These facts imply an extensive influence of dietary supplements over population health and well justify them as a rich source for discovering novel repurposing candidates. In fact, there has been ongoing “secondary repurposing” effort that searches for analogues of already repositioned chemicals (e.g., sildenafil3,4) in dietary supplements. There are tremendous opportunities for informatics to systematically facilitate the hypothesis generation process.

In our previous work of mining health-related issues in 1.3 million Amazon.com consumer reviews5, we found that about 40% of the reviews described certain health benefits from using a grocery food product. The Amazon online store is one of the largest retailers in the United States, with over 300 million users and net sales of $136 billion (in 2016)6. As of 2017 March 6, its numbers of supplements sold by categories were: 19,619 Multi & Prenatal Vitamins, 16,048 (specific) Vitamins, 10,255 Minerals, 35,584 (non-herbal) Supplements, 42,519 Herbal Supplements, and 12,370 Weight Loss products. Given the huge collection of supplements and user base, the consumer feedback may actually serve as an ideal data source for automated surveillance. Currency is another merit of the data, as the reviews are constantly growing and closely reflect the products that people use.

Although there are issues with using consumer reviews (e.g., credibility and sparseness), we believe it is worth developing solutions that can bring any meaningful signal to our attention for advancing science. In this study, we proposed and exercised a dry run of a discovery workflow. Text mining was applied to screen for unexpected benefits of dietary supplements in the consumer reviews, followed by manual curation of the candidate reviews, and hypothesis enrichment by linking to external biological databases. The goal is two-fold: 1) assess content of the data for the target use in repurposing; and 2) execute the prototype workflow and identify issues for improvement.
Methods

We obtained a subset of 2,982,326 Amazon reviews on health and personal care products. The reviews were made available courtesy of McAuley et al.7,8, who batch-fetched in previous work and shared the dataset with the research community. Our methods consisted of three stages, as elaborated below:

1. Text mining of reviews that mention an unexpected benefit: A java program was implemented to extract fields of interest (e.g., product ID, review text, review date) from the JSON file with ~2 million reviews and matched each review text with the following (case-insensitive) regular expression pattern:
   \b((unexpected|unintended|unanticipated|surprising)\s+(effects?|benefits?))\b

2. Manual curation/analysis of the mined reviews: The regex-matched reviews were manually curated by the first author (JF) to determine which ones indeed described a certain unexpected benefit of a dietary supplement (or called the “true positive” reviews). The true positives were further analyzed for characterizing the types of the supplements and the benefits. The ones that did not meet the true positive criterion were also examined and categorized.

3. Hypothesis enrichment for specific findings of interest: To test the feasibility of generating richer hypotheses by knowledge integration, we selected a true positive review where the supplement and unexpected benefit (syndrome relief) were both unambiguous and searched them in biological databases. For the syndrome, we manually identified the corresponding trait in the Genome-Wide Association Studies (GWAS) Catalog9 and its associated genes. As symptoms are also covered in the GWAS traits, this method is not limited to only diseases. For the supplement, the Comparative Toxicogenomics Database (CTD)10 was manually looked up to find its associated genes. In addition, functional similarity of the genes between the supplement and the syndrome was then assessed by using an information-theoretic measure11 to pinpoint possible biological explanation.

Results

Manual curation of the candidate reviews

Out of the 2,982,326 reviews, the regex pattern matched 169 candidate reviews. By reading through the candidate reviews, four categories were induced and summarized in Table 1. Less than half of the reviews (45.6%) contained unexpected benefits of interest (True positive) – with analysis elaborated in the next subsection. Among the true positives, there were five substance-effect associations supported by more than one review. For example, unexpected weight loss from using products with vitamin B2. A comparable portion (45.0%) of the reviews was about “non-dietary” health and personal care products (e.g., heart rate monitor and electric toothbrush), which were not filtered out in implementation of the screening program. The neutral effect category includes reviews with health-irrelevant property (e.g., enhanced flavor) or of debatable benefit (e.g., loss of appetite). The bottom minor category (Unspecified effect) is reviews with non-specific description such as “if you do a little research you may find some surprising benefits to xylitol”. Although infrequent, those irrelevant cases indicate the regex-based approach may still pick up some noise.

Table 1. Categories identified from manually annotating the regex-matched candidate reviews

</tbody>
</table>
Qualitative analysis of the unexpected benefits

By inspecting the true positive reviews and product information, we found that about a half of the consumer-claimed “unexpected” benefits might actually be expected. Given the subjective nature, it is not uncommon that the reviewers were surprised due to lack of domain knowledge or just did not pay attention to the product labels. Nonetheless, there remained a good amount of informative reviews, from which we listed some notable repurposing contexts in Table 2. The examples demonstrate diversity of the potential uses, ranging from relief of symptoms, mental function enhancement, modification of substance use behavior, to deterring of infection vectors.

Hypothesis enrichment by linking to biological databases
From the true positive examples in Table 2, IBS-ashwagandha association (4th row under the heading) was utilized for the enrichment exercise, as the supplement and relief of the condition (IBS, irritable bowel syndrome) are both unambiguous according to the review. Ashwagandha (*Withania somnifera*) is a perennial shrub that has been used as medicinal herb in some cultures. To our knowledge, there is not any literature on the use of ashwagandha for IBS. We were able to identify their associated genes from the GWAS Catalog and CTD respectively (see Table 3). By further looking into the GO annotations, moderate functional similarity between the genes suggests possible biological underpinning of the observed effect. For example, Figure 1 illustrates a couple of the GO Biological Process terms between SOD1 (ashwagandha) and PER2 (IBS), with information-theoretic similarity scores computed using our previously published method. For GO Molecular Function terms, we also observed overlaps such as protein binding (GO:0005515) shared between PER2 (IBS) and HSPA9 (ashwagandha).

Discussion

Consumer reviews as innovation driver

Our results suggest that mining massive consumer reviews may enable (timely) discovery of useful incidents of unexpected dietary benefits. Enhanced with an integrative approach, rich hypotheses can be generated to spark novel research. Below we discuss several noteworthy cases from Table 2:

1. In the enriched analysis of Figure 1, the possible involvement of circadian rhythm and ovarian follicle development offers a biological hint that aligns with evidence of IBS gender disparity as reported in the
We believe systematically linking consumer experience to formal databases will shed light on potentially fruitful pharmacogenomics studies.

2. The product review on improvement in cognitive skills after taking recombinant human growth hormone was written in 2006, while the earliest literature we found regarding such association was published in 2013\textsuperscript{15,16}. It is likely that screening from a large consumer population can help detect useful signals a few years ahead of other formal studies.

3. In 2013, a consumer reported eczema was resolved by dietary resveratrol, which does not seem to have been reported in literature. Interestingly, a US patent was filed in 2001 for external use of resveratrol for treating exfoliative eczema, acne, and psoriasis\textsuperscript{17}. Due to less stringent regulation, this example suggests that supplement-based intellectual property could be nimbly registered as soon as a promising effect is found.

4. In 2013, a consumer reported unexpected sleep improvement by using probiotics tablets. Until 2014 and 2016 respectively, such beneficial effect on mice and human began surfacing in the literature\textsuperscript{18,19}. Since many of the supplements are food-based, we foresee that mining the relevant consumer feedback would expedite hypothesis generation for the cutting-edge frontiers of microbiomics and broadly nutrigenomics.

### Potential model of citizen science

The concept of citizen science\textsuperscript{20,21} has been promoted in various domains. The basic idea is letting motivated lay people participate in research studies and perform tasks such as collecting samples or data. We believe that supplement repurposing is an ideal area to engage the general public into a crowd-sourced style of “observational trial”. The advantages of leveraging massive review data include: diverse product types, large consumer base, and constant monitoring as integrated into daily life. To facilitate this mission, informatics should be able to contribute on vocabulary harmonization and streamlining the integration of data sources. An interesting observation was how some consumers described in reviews that they tested the effect via self-controlled experiment, i.e., verifying the effect by stopping use and resuming again. This suggests that, with moderate scientific training, we could further improve the quality of data collected from general consumers.

### Limitations

As a proof-of-concept study, the review curation was conducted by only one annotator (JF) and without referring to a tested guideline. Due to the novelty in many of the findings, we could not find a proper reference standard for the evaluation. Some product reviews can be anecdotal/subjective by nature and of varying quality dependent on the consumer’s background. It is not uncommon to find inconsistent comments on the supplement-effect from other Internet sources (e.g., the relation between creatine monohydrate and acid reflux). Those inconsistencies could be accounted by justifiable genetic variation or could be just noise from uncontrolled covariates. Multi-ingredient supplements also pose challenges in pinpointing the exact active element that caused the effect. A relevant argument is that the sense of “repurposing” actually becomes indistinct for supplements that are marketed as “all-purpose”. In comparison to approved drugs, supplements also tend to conceal risks that are not well studied.

### Future work

With observing a considerable amount of unwanted non-dietary product reviews, we will try to include a filter based on the finer category labels available in the detailed product information. A more rigorous annotation process will be needed, especially with a formal guideline and execution by multiple annotators. For higher sensitivity in detecting the semantics of unexpected benefits, we will explore natural language processing (NLP) and machine learning techniques. To automate the discovery workflow, a pipeline will be developed by incorporating the NLP and function similarity programs based on our previous work. The throughput can be boosted by implementing batch-lookup with the NCBI E-utilities\textsuperscript{22} and directly processing downloaded GWAS Catalog and the CTD database. These enhancements should jointly contribute to a more accurate estimation of the yield (in terms of generating useful hypotheses) of the overall solution. Lastly, we still need to figure out a suitable reference standard for improving the validity and scalability of the evaluation.
Conclusion

To explore useful information for repurposing dietary supplements, we proposed a workflow of mining unexpected benefits mentioned in massive consumer reviews. The proof-of-concept study involved: 1) automatic matching of clue phrases to identify candidate reviews, 2) manual categorization/analysis of the candidate reviews, and 3) manually linking a novel supplement-disease pair to relevant biological databases for hypothesis enrichment. We found 45.6% of the 169 matched candidate reviews contained user-claimed unexpected benefits of dietary supplements, and about half of them were likely novel. By browsing relevant literature, some of the cases did demonstrate potential value for driving repurposing innovation. The hypothesis enrichment also derived informative functional associations between the supplement and the disease. More rigorous evaluation and validation approaches will be needed. The results show meaningful content in consumer reviews as well as the feasibility of a workflow to facilitate supplement repurposing.

Improving Common Ground Development in Surgical Training through Talk and Action

Yuanyuan Feng, MS, and Helena M. Mentis, MS PHD
University of Maryland Baltimore County, Baltimore, MD, USA

Abstract

In surgical training, senior surgeons and residents rely on more than just verbal utterances to share information and coordinate their work practices – their actions also contribute to and shape the development of common ground. However, the function of actions in the grounding process and how that is interdependent with verbal utterances have not been made explicit. We have investigated actions and utterances using a dialogue act coding scheme that highlights the communicative functions of each act towards common ground development during a laparoscopic surgery. We show that utterances provide detailed information for surgeons to develop content common ground, whereas actions contribute to process common ground development. Thus, utterances and actions, by providing different forms of information, depend on each other to develop and maintain common ground. Based on this understanding, we discuss opportunities in transforming actions into perceivable knowledge on the laparoscopic display that supports effective communication and surgical training.

Introduction

The operating room is acknowledged to be a key learning environment where surgical trainees achieve surgical expertise by collaborating on surgical procedures with senior surgeons. This mentor-apprenticeship model requires timely and accurate information sharing between senior surgeons and surgical trainees – not only do they have to coordinate their actions, but the senior surgeon also has to assess the trainee’s level of knowledge of the case and determine how much direction he or she needs to perform the procedure. Any failures in communication lead to inevitable technical and judgment errors that have a great impact on patient safety. Recently, there has been interest in the design of tools to augment shared displays in supporting communication in the operating room. For instance, procedural updates, expert gaze, and gestures have been found to be critical sources of information that facilitates team information sharing and common ground development. To build tools that visualize such supplemental information, we need a better understanding of the mechanisms through which these sources of information are shared and used in common ground development.

Although there has been extensive effort in the investigation of the contributions of verbal communication made in the grounding process, we know little of how information is shared through physical interactions in collaborative tasks in a complex and information rich environment. In surgical training, senior surgeons and residents rely on more than just verbal utterances to share information and coordinate their practices – they use actions, such as gestures, jointly to explore the operative field, as well as illustrate how to proceed with a procedure. Moreover, actions have been shown to enhance the grounding of communication by replacing utterances – in distributed instructional collaboration tasks (where there is a local worker and a remote helper), workers used actions to provide evidence of comprehension of instructions. Thus, actions can provide necessary communicative and coordinative cues to minimize the collaborative effort in establishing common ground.

In this paper, we investigate the communicative functions of actions and explore how these functions change in the course of in situ laparoscopic training. We utilized a coding schema for identifying an action’s communicative function that has been shown to demonstrate the development of common ground in collaborative decision making tasks. Our analysis exposes not only how a senior surgeon and resident pair communicates through actions compared to utterances, but also how the communicative information provided by actions changes in response to the grounding process. Our findings illuminate opportunities to transform actions into perceivable knowledge that supports effective communication and surgical training.

Background

Communication is more efficient when people share greater amounts of common ground - mutual knowledge, beliefs, and assumptions. People from similar professional backgrounds may have already established some initial common ground. For example, surgeons with similar medical education and surgical training may have developed a shared idea on the general steps of a procedure and the basic motor skills in conducting these steps. In addition, a team constructs and expands their common ground within the on-going experience of the joint activity, as
well as adapts their understanding and acts based on the perceptual elements from the current context\textsuperscript{17, 18}. Thus, common ground is incrementally built on the previous joint actions between team members. As joint experience on a task accumulates, a team becomes more efficient in exchanging information and applying the knowledge gained to their tasks\textsuperscript{10, 19}.

Convertino et al. explained the distinction between content common ground and process common ground in the context of cooperative work, where the coordination of content depends on a shared understanding of the subject (know that), and the coordination of process depends on a shared understanding of the rules, procedures, timing, and manner in which the interaction will be conducted (know how)\textsuperscript{10}. Over the course of a joint task, content common ground is developed throughout a task, whereas process common ground is developed in the early stages and maintained for efficient work\textsuperscript{10, 11}.

Fulfilling communication goals, such as sharing information and repairing understanding, requires both spoken and unspoken communication, such as utterances, actions, gestures, gaze, and facial expressions\textsuperscript{20, 21}. Hand gestures uniquely communicate significant information in cooperative work, such as in assisting in the storing of information, expressing ideas, and mediating interaction in the communication between team members\textsuperscript{22}. Being able to see one’s actions has been shown to replace a worker’s utterances by serving as a tacit acknowledgement in grounding a given instruction\textsuperscript{15}. And a remote helper embodied through a pointing-drawing tool leads to representational gestures, such as directions of the actions and shape of the task objects, thus facilitating task communication and performance time\textsuperscript{23}.

Due to the evidence to date of the integral nature of actions in communication and collaboration, it is of interest to further articulate the relationship between actions and utterances as a function of common ground development and maintenance. In the following study, we investigated the communicative functions of actions and their relationship with verbal utterances within the grounding process. Capitalizing on common ground as an orienting theory, our research extends previous studies in identifying fine purposeful actions and understanding their functions in relation to utterances. With this knowledge, our motivation is to determine how to further support common ground development by facilitating gestural interaction of laparoscopic displays during in situ laparoscopic training.

**Study Design and Data Collection**

The study was based on videos recorded during fieldwork in the operating rooms of the Cambridge Hospital. Human Subject’s approval was granted through the Cambridge Health Alliance IRB. A total of ten laparoscopic cholecystectomy cases were analyzed. The cases included three different surgeons and three different PGY4 residents in different combinations of the two groups. The details of the cases have been published in our previous paper on conversation analysis\textsuperscript{24}.

**Coding Scheme and Procedure**

In this study, the communication content was examined in both dialogues and actions between the attending surgeons and residents. The utterances and actions were coded with the same dialogue act coding scheme, which was developed to understand the development of common ground among interdependent team members in emergency management tasks to provide implications for the design of collaborative systems\textsuperscript{12} (Table 1). This method emphasizes the use of communicative functions to interpret the development of common ground as opposed to linguistic or semantic meaning. We used this coding scheme to understand the functions of actions and utterances in the development of common ground in a complex, collocated task around a shared view. Using the same coding scheme facilitates the comparison of the two forms of communication and their patterns of use.

The first author and a research assistant coded the utterances and actions. For the verbal communication coding, the coders first viewed the videos and coded the transcripts independently. After the first independent coding session, the inter-rater reliability for the coders was found to be Kappa = 0.64. They negotiated for any conflicting codes and then coded again and achieved an agreement of Kappa = 0.87. This was deemed high agreement\textsuperscript{25} and so the remainder of the cases were coded. The inter-rater reliability was analyzed using the Kappa statistic for each case. For any case with Kappa less than 0.7, the two coders negotiated the difference to achieve higher agreement. In the end, the average Kappa score is 0.78, ranging from 0.71 to 0.87.

For the coding of actions with the same dialogue act coding scheme, the two coders were able to disambiguate the task actions from the communicative actions with guidance from the laparoscopic cholecystectomy task analysis\textsuperscript{26}, the laparoscopic surgeons from the Simulation to Advance Innovation and Learning Center at the Anne Arundel Medical Center, and the PI’s (last author) extensive knowledge and experience within laparoscopic surgery. The two
coders first viewed one case together to identify the actions surgeons made to collaborate in the surgery and discuss the functions behind every action. Then, the two coders coded the case separately and compared the codes. For the first round, the inter-rater reliability for the coders was found to be Kappa = 0.63. They viewed the video together and negotiated any conflicts in the code. The two coders coded the case again and the Kappa score was increased to 0.69. A large portion of the conflicts were due to the timing of the actions. The timing of an action was further clarified to be the start of each action. Then, the two coders coded the case separately for the third time and achieved a high inter-rater reliability, Kappa = 0.8. The remainder of the cases were then coded independently by the two coders.

Phase Identification

As the grounding of communication is an ongoing process, we needed to look at the distribution of utterances and actions over the course of surgery. We identified the phases of laparoscopic cholecystectomy based on a hierarchical task analysis of the laparoscopic cholecystectomy procedure26, which includes surgical steps, sub-steps, tasks, sub-tasks and motions. In our study, we used the surgical steps to define the main phases of laparoscopic cholecystectomy: prepare patient, isolate gallbladder, remove gallbladder, and cleanup. The communicative events were grouped into the phases of surgery by matching the event’s occurrence to the phase time stamps.

Data Analysis

The data analysis consists of three parts – the frequency comparison of dialogue acts between utterances and actions, the sequential analysis for the two-chain communicative events, and the Poisson regression for the trend of communication in the grounding process.

In the frequency comparison, the frequencies of the dialogue acts were counted and normalized by the total counts in each case. The frequency of a communicative function was calculated as the sum of the frequencies of the dialogue acts in the corresponding category. Two-tailed Wilcoxon signed rank tests were conducted for the comparison of the frequencies of utterances and actions in each communicative functions and dialogue act.

In the sequential analysis, the two consecutive communication events with repeated codes across dialogue acts for utterances and actions were statistically identified27 and trimmed to meet the assumptions of the chi-square test28. Chi-square tests were conducted to infer any significant patterns among the communicative events. Since we only focused on the patterns with high frequency, a two-chain communicative event was deemed significant if its adjusted residual was greater than 2. The conditional probabilities were used to compare the frequencies between different significant patterns.

Poisson regression models with repeated measures were developed to identify the trends of communicative functions of utterances and actions over the four phases of the surgery. The counts of dialogue acts in frequency comparison were used with a different normalization – they were normalized based on the total counts in each phase, instead of each case. In this way, we can compare the frequencies between phases within each code. The frequency of communicative function was the combination of the dialogue acts that fall into its category.
Results

Of the ten laparoscopic cholecystectomy cases in this study, 657 minutes of operative time were assessed. In total, there were task-related 3207 utterances and 2414 actions taking place between attending surgeons and residents.

The Communicative Function of Utterances and Actions

To begin to uncover the communicative functions of actions compared to utterances in the grounding process, we first compared frequencies at the dialogue act level.

Information sharing through the direct providing of information (AI) or through a query-reply process (Q-R), was overwhelmingly verbal in nature. Utterances were dominantly used for adding information (AI) ($Z = 2.803, p = 0.005$), queries (Q) ($Z = 2.803, p = 0.005$), and replies (R) ($Z = 2.803, p = 0.005$) (Figure 1A). However, the effort the team spends in explaining the presented information to ensure all the team members reach the same understanding tended to engage actions throughout the collaborative task. We can see that surgeons preferred verbally verifying their own understanding (CH) ($Z = 2.805, p = 0.005$), but they engaged actions in clarifying the information (CL) ($Z = -2.497, p = 0.013$) or showing their acknowledgement (AC) ($Z = -2.803, p = 0.005$) (Figure 1B). For instance, when dissecting Calot’s triangle, the resident verified his understanding by saying, “so this is the junction, right?” (CH). The attending surgeon then verbally clarified the anatomy and pointed to the common bile duct with his instrument (CL). With this information, the resident inserted the instrument and dissected above the common bile duct (AC). And managing the process itself further engaged actions to a large extent above that of verbal utterances. Instructions (MN) were usually provided in both utterances and actions ($Z = 1.478, p = 0.139$), while judgment (J) ($Z = -2.191, p = 0.028$) and agreement (AG) ($Z = -2.191, p = 0.028$) were shown in actions (Figure 1C). For instance, when removing the gallbladder from the liver bed, the resident pulled out the instrument to show his judgment that the dissection was completed on the current side of the liver bed (J). The attending surgeon agreed with him by turning the gallbladder over (AG).

Thus, the comparison of frequencies in communicative functions between actions and utterances reflects that utterances are often used in explicitly presenting selective information, while actions are more frequently taken to negotiate how to proceed with the procedure. For example, in ligating the cystic duct, the attending surgeon verbally identified the duct (AI) and then the resident moved his instrument toward the structure to show his acknowledgement (AC). The attending surgeon then verbally directed the resident to the distal of the duct (MN). The resident pointed his instrument at the clipping location he selected based on the attending surgeon’s instruction (J) and waited for the attending surgeon’s agreement (CO). By holding the structure still, the attending surgeon tacitly approved the resident’s selection (AG) and the resident proceeded with the clipping action (AC).

According to Convertino et al.¹⁰, as content common ground is the selective sharing of information and process common ground is the management of the procedures and process, the observed distinction between actions and utterances indicates that the actions are predominantly a function of process common ground. On the contrary, the utterances tended to serve to share information that was required by the team and thus are a function of content common ground.

Sequential Frequency Analysis of Utterances and Actions

Frequency analysis provided a high-level understanding of the predominant function of utterances versus actions; however, utterances and actions are not siloed phenomenon. There is a clear relationship between these two mechanisms of coordination. We conducted a sequential frequency analysis in order to articulate the relationship between utterances and actions with regards to communicative function. Lag sequential analysis allows us to examine the immediate response, either by utterances or actions, after a given communicative event. We included
repeated codes in our analysis. Thus, in total, we received 5559 two-chain communicative events across the dialogue acts for utterances (22 codes) and actions (22 codes).

We first constructed a contingency table with all codes for both the given and target events. Due to the high dimensions, there were 1682 cells (91.0%) with an expected value less than 5. In order to meet the assumptions for chi square test, we did two steps for trimming the data. First, we identified and deleted the codes that led to a cell with an expected value less than 1. Next, we compared the total counts for the codes that had cells with expected values less than 5. The codes with smaller counts were further deleted. The trimmed data consisted of nine dialogue act codes for the given and target events, with 15 cells (18.5%) having expected value less than 5 and the minimum expected count of 1.63. The chi square test over this data set shows that the target events significantly depend on the given events \( \chi^2(64) = 5856.79, p < 0.0001 \). The adjusted residual of each cell allowed us to identify 15 significant two-chain communicative events with adjusted residuals greater than 2 among all others. In order to make sense of these pairs, we created a diagram with the relationships between the events.

As shown in Figure 2, the significantly occurring communicative pairs grouped into two clusters that are related to transferring information (on the left) and managing process (on the right). In the transferring information cluster, information was typically added by an attending surgeon through utterances (Att_AI_u) accompanied by an action (Att_AI_a) and then the resident verbally sharing information (Res_AI_u). This pattern was often used in identifying anatomy. For instance, the attending surgeon would first verbally describe the structure (Att_AI_u), and then move the tissue (Att_AI_a), grasping and exposing embedded structures. Through these actions coupled with the utterances, the resident perceives the described anatomy. Although actions can present explicit information to the residents, they were not typically decoupled from utterances. Furthermore, we observed that the actions for adding information were taken depending on the role of the communicator. The residents seldom used actions to describe or reference to any structure, however, the attending surgeons did in abundance.

In the managing process cluster, attending surgeons either verbally instructed the residents or physically guided the process. This is evidenced by the two loops observed in the cluster – the action loop on the bottom right and the utterance loop on the top right of the diagram in Figure 2. In the action loop, the attending surgeon used actions to request the resident to perform a movement (Att_MN_a), which was always indicated as understood by the residents with the action of acknowledgement (Res_AC_a). After fulfilling the requested task, the residents presented their own judgments through actions (Res_J_a), which were recognized and agreed on by the attending surgeons (Att_AG_a). This loop was often observed when the residents were dissecting the anatomy. For instance, the attending surgeon grasped the tissue around the cystic artery (Att_MN_a) and the resident inserted the instrument dissecting it (Res_AC_a). When the task was done, the resident stopped dissecting and pulled back the instrument (Res_J_a). The attending surgeon would then agree with the outcome by releasing the tissue and grasping another part of the anatomy for the next step of dissection (Att_AG_a).

In the utterance loop, the attending surgeons often would verbally inform the residents of the next step of the process (Att_MN_u). Sometimes, the verbal instructions were accompanied with an attending surgeon’s clarification action (Att_CL_a) when a precise movement was required. This loop was often observed when the team would move from one task to the next. For example, the attending surgeon informed the resident to dissect the back of the gallbladder by saying, “Alright. Now let’s see what’s on the back” (Att_MN_u), before he turned the gallbladder over (Att_CL_a). With the instruction, the resident stopped dissecting and pulled back his instrument to leave enough

Figure 2. Significant communicative patterns among ten cases – information sharing cluster on the left and process management cluster on the right. (Att: attending surgeons, Res: residents, u: utterances, a: actions. The frequency of each pair is shown as numbers in the diagram.)
space for the turning action (Res_AC_a). The clarification actions happened when a movement should be exactly executed. For example, the attending surgeon first verbally requested the resident to pull the gallbladder to the upper left (Att_MN_u), and then he identified the most appropriate position for the gallbladder. So the attending surgeon would point to the anatomy with his instrument (Att_CL_a) showing the resident where to grasp and pull.

We are intrigued to observe a link between these two clusters – the residents’ acknowledgement and the attending surgeons’ adding of information. This link indicates that an agreement in process management, i.e. process common ground, leads to an update of the task content information sharing, i.e. content common ground. Thus, although we learned from the prior analysis that predominately utterances are a function of content common ground and actions are a function of process common ground, from this sequential analysis we understand that the actions taken to manage process common ground are intimately tied back to the successive task’s need for continual management of the content common ground.

Changes in Utterances and Actions Throughout the Grounding Process

Our third set of analyses were to uncover how the grounding process changes the communicative needs for utterances and actions. As we know that common ground increases as a team collaborates over a task over time, we present the comparison of frequencies in utterances and actions over the course of surgery.

As shown in Figure 3, utterances and actions followed different patterns across the entire surgery. Phase 1 begins with the first incision followed by the surgeons putting the laparoscope into the abdominal cavity. This was the first time surgeons saw the anatomical structures that they would operate on. They needed to describe their understanding of the structures to their partner. They continued to verbally add information regarding the context until they achieved a mutual understanding of the operative field. This continuous stream of adding information increased in Phase 2 with the delicate task of dissecting and exposing the anatomy to be clipped and cut, but then we see a decrease in the verbal adding of information in Phase 3. At this point, the content common ground had been established and surgeons shifted their attention to negotiate how to perform the tasks and to develop a mutual understanding of the process. After taking out the gallbladder, the surgeons moved onto Phase 4, which required surgeons to inspect both the operative field and the surrounding area and cleanup any remaining fluids and address any residual bleeding. The surgeons needed to verbally update their understanding of anatomy in order to continue to coordinate on the procedure itself. Thus, the trend for information transfer increased again and process management decreased.

Actions displayed a different pattern than utterances when looked at across the different phases of the surgery. Compared with utterances, process management and checking understanding through actions had a high frequency in Phase 1, when the initial common ground of the surgical practice had already been developed before the work, and decreased in Phase 2, when the case based information was transferred in abundance. Then, as the amount of new information that needed to be understood and shared decreased during Phase 3, more actions were used by the surgeons to manage the process and ensure that they are on the same page to proceed. As the surgeons moved onto Phase 4, which involved new tasks, the actions for managing process decreased, while the actions for checking understanding continued to grow. This shows actions were a fundamental aspect of coordinating the process and checking understanding after they verbally transferred the information.

To assess the significance of these trends, we fit the Poisson regression model with repeated measures using normalized counts as the dependent variable and phases, communicative functions and their interactions as independent variables. For utterances, the frequency of verbally transferring information is significantly higher in Phase 1 (\( \beta = 0.618, p = 0.006 \)) and lower in Phase 3 (\( \beta = -0.417, p = 0.012 \)), compared to managing process. For actions, the frequencies of actions in information transfer is significantly greater in Phase 2, compared to checking information (\( \beta = 1.433, p < 0.0001 \)) and managing process (\( \beta = 1.392, p = 0.001 \)).

![Figure 3](image_url). Frequencies of transferring information, checking understanding and managing process over the phases.
We then divided the two-chain communicative event data based on the identification of the four surgical phases. For each phase, we trimmed the data to meet all of the assumptions for a chi-squared test. With the trimmed datasets, the dependency is significant between the given and target event for all four phases ($p < 0.001$). We used adjusted residual ($>2$) to identify the significant pairs. Figure 4 shows the change of communication patterns over the course of surgery. Each surgery started with attending surgeons adding information, which led to a series of acts in process management (Figure 4A). When a team started to collaborate, their common ground was relatively low compared to the rest of the phases. A team first needed to quickly build up enough mutual understanding of the task and anatomical structure that was specific to the patient before them. Thus, in Phase 1, collaboration was driven by verbally adding information from the attending surgeons (Att_AI_u), which has been shown to be the most efficient mechanism for transferring information.

Figure 4. Two-chain communicative events for each phase of the surgery. (Att: attending surgeon, Res: resident, u: utterances, a: actions. Frequency of each pair is shown as the numbers in the diagram.)

As a surgery proceeds to Phase 2, information transfer and process management become two separate efforts without any links between them. Information was added by both the residents and the attending surgeons via utterances or actions, while process management was driven by the verbal instructions from the attending surgeons (Figure 4B). As the content common ground accumulates, the teams had adequate background information for them to develop strategies in performing the task. For example, the team had already identified the location and position of the gallbladder, the liver and the duodenum. Now their task was to expose and dissect the gallbladder and its accessory structures. Thus, they did not need to wait for more information in order to negotiate where and how to dissect. Meanwhile, the team kept adding information and updated their understanding of the content to make sure they were working on the same page.

In Phase 3, as shown in Figure 4C, most arrows direct from process management to information transfer, which indicates new information was put forward when there was a need identified in managing the process. The link between the attending surgeons’ verbal addition of information (Att_AI_u) and the residents’ physical demonstration of their own judgment (Res_J_a) further explains the usage of the information – to aid residents’ decision making in planning and performing the surgery.

Finally, in Phase 4 (Figure 4D), information transfer and process management became separate clusters again. Since Phase 4 contains a different set of surgical skills and visual interpretation – cleanup and suture – we observed that
the communicative patterns follow that of Phase 2: the surgeons verbally added information to develop the content common ground, while physically exchanging information for the process common ground.

Discussion

In this paper, we presented a series of analyses investigating the communicative functions of actions between an attending surgeon and a resident. Observing the collaboration between attending surgeons and residents in real operations allows us to identify and explain different ways actions are used in communicating information, as well as helps us to understand how the communicative functions change as common ground grows. This in turn provides guidance for gestural interaction of laparoscopic displays during in situ laparoscopic training.

We found that utterances and actions provide different communicative functions in discourse. Utterances were frequently used to explicitly add information. On the other hand, actions were frequently used to indicate one’s understanding. The actions provide two types of information – the task field and the physical activity. When the residents directed the instrument to arrive at the target location as indicated by the attending surgeons, they showed that they understood the instructions without spending additional effort in articulating their understanding verbally. This reflects the assumptions made by residents that the attending surgeons would directly observe the actions, situate the actions in the task field, and interpret the actions according to the instructions. In other words, the physical activity is first recognized and the task field is the context that provides meaning to the physical activity.

We also see in our third set of analyses that the communicative function of utterances and actions complement each other as the procedure progresses – actions are predominantly a function of process common ground and utterances are a function of content common ground. And, as demonstrated in Figure 4, the content common ground and process common ground are interdependent. Thus, the development of content and process common ground was bound together for surgeons to efficiently coordinate the procedure. Correspondingly, the utterances and actions were used interdependently in the grounding process.

The understanding of the communicative functions, rather than the semantic form, of actions and utterances and the way they jointly contribute to the communication in the process of grounding are crucial for designing systems to support collaboration on physical tasks via a shared view. Our findings show that utterances and actions work interdependently with each other, in the way that utterances are used as a function of content common ground and actions are used as a function of process common ground. This interdependency highlights the needs to not only see actions in the course of collaborative work, but also understand the meanings behind the actions in the shared view.

Seeing the Actions

What we have seen is that actions tacitly convey information to the collaborators. We found that the attending surgeons used actions to not only inform the residents of which task to perform, but also to control how the task was accomplished. Thus, markings and gestures on the shared display can show which target should be acted on, what motor skills should be taken, in which directions the actions should be conducted, and to what the end point in the procedure. In this case, providing explicit marks, such as arrows, measures, and tools, is useful in making the information perceivable and persistent along with pointing or drawing gestures. For example, to perform a suture, a surgeon can use the pointing or drawing gestures to explicitly locate an exact target to which the worker should attend. The surgeon can also add an arrow and adjust its direction to illustrate which direction the first stitch should be.

Providing such tools is also in agreement with prior work that has shown that mediated communication is more effective with annotation and gesturing tools. For instance, when provided with drawing/pointing tools, we see that gestures and annotations lead to shorter, more efficient communication and quicker task performance, pointing is preferred over speaking, verbal interactions often include gestures such as circles and arrows, and often implicit gesturing is preferred over explicit drawing. Thus, as we move towards building new systems for telestration over surgical video, we are inspired to focus our attention on such gestures and drawing that facilitate process common ground in order to further explore whether preferences for drawing tools is associated with more efficient communication around process management.

Knowledge in the Actions

For most surgical training, the purpose is not merely completing the task at hand. Rather, the aim is to help the residents to develop adequate knowledge, so that they can be able to work independently in the future. Thus, understanding why the actions should be taken is a necessary part of the collaboration. The knowledge behind the actions is embedded in the development of the content common ground. As shown in our study, the content common

703
ground is achieved mostly through verbal communication, which serves for adding new information. Compared to utterances, actions have their limitations in presenting a piece of information. On the other hand, we found both actions and utterances could convey the instructions to coordinate the process. Thus, design for team collaboration should avoid the use of gestures to explain the content, while encourage the use of gestures to guide the process to release the grounding effort in verbally communicating the meaning behind the actions.

In this case, designers should consider the temporality feature of the grounding process. Our study suggests that content common ground is first developed, followed by process common ground. Thus, at the beginning of a task, the effort should focus on verbal communication for a team to efficiently achieve content common ground. As the task moves on, more effort is expected to be on process common ground, wherein the gestures can be most useful.

Limitations

In our study, we investigated the spoken and unspoken communication between an attending surgeon and a resident during in-situ training of a laparoscopic cholecystectomy. The strength of these cases is that most surgical actions taken by surgeons are shown in the laparoscopic video. Thus, it provided a rich collection of communicative actions in a shared view for collocated settings. However, we acknowledge that knowledge from the entire surgical team, including nurses, anesthetists, and technicians, is of importance for the success of the surgery. Thus, our findings need to be examined for the design of groupware for the entire surgical team. Our study is also limited to laparoscopic cholecystectomy cases. Although laparoscopic cholecystectomy is an essential and fundamental procedure in the laparoscopic training for general surgery residents, our results need to be further validated to be applicable on a larger scale, especially for urgent cases or intraoperative complications. In addition, the surgeons in our study have completed professional training in general surgery. Before collaborating on a case, they shared a mutual understanding of the guidelines for surgery. Thus, we observed a quick assessment of ability at the beginning of the surgery. However, in cases, where team members come from different backgrounds, it may take a longer time for the team to develop a shared understanding.

Conclusion

In this study, we investigate the communicative ability of action in common ground development between a resident and an attending surgeon in laparoscopic surgical training. We found that utterances provide detailed information for surgeons to develop content common ground, whereas actions contribute to process common ground development. In this, we showed utterances and actions depend on each other in the development and maintenance of common ground. Based on our findings, we provided design guidelines supporting the seeing of actions on a shared display and the educational needs of understanding the meaning behind the actions.

Routine self-tracking of health: reasons, facilitating factors, and the potential impact on health management practices

Abstract

Despite a growing interest in self-tracking of one’s health, what factors lead to self-tracking routinely (i.e., collecting data at regular intervals), and the effects of this behavior, remain largely understudied. Using data from the Pew Survey on Tracking for Health, we examined the patterns of self-tracking activity to understand reasons for this behavior and its impact on health management practices. We tested multiple logistic regression models to assess the influence of different predicting variables, and to find whether routine self-tracking leads to positive change to one’s approaches to health management. Our results suggest that recent visits to emergency care and the type(s) of tracking tools used are significant predictors of routine self-tracking activities. Further, the results suggest that routine self-tracking, as opposed to occasional, event-triggered tracking, is more likely to result in positive changes to health management approaches. Our findings also highlight barriers to and opportunities for designing useful and usable tools to facilitate self-tracking and empower patients to become more proactive in managing their own health.

Introduction

According to a 2012 Pew Research Center survey1, 69% of U.S. adults use tracking to manage their health or that of a loved one. Self-tracking is defined as the practice of repeatedly recording information such as behaviors, thoughts, and feelings about oneself. It encompasses collecting data and reflecting on it in order to acquire knowledge or achieve a goal, such as behavior change5. Self-tracking health information has been practiced for several decades using methods such as pen and paper, or just memory12. This practice has recently gained increased attention with the popularity of mobile technology and its ability to facilitate recording health information5. Self-tracking with the use of modern technology, such as smartphones and wearable devices, has been the subject of several recent studies8–11. The practice of tracking and the knowledge that the data tracked may provide can bring awareness and support health behaviors, thus helping in improving quality of life4. It can also improve patient engagement in their own care, since it allows patients to play a more active role in their disease management by better understanding their health conditions and coping with treatment and communicating with providers5,6. Therefore, self-tracking is also expected to improve patient-provider communication7.

Many self-tracking studies focus on tracking diet or exercise. These studies approach self-tracking either for preventative health management, for personal curiosity, or for learning and promoting a healthier lifestyle. For example, Miller and Mynatt13 developed StepStream, a school-based pervasive social fitness system, to encourage adolescents to improve their attitudes and perceptions towards physical activities. In another study, Cordeiro et al.14 analyzed the challenges people face when tracking food intake in order to explore opportunities to improve the support of diet tracking activities.

Other studies have approached self-tracking by focusing on its ability to assist in chronic disease management, since chronic illnesses usually require long-term treatment and management activities. The collection and reflection on the collected data can help people suffering from these conditions in their disease management by improving their knowledge about the illness, identifying triggers, and controlling health indicators such as glucose levels or blood pressure. Studies focusing on these aspects generally aim to control or mitigate symptoms and to prevent or delay disease progression. For example, Mamykina et al.15 developed and performed a deployment study of MAHI (Mobile Access to Health Information), a distributed mobile application to assist newly diagnosed diabetes patients in learning about their condition. Other similar studies focused on cancer16,17, heart conditions8,18, irritable bowel syndrome19,20, asthma21,22, and many others.

Collecting, registering, and reflecting on the data are the most fundamental steps of self-tracking, and the frequency with which data is captured and recorded can vary. Approximately half of U.S. adults who self-track record their data

†The first two authors wish to be regarded as joint First Authors.
routinely (e.g., every day or every two weeks), and half only track when they experience changes in their health. Past work has found that routine tracking is important for reflection, which is a necessary step towards common goals of tracking (e.g., behavior change), and included recommendations about how often to self-track. Li et al. describe that reflection can happen in short and long term. The former happens in a short time after collection, and helps to make users aware of their current status. The latter happens days or weeks after collection and involves deeper self-reflection, allowing users to identify patterns by comparing information from different periods. Through short term reflection, routine tracking can improve self-knowledge by providing more opportunities to reflect after collecting data. Routinely tracking is also important to long-term reflection, since missing data can limit users’ ability to interpret and reflect on their data. Although routinely registering personal data could influence self-tracking practices, little is known about what leads users to self-track routinely, and what are the outcomes of doing so.

In this study, we examined predictors of routine self-tracking behavior and its effects on health management based on a reanalysis of the data collected by the 2012 Pew Survey on Tracking for Health. We conducted a quantitative analysis of the data using binomial logistic regressions to understand what leads to routine self-tracking behavior and how this behavior subsequently influences health management practices. The two main research questions that we aimed to address through this study are:

**Research Question 1:** What factors predict routine self-tracking behavior?

**Research Question 2:** Is routine self-tracking associated with improved health management practices?

The rest of the paper is organized as follows. First, we describe the methods used in the research. Then, we present the findings followed by the discussion. Finally we present the limitations of the study and conclusions.

**Methods**

The analyses reported in this paper were based on the Pew Survey on Tracking for Health conducted between August 7 and September 6, 2012. The survey was administered through phone interviews in both English and Spanish, and involved a total of 3,014 adults living in the United States. Among them, 55.6% were female. The median age was 53.

**Data**

Each survey began with questions about demographic information (e.g., age, income) and health status (e.g., health rating, chronic conditions, recent changes). Then, the survey asked questions specifically about self-tracking, such as whether the respondent tracked fitness-related information (weight, diet, or exercise) or other health indicators (e.g., blood pressure, glucose). The survey then asked the method(s) that the respondent used to do self-tracking, as well as its effects, such as whether self-tracking affected their approach to self-management, or whether it led them to ask questions to physicians. The full instrument of the survey is provided on the Pew Research Center website.

In this study, we included all survey questions pertinent to our research objectives. They are listed in Table 1. Because we are interested in the characteristics of the respondents who used self-tracking to manage their own health, in our analysis, we included only those who answered “yes” to one of the following two questions: 1) whether they tracked their own weight, diet, or exercise routine (Q24); and 2) whether they tracked other health indicators such as blood pressure, blood sugar, sleep patterns, and headaches (Q25). Participants who tracked health data for others (e.g., family members) but not for themselves were excluded from our sample. Those participants who tracked health data both for themselves and for others were included.

Our two research questions focus on Q27, which asks the respondents, with respect to “the health indicator you pay the MOST attention to,” whether they self-track this indicator routinely, or if they collect data only when something comes up or changes (see Table 1). In this study, routine self-tracking is characterized by measuring and recording data continuously at regular intervals, such as daily or weekly. Those who do not track routinely might only record events when they experience a change in their health, or adopt a new habit. We refer to the first type of behavior as “routine self-tracking,” and the second type as “occasional, event-triggered self-tracking.”

**Data analysis**

To answer the first research question, what factors predict routine self-tracking behavior, we analyzed the responses to questions Q3 (health problems or conditions the respondent lives with), Q4 (major health events in the past 12 months,

</tr>
<tr>
<td>Q4 In the last 12 months, have you personally...</td>
<td>1) Faced a serious medical emergency or crisis? 2) Gone to the emergency room or been hospitalized unexpectedly? 3) Experienced any significant change in your physical health, such as gaining or losing a lot of weight, becoming pregnant, or quitting smoking?</td>
</tr>
<tr>
<td>Q24 Now thinking about your health overall... Do you currently keep track of your own weight, diet, or exercise routine, or is this not something you currently do?</td>
<td>1) Yes, keep track 2) No, not something R currently does</td>
</tr>
<tr>
<td>Q25 How about any other health indicators or symptoms? Do you happen to track your own blood pressure, blood sugar, sleep patterns, headaches, or any other indicator?</td>
<td>1) Yes 2) No</td>
</tr>
<tr>
<td>Q26 Thinking about the health indicator you pay the MOST attention to, either for yourself or someone else, how do you keep track of changes? Do you use...</td>
<td>1) Paper, like a notebook or journal 2) A computer program, like a spreadsheet 3) A website or other online tool 4) An app or other tool on your phone or mobile device 5) A medical device, like a glucose meter 6) Or do you keep track just in your head? 7) Other</td>
</tr>
<tr>
<td>Q27 How often do you update your records or notes about this health indicator? Do you do this on a regular basis, or only when something comes up or changes?</td>
<td>1) Regular basis 2) Only when something comes up or changes</td>
</tr>
<tr>
<td>Q28 Do you share these health tracking records or notes with anyone, either online or offline?</td>
<td>1) Yes 2) No</td>
</tr>
<tr>
<td>Q30 In which of the following ways, if any, has tracking this health indicator affected your own health care routine or the way you care for someone else?</td>
<td>1) Has it affected a decision about how to treat an illness or condition? 2) Has it changed your overall approach to maintaining your health or the health of someone you help take care of? 3) Has it led you to ask a doctor new questions, or to get a second opinion from another doctor?</td>
</tr>
</tbody>
</table>
such as an ER visit), Q26 (tools used to track the health indicator that the respondent pays the MOST attention to, such as a notebook or a computer program), and Q27 (routine tracking or occasional, event-triggered tracking). We hypothesize that whether an individual routinely tracks the health indicator that she or he pays the most attention to (Q27) is a function of the person’s health conditions (Q3); major recent health events (Q4); and the tool(s) used (Q26).

To answer the second research question, is routine self-tracking associated with improved health management practices, we analyzed whether the tracking behavior—routine or occasional, event-triggered (Q27)—may predict responses to Q30. Possible responses to Q30 include: (1) whether self-tracking affected the respondent’s decision(s) about how to treat an illness or condition; (2) whether it changed the respondent’s overall approach to health management; and (3) whether it led to asking clinicians new questions, or to looking for second opinions. We hypothesize that routine tracking, as opposed to occasional, event-triggered tracking, will more likely lead to a positive response to one or more of the Q30 options. We were not able to analyze other aspects of health management, such as those that involve family members and caregivers, as the survey did not cover them.

In both models, we controlled for age, sex, socioeconomic indicators (education, ethnicity, and income), and overall perception of one’s health (Q2: excellent, good, fair, or poor). In the second model, we also included the independent variables used in the first model (e.g., Q3 health conditions, and Q4 major recent health events) as control variables.

Findings

Descriptive statistics

Among the 3,014 respondents surveyed, 1,941 (64%) reported that they performed some form of health-related self-tracking activities. These 1,941 respondents are hereafter referred to as “study population.” Table 2 describes the study population (N=1,941) dichotomized into two groups based on their self-tracking style (routine vs. event-triggered). Out of the 1,941 respondents in the study population, 992 were routine self-trackers; and 949 only tracked occasionally when triggered by events.

The mean age of the respondents in the routine group was 56 years; and for those in the event-triggered tracking group it was 50.7 years. Reported health rating was not significantly different between the two groups, but a higher proportion of the respondents who tracked their health routinely reported that their health was fair (16.4%) or poor (5.1%), and a smaller proportion as excellent (27.1%), compared to the event-triggered group (14.2%, 3.3%, and 31%, respectively). This result suggests that those respondents who perceived their health to be worse were more likely to engage in routine self-tracking activities, but the differences are not statistically significant.

*p<0.05
Most respondents with diabetes or high blood pressure self-tracked routinely \((p < 0.001)\). The difference was not significant for those with lung diseases (e.g., asthma, bronchitis, emphysema), heart disease (including heart failure and heart attack), and cancer. This difference may arise from health providers’ recommendations for patients with these conditions to use self-tracking. Both the reduced effort required for tracking using home devices, such as glucose meters, and the recommendation given by health providers may encourage routine self-tracking practices.

Among those who experienced severe health events such as ER visits in the last 12 months, a larger proportion self-tracked routinely \((p < 0.05)\). For other health changes, such as becoming pregnant, losing or gaining a lot of weight, or quitting smoking, the difference was not significant. Experiencing a health crisis, or seeking health care from an emergency department, constitute more severe health events in comparison with other health changes, thus severe health events might be more impactful for self-tracking practices.

While there was no significant difference between the event-based tracking and the routine tracking groups regarding fitness-related indicators and activities (Q24), a significantly larger proportion of those who track other health indicators (e.g., blood pressure, blood sugar, sleep patterns, and headaches - Q25) do so routinely \((p < 0.001)\). Most respondents who shared data collected through self-tracking also tracked routinely \((p < 0.01)\). In addition, the two groups differ significantly in their use of self-tracking tools. Most respondents who used pen and paper, computer programs, mobile apps, medical devices (e.g., blood pressure cuff) \((p < 0.001)\) or websites \((p < 0.05)\) self-tracked routinely. On the other hand, a larger proportion of those who only kept data in their memory \(i.e.,\) measuring but not registering the data) only self-tracked after a health related event \((p < 0.001)\). It is possible that those who are more diligent about tracking are more likely to track routinely, register, and share their data. But registering and sharing data could also influence users to self-track routinely.

The number of respondents who claimed that tracking activities had affected any decision about a treatment or changed their approach concerning health management was significantly higher among the group who performs tracking routinely \((p < 0.001)\). The third option, which asked whether tracking activities led respondents to ask new questions to health providers or to look for a second opinion, resulted in no significant difference between the two groups.

In summary, routine tracking was more common amongst those who tracked indicators not related to fitness, those who shared their data, and recorded their data on paper or on a digital system. Most respondents who reported that tracking had changed a decision about health, or changed their self-management approach, self-tracked routinely. Because these variables may correlate amongst one another, we used binomial logistic regressions to learn which were significant predictors of routine tracking practices, and to find whether routine tracking influenced reported effects of self-tracking on health management.

**Model testing results**

In this section, we present the results from the logistic regression models, which are reported in Table 3 and Table 4.

**Research Question 1: What factors predict routine self-tracking behavior?**

As shown in Table 3, the model results indicate that age \((p < 0.01)\), recent visit to the ER \((p < 0.05)\), and use of a majority of self-tracking tools are associated with a higher likelihood of adopting the routine tracking behavior. When the respondent relied on memory to do self-tracking, the chance that she or he would collect data routinely is significantly decreased \((p < 0.05)\). Gender, chronic conditions, and recent health crises or changes do not appear to have a significant effect.

These results indicate that, regardless of other conditions, the probability of routine self-tracking is higher for those who had recent ER visits and those who use technological tools. It is possible that people become more vigilant with their health after having a severe health event warranting a visit to the ER, which leads them to become more diligent in their tracking behavior; and that the use of technological tools such as websites and tracking apps facilitates this practice.

**Research Question 2: Is routine self-tracking associated with improved health management practices?**

Through three binominal logistic models, we tested whether the routine self-tracking behavior leads to better health management practices. The results are reported in Table 4. Because none of the control variables have a significant
effect, they are omitted from the table.

As shown in Table 4, as opposed to occasional, event-triggered tracking, those who self-track their health routinely have a significantly higher likelihood of changing their overall approach to maintaining health ($p < .01$). Further, routine tracking is negatively associated with asking new questions from doctors, or seeking second opinions. This result may be because this population, possibly through routine self-tracking, has become more knowledgeable about coping with their illnesses or conditions. Thus, they might have become less inclined to ask new questions or seek second opinions. Finally, we found no correlation between routine self-tracking and the likelihood of altering decisions on how to treat an illness or a condition.

**Discussion**

In our analysis, we investigated if factors such as the person’s health conditions, major recent health events, and the tool(s) used could predict routine self-tracking. We found that having had a recent emergency visit was the only significant health related predictor of routine self-tracking. This increased use of routine tracking practices may be motivated by a need to recover from the crisis, or manage continuing health outcomes resulting from the crisis by learning how to handle it or tracking symptoms. More routine tracking suggests that these people take the practice more seriously, or have a stronger reason to engage in it. This finding suggests that it might be worthwhile to investigate the use of self-tracking by patients who are discharged after a visit to an emergency or urgent unit, both to understand their current practices and to better support their health management after being discharged. It is likely that this demographic represents an opportunity for new technology that aims to support their needs.

The results also suggest that using electronic tools might help to increase routine tracking behavior. Those who used computer programs, websites, mobile applications, and medical devices were significantly more likely to routinely register their data, while those who only kept their measurements by memory were much less likely to use tracking routinely. Concerning the non-electronic tools approached by the survey, using only memory to track health indicators actually presented a negative correlation with routine tracking, while the results for pen and paper were not significant. Electronic tools for registering the tracked data, such as computer programs, websites, and mobile applications, might encourage routine tracking activities through the use of reminders, or features that encourage higher engagement or participation (e.g., social features, and game-like features such as medals and achievements). This finding indicates that, in cases wherein routine tracking is desired or important, users should seek to utilize electronic tools such as computer software or mobile applications to measure or record their data, and avoid keeping their data only by memory. It is also important to investigate the reason for this effect, to better understand what specific aspects of self-tracking tools offer support for tracking routinely.

We also investigated whether routinely self-tracking health indicators could be associated with improved health man-

</table>
agement practices. Our results suggest that people who track routinely might become more knowledgeable about their health, and, as a result, adapt their health management approach based on their experiences with tracking, asking less questions to their clinicians. This finding indicates that, in comparison with event-driven tracking, routine tracking might better support patients’ self-efficacy and better assist them to improve their self-management skills. Because both self-efficacy and self-management skills are associated with improved health outcomes26, 27, these results indicate that routinely self-tracking could have a significant beneficial impact on users’ health. While the data analyzed is self-reported and cannot lead to conclusions regarding causality, our results can provide enough evidence to motivate future studies on the effects of routine self-tracking that examine such outcomes in more depth. In particular, future studies should investigate different aspects of health management that are not covered in this analysis, such as the role of caregivers and health outcomes.

In summary, the study results indicate that routinely tracking health indicators can have a significant effect on people’s approaches to their health management, and that might be caused by an increase in self-efficacy. Further, we have found that electronic tools used in tracking are very strong predictors of routine self-tracking, suggesting that they may encourage measuring and recording data at regular intervals. Lastly, we found that people who have had emergency visits to a hospital in the last 12 months are approximately 50% more likely to routinely track health indicators, suggesting that the process of recovery, or learning how to handle new health developments, are situations wherein tracking might be particularly important for patients.

At the same time that routine tracking might improve the results of health management, and it should be supported and encouraged by self-tracking technologies, different users might value routine tracking more than others. For instance, our results indicate that younger people, and those who have not visited the ER recently, are less likely to routinely self-track. In these cases a system that demands routinely tracking to present valuable results may not be desired by the users. These systems should support users’ priorities and capabilities.

This study has several limitations. Because the survey collected self-reported data, it is not possible to attribute causal relationships based on its analysis. The data is likely subject to bias associated with this type of data collection (e.g., social desirability bias, selection bias, acquiescence, halo effect). Additionally, because respondents might track multiple variables using different methods, and the data does not differentiate between these cases, it is possible that these instances created noise in the results. Further, the data provide limited detail regarding health outcomes, the exact variables tracked by each respondent, and the different tools used. These characteristics limit the conclusions that can be drawn from analyses. Lastly, because the survey was conducted in 2012, the influence of technologies on self-tracking activities might have changed due to the increasing popularity of mobile devices, and to new technologies that might have become available since.

Conclusion

Through an analysis of data obtained from the Tracking for Health survey1, we have investigated what health and demographic factors influence routine self-tracking practices, and how continuously measuring and recording data at regular intervals affects health management practices. Our results indicate that older people and those who have recently experienced a health emergency are significantly more likely to self-track routinely. Utilizing electronic self-tracking tools, such as smartphone applications, also increased the probability of routine tracking. Lastly, we found that those who routinely self-track are significantly more likely to report that tracking has influenced their health management practices.

A Cross-Sectional Study of Prominent US Mobile Health Applications: Evaluating the Current Landscape

Pierre-Antoine Fougerouse, MD¹, Mobin Yasini MD, PhD², Guillaume Marchand, MD², Oliver O. Aalami, MD¹

¹Stanford University School of Medicine, Department of Surgery, Division of Vascular Surgery, Palo Alto, United States; ²DMD Santé, Research and development department, Paris, France

Abstract

Mobile health (mHealth) could offer unprecedented opportunity to provide medical support closer to the users. We have selected some relevant criteria to describe 100 apps from Google Play store and Apple’s App Store’s top suggestions in medical category. These characteristics were compared based on the paid or free nature of the apps, the target users: consumers or healthcare professionals, and the platform: Android or iOS. Seventeen provided functionalities and 27 medical subjects covered by these apps were also extracted. Our study shows that even in top rated mHealth apps, a high proportion lacks some basic criteria regarding the quality of the apps including the presence of a privacy policy, describing content sources, participation of the target users in the app development, etc. Paid apps did not ensure better quality compared to free apps. The current mHealth market is not mature enough to be used widely and recommended by healthcare professionals.

Introduction

Mobile health (m-health) is a subdivision of the eHealth phenomenon that is in a perpetual state of active refinement. There is a vast amount of potential for m-health to positively affect health and healthcare processes¹. Mobile apps offer an unprecedented opportunity to provide medical support at the time/location of the demand². This opportunity can be harnessed by the general public (e.g. patients) or healthcare professionals who are in need of various specialized tools (means of interdisciplinary communication, ready access to health and medical information, simple consultation of medical records, and clinical decision-making support systems)³.

Although m-health apps are a relatively recent development, their virtual presence is exploding with no indication of slowing any time soon. There are over 259,000 health-related applications (apps) available in app stores (e.g. Google Play and Apple’s iOS “app store”) for smartphone devices. Approximately 100,000 m-health apps have been added as of the beginning of 2015⁴. Each month, about 1,000 new applications are put on the market⁵. These apps proffer myriad functionalities, ranging from simple text message reminders to platforms designed for sophisticated disease management. Naturally, the growth of the m-health market correlates with the increase in usage these apps are experiencing. In the next several years, upwards of three million free downloads and circa 300,000 purchased downloads are expected to be made of mHealth applications in the United States alone⁶. These values exhibit a swift rise in the prevalence of mobile technology in the medical and wellness fields. Being readily accessible and simple to procure ensures that smart devices (smartphones and tablets) are made very attractive in the eyes of medical professionals. We are reaching a turning point in the use of mobile technology in healthcare. Therefore there is a pressing need to ensure that patient safety is not compromised post-maturation of the field⁷. The continually-rising number of mHealth apps and the variety of obtainable functionalities render it burdensome for any kind of user (health professional or patient) to ascertain which apps excel in terms of quality.

There exist a great deal of potential dangers, and the reliability of some mHealth apps was investigated in several works of literature⁸–¹⁰. The involvement of a medical professional in the development of a given application¹¹, the accuracy and reliability of the content as utilized in diagnosis and patient management¹², the potential danger of camera functionalities in mobile devices to judge whether skin lesions are suspicious¹³,¹⁴, and deficiencies in self-management applications (in both diabetes¹⁵ and asthma¹⁶) were called into question by various researchers.

While the growing popularity of m-health is well-documented, its impact is not. The reported implications of mHealth interventions are mixed, with studies exhibiting modest benefits for some clinical diagnosis and management support outcomes¹. Furthermore, the information provided in app stores does not permit users to ascertain the quality of apps. The existing five-star rating system currently in use is not a reliable assessment method¹⁷. One is faced with a veritable
jungle of health-related apps, including very good apps as well as those that endanger patient/physician safety. In order to address this deficiency in today’s mobile health market, a research study was proposed to assess the current standing of mHealth applications available for download in the United States. We were interested in determining whether or not the current market could be considered a reliable source of medical applications. The main aim of this study was therefore to isolate characteristics of health apps currently available and identify existing gaps.

Methods

In collaboration with medical doctors from France and Stanford University, we have conducted a cross-sectional descriptive study of the top 100 medical applications available in the Google Play store and Apple's App Store. We selected the top 25 free apps from the App Store followed by 25 of the same from the Google Play Store. When an app appeared in both stores, it was only selected once and passed over in favor of the following app. For the payed apps we employed the opposite strategy, beginning with the Google Play Store and only afterwards the Apple Store. If the reported purpose of the app had no relation to medicine, it was not selected. Other exclusion criteria were that no apps that encapsulated other apps (a mini store of apps) and paid apps more expensive than 70 dollars were not selected.

The order of apps on the top lists are very subject to change. In the beginning of January 2017, we selected our apps in compliance with the aforementioned criteria. We did not alter our choices over the course of the study. The working group was composed of four physicians invested in medical informatics. The apps were installed on a relevant mobile device and analyzed one by one by each group member.

In order to define the criteria used over the course of the study, we hypothesized that we could utilize key elements of the mHealth Quality (mHQ) process. We have isolated from said process the most relevant criteria to assess the American market. The extraction criteria included informative and assessment criteria.

Apart from the characteristics of the app, we have analyzed each app to evaluate the use cases (functionalities) imparted by the app according to a previously published model of use cases for mHealth apps. We have also determined the relevant medical subject/specialty related to each app.

Each member of the working group had an Excel table to fill for each app. We organized a weekly meeting to discuss differing opinions and reach a consensus.

Descriptive data were provided for each criterion. The characteristics of both free and paid apps were compared according to their target demographic (consumers or health professionals) as well as the platform (iOS and Android). Chi-Square test was used to determine whether there was a significant difference between the elements of the information in the categories and P < 0.05 was considered statistically significant.

Results

Half of the analyzed apps were installed on Android phones, and the other half were installed on iOS ones. From each platform 25 paid apps and 25 free apps were selected. Whilst performing the selections, three apps were excluded from the study due to their non-medical nature. One app was not selected due to its high price and two others were excluded because they were essentially a mini store of apps.

The selected criteria were divided into informative elements and assessment elements. The informative elements include type of owner (start-up, corporation, patient association, etc.), target user, the topic the app was attempting to address, whether or not it belonged to the appendix A, B or C of the FDA document on Mobile Medical Applications, etc. Assessment elements include the existence of general terms and conditions of use, existence of privacy policy, presence of a health professional during app development, citation of content sources, etc. Table 1 provides descriptive explanations of various criteria and distribution of apps.

Most app criteria were evaluated in all 100 of the analyzed apps. However, some criteria were not applicable to all apps. For example, "user consent to personal data collection" and “ability to link to a connected device in order to collect data” were rendered obsolete for apps whose purpose was not to collect personal health data. The aforementioned criteria were only applicable to 58 apps. Another example is "citation of the content sources or bibliographic references" and "medical content is kept up to date" because only 71 of selected apps include medical content.

The pecuniary nature of some apps caused a significant difference (p<0.001) between those addressed to consumers and those targeting healthcare professionals. Apps whose target demographic consisted mostly of healthcare professionals were less likely to be free to download. However, 28% of free apps had in-app integrated purchases.

We did not find a significant difference between target users of Android vs. iOS apps, none of the two major markets is oriented more towards consumers or healthcare professionals.

Seventy apps presented a means of contacting the owner via email. There was no significant difference between free and paid apps, between those addressed to consumers vs. healthcare professionals, or between the two platforms. 26% of selected apps provide a hotline to address users’ potential queries. There was a significant difference ($p < 0.009$) between free and paid apps: free apps provide more hotline services than paid ones.
More than half of the apps did not provide general terms and conditions of use. We found no substantial difference in availability between Android/iOS apps or between consumer-targeted/healthcare-professional-targeted ones. However, a larger amount of free applications offer general terms and conditions in juxtaposition with paid apps ($p<0.016$). This phenomenon occurs once again with the availability of privacy policies. Free apps include privacy policies more frequently than paid apps ($p<0.001$).

Only 59% of the apps collecting user health data require the explicit consent of their users pre-collection, and free apps were once again superior ($p<0.001$). No difference was found when we compared the two major platforms and target users.

There was only one app that boasted an ethical chart. This app was free, meant for healthcare professionals, and available in the Top 25 of both the Google Play and App stores (in compliance with the aforementioned selection criteria we studied the iOS version).

Seventeen disparate use cases were discovered in the 100 analyzed apps according to the Yasini and Marchand Model$^3$. Six use cases were related to health professionals and eleven to consumers. We discovered 226 use cases in these apps, meaning that the average number of use cases provided by each app is 2.26. Table 2 illustrates the various uses cases and their frequency in the selected apps.

C: Consumers, HP: Healthcare Professionals

We were able to classify the chosen apps in 27 subject groups, of which 15 were consumer-oriented and 12 targeted health professionals. For consumer-targeted applications the most well-covered subject was general health status (29%), most often exhibited by apps attempting to centralize all patient data in order to provide a comprehensive synthesis of such. We also noted that an integral portion of consumer apps (18%) focused upon women's health issues such as menstrual cycles and pregnancy concerns. The subject of eight apps (12%) was managing the use and cost optimization of medications.

For apps directed towards healthcare professionals, atlases of anatomy dominated (26%). Second place was held by applications that could be harnessed by professionals of all medical specialties (20%) (e.g. drug databases). 17% of apps specifically for healthcare workers dealt with emergency medicine, and 11% of apps were created to aid students’ exam preparation. Figure 1 portrays the various subjects and their relative frequency.
Discussion

In this study, we analyzed 100 US mHealth applications available in the medical category of the Google Play store and Apple's iOS App Store. We described some of the characteristics of these apps including the app's target user, the app provider, presence of a physician in the core team of the company owning the app, providing the content sources when relevant, and providing terms and conditions of use and privacy policy. We also extracted the subjects they dealt with and their various use cases.

Although we have only analyzed the apps in the medical category, we have excluded three apps because of non-relevant topic to medicine. One of these apps was a music app and two others were games (that were not considered as serious medical related games). This shows that even in the top-rated apps in the market stores, some apps are not well categorized.

Contrary to our impression, paid apps did not provide a more qualified profile compared to free apps based on the evaluated criteria. This may be explained by the fact that mobile apps are often used by providers as another marketing tool to create loyal users. mHealth market is still in the phase that the app providers want to build their brand image and get their name out. Therefore, most of the providers select free apps to increase the download rate and potentially provide more qualified apps to keep their users continually.

Various mHealth apps collect and offer critical and private patient data. The data may be entered directly by the user, collected with the built-in features of the smart device (e.g., camera, microphone), an external sensor, or a connected device (e.g., connected thermometer). These data need a special focus on information security and privacy of mHealth
Potential damage to users through information security and privacy infringements have been discussed in various studies\textsuperscript{20–22}. Our study shows that still about half of the analyzed apps do not provide terms and conditions of use or privacy policy. The situation becomes more dramatic when we consider that the analyzed apps come from the top of the App Stores.

The involvement of healthcare professionals in mHealth apps development processes is another important criterion that ensures the reliability of health information\textsuperscript{17,23,24}. This study showed that 61\% of the studied apps were produced with the participation of a health professional in the core team of the app owner. Other studies in the literature reported the rate of this involvement between 12.8 \% to 48\% of analyzed apps\textsuperscript{20,24}. Although in our sample of apps we found a higher rate of professional involvement in the development of the apps, this is not yet satisfying particularly for the top listed apps of the App Stores.

It is critical that medical applications provide content that are accurate and reliable\textsuperscript{25} because patients and healthcare professionals can make critical decisions based on information provided by an app. We did not find the content source for 44\% of apps that provide medical information to their target users. When mHealth apps disseminate medical information, which was the case for 71\% of the analyzed apps, the information must be developed on the basis of reliable information resources and references. This study showed that 44\% of these apps did not mention their sources. This lack of transparency of the apps about the sources is in line with other studies in the literature who call in to question the adherence of the apps to established guidelines\textsuperscript{20,24,25}.

None of the studied apps could be considered as a medical device according to FDA classification\textsuperscript{19}. However, half of these apps were considered as borderline apps (group B). The need for regulating the apps is a real challenge of today’s mHealth market. The percentage of apps that resort to FDA authorization or other existing certifications (like European CE for medical devices) is too low. This shows that the market is not yet enough mature to the assessment and certification processes.

Various apps were multifunctional and provided various use cases in different medical fields. This indicates that the iOS and Android App Stores offer a wide selection of mHealth apps with a real diversity of usages that makes mobile devices ready to do almost everything in every medical specialty. However, this diversity prevents a “one size fits all” approach to ensuring the quality of these apps and information security\textsuperscript{18,21}.

One of the limitations of our study was the number of studied apps. The top-rated apps in the App Stores are based on the five-star rating that the users provide, number of downloads and some other criteria. However, the number of downloads may differ according to the target users of the apps (an app for diabetic patients may be downloaded more than an app that is addressed to the patients affected with a rare disease) and the five-star rating is not a reliable assessment system\textsuperscript{17,26}. In this study, we have selected all the studied apps from US App Stores. Further research with a multi country design and a more important number of apps to analyze is the real solution to validate these results.

Conclusion

mHealth apps could provide seamless access to adapted and context oriented health information and have the potential to decrease global health burdens. However, despite these promising potentials, there are some barriers and risks that prevent the users to trust mHealth apps. Recognizing these elements by all the stakeholders including app providers, app stores and users may lead to removal of these risks step by step. We are faced with a plethora and diversity of available mHealth apps. Therefore, implications for assuring the quality, security and privacy seem to be unclear and complex. Our study shows that the current situation of mHealth apps in general is not yet enough mature to be used widely and recommended by health professionals in the US market. Further research and development efforts are required to facilitate the wide range integration of mHealth apps in the real clinical pathways. These efforts could be designed in various axes including disseminating related guidelines for the users or app developers, implementing regulatory certification programs, designing adapted studies to reveal clinical evidence of mHealth apps considering the fast-paced nature of technology, and educating and encouraging app providers to protect their apps from information security and privacy and to test the usability and ergonomic aspects of their apps. Taking the right strategies in the future will help to benefit from the potential of mHealth apps to transform and improve the health care ecosystem and limit the barriers and risks.

Achieving Logical Equivalence between SNOMED CT and ICD-10-PCS
Surgical Procedures

Abstract
Surgical procedures are coded in SNOMED CT in the electronic health record and in ICD-10-PCS in administrative systems. We compared the logical definitions of SNOMED CT concepts to the ICD-10-PCS axial components to identify overlap and gaps. The biggest discrepancy was in the surgical approach which was specified in all ICD-10-PCS codes but only in 8.7% of SNOMED CT surgical procedures. Among the top 100 commonly used ICD-10-PCS codes, 25% could be matched fully in meaning and logical definition to pre-coordinated SNOMED CT concepts. Using post-coordination, it was possible to represent the full meaning of 86% of ICD-10-PCS codes. Logical mapping between SNOMED CT and ICD-10-PCS is feasible but will be more productive if more SNOMED CT concepts can become fully-defined. Short of full logical matching, partial logical matches can also be useful in suggesting candidate maps for expert review and to support interactive post-coordination.

Introduction
The Standardized Nomenclature of Medicine, Clinical Terms (SNOMED CT) is steadily gaining momentum as the emerging international clinical terminology standard. The number of member countries has more than tripled (increased from 9 in 2007 to 30 in 2017) since the establishment of the International Health Terminology Standards Development Organisation (IHTSDO) in 2007. In early 2017, the IHTSDO has acquired the new name SNOMED International. SNOMED International now covers most primarily English speaking countries.¹ In the U.S., the Meaningful Use of Electronic Health Record (EHR) incentive of Centers for Medicare and Medicaid Services (CMS)², ³ specifies SNOMED CT as the terminology for the encoding of problem lists and procedures for the EHR, among other data elements. A similar effort is underway in Belgium to encourage the meaningful use of EHR and the use of standard terminologies like SNOMED CT.⁴ The adoption of SNOMED CT for clinical documentation is anticipated to increase steadily as the number of member countries continues to grow.⁵, ⁶

In the U.S. and in Belgium, for administrative and reimbursement purposes, hospital-based medical procedures are being reported in ICD procedure codes. Since 2015, ICD-9-CM procedure codes have been replaced by ICD-10-PCS (International Classification of Diseases, 10th Revision, Procedure Coding System) in both countries. ICD-10-PCS is a brand-new procedure classification system created by the U.S. Centers for Medicare and Medicaid Services (CMS) through a contract with 3M Health Information Systems.⁷ Other countries that have been using ICD-9-CM are expected to make similar transition to ICD-10-CM and ICD-10-PCS. For example, Spain has made the switch in 2016 and Portugal in March 2017.

While SNOMED CT and ICD-10-PCS are both used to encode procedures, they are designed with different principles to serve their specific purposes. It is likely that both coding systems will continue to be used. One way to mitigate the problem of having clinical and administrative data coded in disparate coding systems is to develop a map between the two systems. Under SNOMED International, there is a SNOMED CT to ICD-10-PCS Mapping Project Group with participation from U.S., Spain and Belgium to explore the creation of such a map.⁸ The group has studied various ways of automatically mapping between the two terminologies. These methods include lexical matching of the ICD-
10-PCS index, indirect mapping through the General Equivalence Map (GEMs, published by CMS) and ontological alignment between the SNOMED CT attributes and ICD-10-PCS axes. Among these approaches, lexical mapping has higher precision (89% of maps are useful) but low coverage (only 3% of SNOMED CT surgical procedure concepts can be mapped). Indirect mapping through GEM has lower accuracy (76% of maps are useful) but can find map for 10% of SNOMED CT surgical procedures. Ontological mapping has the lowest accuracy (45% of maps are useful) but can find map for 46% of the SNOMED CT procedure concepts studied.

In this study, we are expanding on our effort in ontological mapping. There are two prerequisites in order for ontological mapping to work. First, there has to be a high degree of similarity or compatibility between the underlying concept models of both systems. Second, the existing contents must be modeled adequately to support automatic mapping between both systems. Based on a list of frequently used ICD-10-PCS surgical procedure codes from a hospital information system, we assessed the extent to which the SNOMED CT concept model can cover the meaning of ICD-10-PCS codes. We also examined the degree of modeling of existing (pre-coordinated) SNOMED CT concepts and the feasibility of using post-coordination to achieve logical equivalence between SNOMED CT and ICD-10-PCS surgical procedures. We report our findings here and discuss the implications of our findings with respect to the quality of SNOMED CT modeling and the practicability of ontological mapping.

Methods

ICD-10-PCS is a radical departure from ICD-9-CM in terms of structure and design. Each procedure is defined by seven components (axes) namely section, body system, root operation, body part, approach, device and a 7th character for a qualifier if applicable. On the SNOMED CT side, procedure concepts are similarly defined by components (attributes) such as procedure site, method, access, device etc. The basis of ontological mapping is to align the ICD-10-PCS axes and SNOMED CT attributes in order to identify equivalence in meaning by comparing the logical definitions of concepts. In this study, we did a quantitative analysis of the attributes used in existing SNOMED CT surgical procedures and compared them to the corresponding components in ICD-10-PCS to identify overlaps and potential gaps.

We acquired a list of ICD-10-PCS codes with usage frequencies extracted from the data warehouse of Nebraska Medicine - Medical Center, a 600 acute-care bed facility with more than 1,000 physicians in all major specialties and subspecialties. In our study, we focused on medical and surgical procedures from section 0. The various sections can be distinguished by the first digit of the ICD-10-PCS code (e.g., 0 = medical and surgical, 1 = obstetrics, 2 = placement, etc.). Medical and surgical procedures represent the majority (86%) of all ICD-10-PCS codes. We identified the 100 most frequently used ICD-10-PCS medical and surgical procedures (codes beginning with 0). For each ICD-10-PCS code, two authors (JX and FA) independently looked for the SNOMED CT concept that most closely matched the meaning of the ICD-10-PCS procedure (meaning match). The meaning of the SNOMED CT concept was determined by its fully-specified name. The meaning match was characterized as exact or partial. For exact meaning matches, the logical definition of the SNOMED CT concept was examined to see whether it captured the full meaning of the ICD-10-PCS procedure (logical match). If the logical definition did not completely match the ICD-10-PCS procedure, it was extended according to the SNOMED CT concept model to see if full logical equivalence could be achieved. If full logical equivalence could not be achieved, the reason was recorded. The reasons might include: limitation of SNOMED CT concept model, missing necessary attribute, missing necessary value. For cases that the closest SNOMED CT concept was a partial meaning match, that SNOMED CT concept was used as the template to construct a post-coordinated SNOMED CT expression to capture the meaning of the ICD-10-PCS code as fully as possible. If full logical representation was not possible with post-coordination, the reason of failure was recorded. Results from the two reviewers were compared and differences discussed with a goal to reach consensus. A third reviewer (KWF) cast a third vote if consensus could not be reached. All three reviewers (all physicians) together discussed cases in which there was exact meaning match but incomplete logical match to see if the missing defining element was clinically significant. We found this to be necessary because some of the ICD-10-PCS component values were clinically trivial and missing them would not cause ambiguity in the clinical context. For example, circumcision was defined in ICD-10-PCS as having the external approach. Since there was no other approach to perform circumcision,
missing the external approach in the logical definition was considered not clinically significant. The review procedure is summarized in figure 1.

Figure 1. Finding meaning and logical definition match for ICD-10-PCS codes (FSN: fully-specified name)

**Results**

**Concept model analysis**

There are 19,796 surgical procedures in the January 2017 release of SNOMED CT identified as descendants of the concept *Surgical procedure (387713003)*. In the SNOMED CT concept model, 24 attributes (excluding the attribute *Is a*) are allowed for the modeling of procedures. (Table 1) The frequency of usage of these attributes is highly variable. For example, while the *Method* attribute is used in all concepts, 9 attributes (e.g., *Procedure morphology, Indirect morphology, Procedure device*) are used in less than 1% of concepts.

Table 1. Frequency of use of attributes in SNOMED CT surgical procedure concepts

In ICD-10-PCS, there are seven axes each corresponding to a specific aspect of a procedure. (Table 2) The ICD-10-PCS code is made up of seven alphanumeric characters, one for each axis. The first five axes are always populated...
with clinically meaningful values (e.g., stomach, excision). In axis 6 (device) and axis 7 (qualifier), a placeholder value (Z) is allowed for null values when a component is absent (i.e., no device, no qualifier). Table 2 shows the proportion of ICD-10-PCS codes (2016 version) with non-null values for each of the axes, compared to the proportion of SNOMED CT concepts with attributes corresponding to a particular axis. For example, the root operation is always specified in ICD-10-PCS and a Method attribute is always present in SNOMED CT. Body system and body part are specified in all ICD-10-PCS codes. In SNOMED CT, body site is modeled by three attributes: Procedure site and its two children Procedure site – direct and Procedure site – indirect. Procedure site – direct denotes the body structure that is the direct aim of the procedure. For example, Amputation of the foot has Procedure site - direct = Foot structure. Procedure site – indirect is used when the body structure is not the direct target of the procedure. For example, Removal of calculus of urinary bladder has Procedure site – indirect = Urinary bladder structure. The more general attribute Procedure site is used to model high-level grouper type concepts such as Procedure on colon. However, sometimes the use of Procedure site and Procedure site – direct attributes is conflated. So in our analysis, body system and body part in ICD-10-PCS are considered to be equivalent to any of the three procedure site attributes in SNOMED CT. Overall, 97.1% of SNOMED CT concepts have at least one of the procedure site attributes. In ICD-10-PCS, body sites can also be used in axis 7 to denote the second body part of a bypass procedure (which typically connects two body parts). For example, for Bypass stomach to jejunum, axis 4 has the value stomach and axis 7 has value jejunum. In SNOMED CT bypass procedures, both anatomic sites being connected are represented as Procedure site – direct attributes. So in the case of bypass procedures, Axis 7 corresponds to the second (if present) Procedure site – direct attribute in SNOMED CT. There are other uses of axis 7 (e.g., diagnostic) which correspond to other SNOMED CT attributes (e.g., Has intent). Overall, while there are 17.2% of ICD-10-PCS codes with non-null axis 7 values, while 8.9% of SNOMED CT concepts have some corresponding attributes. The biggest discrepancy between SNOMED CT and ICD-10-PCS is in the surgical approach value, which is present in all ICD-10-PCS codes but only in 8.7% of SNOMED CT concepts.

Table 3. Meaning and logical definition match between SNOMED CT and ICD-10-PCS and the distribution of missing attributes

The following is a detailed explanation of each match category with examples.

1. **Exact meaning match, full logical equivalence** (1 case)

   The ICD-10-PCS procedure *Occlusion of Bilateral Fallopian Tubes, Open Approach (0UL70ZZ)* matched exactly the meaning of the SNOMED CT concept *Open bilateral occlusion of fallopian tubes (176936004)*. The SNOMED CT logical definition fully captured the ICD-10-PCS components as shown below (drawn according to SNOMED CT Diagramming Guide\(^{16}\), omitting *Is a* relationships, same below):

   ![Diagram](image)

2. **Exact meaning match, close logical equivalence** (24 cases)

   The meaning of the SNOMED CT concept and ICD-10-PCS procedure matched exactly but the SNOMED CT logical definition did not capture all the ICD-10-PCS components. However, the missing component was considered clinically trivial. For example, ICD-10-PCS procedure *Resection of Appendix, Percutaneous Endoscopic Approach (0DTJ4ZZ)* exactly matched the meaning of *Laparoscopic appendectomy (6025007)*, which had these attributes:

   ![Diagram](image)
Strictly speaking, this was not an exact logical match for two reasons. First, the percutaneous approach was not represented. Moreover, ICD-10-PCS made a distinction between removal of the whole (resection) and part (excision) of a body part. In order to be logically equivalent, Entire appendix would have to be used instead of Appendix structure for the Procedure site – direct attribute. However, we did not consider these differences to be clinically significant because typically laparoscopic surgery was done percutaneously, and appendectomy implied removal of the whole appendix. Omitting these attributes did not significantly change the meaning of the concept. The logical match was close enough in the clinical context. Other examples of close logical matches included omission of the approach for endoscopic procedures (specified as ‘via natural or artificial opening’ in ICD-10-PCS) and the intent in biopsies (specified as ‘diagnostic’ in ICD-10-PCS). To facilitate automatic logical mapping, it would be possible to add back the missing attributes algorithmically (see Implications for logical mapping in Discussion).

3. Exact meaning match, partial logical equivalence (7 cases)

In these cases, the meaning match was exact, but the omission in the logical definition was clinically significant. For example, ICD-10-PCS procedure Bypass Stomach to Jejunum, Percutaneous Endoscopic Approach (0D164ZA) matched exactly the meaning of 307195003 Laparoscopic gastroenterostomy (307195003) with the following attributes:

The components of the ICD-10-PCS code could be captured completely by replacing the attribute Procedure site – indirect = Digestive tract structure by two attributes Procedure site – direct = Stomach structure and Procedure site – direct = Jejunal structure. Of the 7 cases we found, 6 cases could have completely matching logical definitions using the existing SNOMED CT concept model. In the remaining case of the ICD-10-PCS procedure Excision of Stomach, Percutaneous Endoscopic Approach, Vertical (0DB64Z3), complete logical representation in SNOMED CT was not possible because the surgical method (sleeve resection or vertical resection) was not available in SNOMED CT to fully represent the procedure in Laparoscopic sleeve gastrectomy (427074001).

4. Partial meaning match, full representation possible by post-coordination (56 cases)

The SNOMED CT concept matched part of the ICD-10-PCS meaning and a post-coordinated expression could be constructed based on that SNOMED CT concept to represent all the ICD-10-PCS components. For example, the ICD-10-PCS procedure Dilation of Left Ureter with Intraluminal Device, Via Natural or Artificial Opening Endoscopic (0T778DZ) was partially matched in meaning to Insertion of stent into ureter (428817001). If we changed the Procedure site - indirect attribute value to Structure of left ureter and added the attribute Using access device = Endoscope, device we could capture all the components of the ICD-10-PCS procedure.

Partial meaning match found in SNOMED CT concept Insertion of stent into ureter (428817001):
Post-coordinated expression could be created to express full meaning of ICD-10-PCS code *Dilation of Left Ureter with Intraluminal Device, Via Natural or Artificial Opening Endoscopic (0T778DZ)*:

5. Partial meaning match, full representation not possible by post-coordination with current SNOMED CT concept model (13 cases)

In these cases, full representation of the ICD-10-PCS meaning was not possible because of one of the following reasons:

- Cardinality – the current SNOMED CT description logic profile was not able to express the exact number of occurrence of an attribute. So it was not possible to capture the number of bypass grafts in this ICD-10-PCS procedure *Bypass Coronary Artery, Two Arteries from Aorta with Autologous Venous Tissue, Open Approach (021109W)*.
- Absence of body part concept – there was no SNOMED CT body part concept corresponding to the ICD-10-PCS procedure. For example, in the ICD-10-PCS procedure *Insertion of Monitoring Device into Upper Artery, Percutaneous Approach (03HY32Z)*, upper artery is defined as any artery above the diaphragm in ICD-10-PCS. In the anatomy model of SNOMED CT, there was no such corresponding body part concept.
- Absence of surgical action concept – the required action concept was not available in SNOMED CT. For example, in the ICD-10-PCS procedure *Extraction of Abdomen Skin, External Approach (0HD7XZZ)*, extraction referred to removal by any means other than surgical excision, e.g. debridement. In SNOMED CT, there was no action concept corresponding to ‘non-excisional removal’.

**Discussion**

SNOMED CT distinguishes itself from most other terminologies by its description logic underpinning. The logical definition of concepts makes it possible to compute concept equivalence and subsumption, among other things. ICD-10-PCS is a compositional terminology which makes it inherently computable. This makes it possible, at least in theory, to develop a computational way to link the two terminologies.\(^{17,18}\) For this to work, we have to assume that the SNOMED CT logical concept model is able to represent the meaning of ICD-10-PCS procedures and that existing concepts are modeled sufficiently for this purpose. This study examines these assumptions and identifies some hurdles which need to be overcome.
Improving SNOMED CT logical definitions and concept model

Currently, only 42% of all SNOMED CT procedure concepts are designated as fully-defined. This means that in about 60% of procedures, some essential defining attributes are missing and that the meaning of the concept is not fully reflected by the logical definition. Increasing the proportion of fully-defined concepts will improve the capability of SNOMED CT to support computation. The proportion of fully-defined concepts has been recognized by SNOMED International as an important quality metric for SNOMED CT. It is a daunting task to completely model tens of thousands of concepts and some prioritization is necessary. In this study, we have identified some commonly performed procedures in clinical practice which would be a good place to start. In our opinion, the highest priority should be given to those concepts that match an ICD-10-PCS procedure completely in meaning but the logical definition is incomplete because of the omission of some clinically significant attributes (about 7% of cases in our study). These concepts already exist in SNOMED CT and additional work is needed to make their definitions more complete. We are proposing that only attributes which are clinically meaningful and significant to be added, because omitting them can lead to ambiguity in the clinical context. Improving the logical definition of these concepts will not only facilitate mapping to ICD-10-PCS, but will avoid potentially erroneous results in description logic computation e.g., for data aggregation and inferencing. Next-in-line would be the cases with partial meaning matches which can be fully represented by the existing concept model. This represents a larger number of cases (56% of cases in our study) and will require significantly more effort. To match the full meaning of these ICD-10-PCS procedures, new concepts that are sufficiently modeled will need to be added to SNOMED CT. Can we justify the effort? The answer depends on whether adding the concepts will provide high enough utility to SNOMED CT users. We would argue that for procedures that are indeed commonly performed but missing in SNOMED CT, the effort will be worthwhile. Our study data set is based on a single hospital and may not be representative enough. To identify the list of priority concepts to work on, SNOMED International will need to gather more data sets from representative sources.

Cases that cannot be fully represented with the existing concept model present another challenge. We have identified three kinds of reasons for failure. In a small number of cases in our study, full logical representation cannot be achieved because of the problem of cardinality. The current SNOMED CT description logic profile cannot specify the number of occurrence of an attribute. Adding that capability to the SNOMED CT logic profile would be a significant change. We do not think that the ICD-10-PCS mapping use case alone is sufficient to justify this. The other cases in our study involve missing body structure or method concepts. Adding new concepts (provided that they are compatible with SNOMED CT editorial principles) generally requires less effort and causes less disruption. For example, adding the body structure concept Part of greater omentum will enable the full representation of the ICD-10-PCS procedure Excision of Greater Omentum, Open Approach (0DBS0ZZ). Adding the method Sleeve resection will allow the concept Laparoscopic sleeve gastrectomy (427074001) to become fully defined.

Implications for logical mapping

Our study can shed light on the feasibility and expected yield of using ontological alignment to map between SNOMED CT and ICD-10-PCS. In general, the SNOMED CT procedure model aligns reasonably well with the ICD-10-PCS axes. With the existing SNOMED CT concept model and existing attributes and values, 86% of ICD-10-PCS procedures can be fully represented as a SNOMED CT expression. By adding some new body part and method concepts, the coverage can go even higher. This speaks to the overall feasibility of logical mapping.

However, based on the existing modeled content in SNOMED CT, only a small proportion of cases can be mapped completely using the logical definition. This includes the cases we identified as full and close logical definition matches (25% of cases in our study). The ideal scenario is a full meaning and definition match, but it only occurs in one case. The cases with exact meaning match and close definition match are also amenable to logical matching. Since the missing attributes in these cases are clinically trivial, they can be implied and added automatically based on other characteristics of the procedure. For example, Access = Percutaneous approach can be added to all laparoscopic procedures, and Has intent = Diagnostic intent can be added to all biopsies. This will then allow fully-automated logical mapping to ICD-10-PCS procedures.
To increase the yield of logical mapping for the other cases will be more difficult. One solution would be for SNOMED International to improve the coverage and enrich the logical content of commonly performed procedures as discussed above. Whether this will occur depends on the availability of resources among various competing priorities.

So far, our discussion has focused on full logical equivalence between a SNOMED CT concept and an ICD-10-PCS procedure. However, even with the existing SNOMED CT content, partial logical matches can be found for most cases. Usually, a broader SNOMED CT concept can be found matching some (but not all) of the ICD-10-PCS components. For example, the ICD-10-PCS procedure *Resection of Spleen, Open Approach (07TP0ZZ)* can be matched through partial logical matching to *Total splenectomy (174776001)* in SNOMED CT through the attributes *Procedure site – direct = Entire spleen* and *Method = Excision – action*. The only missing attribute is the open approach. From a mapping perspective, these partial matches can be useful. One potential use case will be to suggest candidate mappings to human reviewers to expedite the creation of a manually-validated map. Another possible use case is to support real-time interactive post-coordination by clinical users. Starting with a partial match, the system can prompt the user to provide additional information until a full match is achieved. For example, when the user types in ‘splenectomy’, a list of SNOMED CT concepts will appear in a pick list. When the user picks ‘total splenectomy’, the system will further prompt the user to pick between open and laparoscopic approach. This is because based on the partial logical matching, *Total splenectomy (174776001)* is mapped to two ICD-10-PCS procedures: *Resection of Spleen, Open Approach (07TP0ZZ)* and *Resection of Spleen, Percutaneous Endoscopic Approach (07TP4ZZ)* and the user can click on the appropriate choice to hone in on the optimal ICD-10-PCS code. Furthermore, the system can also add either the attribute *Access = Open approach - access* or *Using access device = Laparoscope, device* to the logical definition of the concept *Total splenectomy*, thus creating a post-coordinated expression that fully captures the meaning of the chosen ICD-10-PCS procedure. In addition to cases with missing attributes, partial logical matching can also handle cases in which an exact match in the value of an attribute cannot be found. For example, an ICD-10-PCS procedure on the left jugular vein can be partially matched to a SNOMED CT procedure on the jugular vein. At the time of data entry, the user picking this SNOMED CT concept will be prompted to specify the laterality, which can also be captured in as a post-coordinated expression. One important consideration when using real-time post-coordination for data capture is to minimize the number of clicks needed to find the optimal code. We are building an experimental tool to study the different ways of presenting and prompting for additional information.

We recognize the following limitations in our study. We only focused on surgical operations in ICD-10-PCS and SNOMED CT but the scope of the two systems includes other types of medical procedures (e.g., obstetrical procedures, imaging studies). Our study sample was based on data from one hospital and the results may not be generalizable.

**Conclusion**

Logical mapping between SNOMED CT and ICD-10-PCS by aligning the SNOMED CT defining attributes and ICD-10-PCS axes is feasible. The biggest gap is in the surgical approach which is specified in all ICD-10-PCS codes but only in 8.7% of SNOMED CT concepts. However, in some cases the missing attributes are not clinically ambiguous and can be implied. In 25% of ICD-10-PCS codes, there is exact meaning and close logical match to a pre-coordinated SNOMED CT concept. Overall, 86% of ICD-10-PCS codes can be represented completely by the existing SNOMED CT concept model.

Abstract

We propose a computational framework for automated cancer risk estimation of thyroid nodules visualized in ultrasound (US) images. Our framework estimates the probability of nodule malignancy using random forests on a rich set of computational features. An expert radiologist annotated thyroid nodules in 93 biopsy-confirmed patients using semantic image descriptors derived from standardized lexicon. On our dataset, the AUC of the proposed method was 0.70, which was comparable to five baseline expert annotation-based classifiers with AUC values from 0.72 to 0.81. Moreover, the use of the framework for decision making on nodule biopsy could have spared five out of 46 benign nodule biopsies at no cost to the health of patients with malignancies. Our results confirm the feasibility of computer-aided tools for noninvasive malignancy risk estimation in patients with thyroid nodules that could help to decrease the number of unnecessary biopsies and surgeries.

Introduction

The incidence of thyroid nodules, both benign and malignant, has been consistently increasing in the United States in the recent decades. Much of this increase, it is believed, is due to increased utilization of imaging, with concomitant increased detection of asymptomatic thyroid nodules. In fact, autopsy studies report that up to 50-67% of adults nationwide are expected to have thyroid nodules, while only 0.2% of the population is reported to have thyroid cancer. Current definitive diagnosis of thyroid nodules requires tissue biopsy or even surgery, while only 5-7% of these nodules are found to be malignant. This inevitably exposes the majority of the patients to unnecessary health risks associated with these invasive tests and increases societal healthcare costs substantially. Therefore, there is a critical need for methods to reliably estimate the malignancy risks of thyroid nodules to decrease the number of invasive interventions being performed in low-risk benign nodules. Intensive research has been underway in the radiology, endocrinology, and surgery communities to attempt to identify those patients at high risk and who merit invasive diagnostic intervention, yet despite this, accurate diagnosis based on imaging findings remains very challenging.

Ultrasound imaging (US) is the standard-of-care imaging modality used to visually assess the risks of malignancy, define the necessity of biopsy-based definitive diagnosis and guide the fine-needle aspiration biopsy. In its recent guidelines for 2015, the American Thyroid Association recommends biopsy for thyroid nodules at size thresholds specified for five nodule appearance patterns associated with different risks of malignancy. However, such pattern-oriented approaches are not collectively exhaustive descriptors of nodule appearance in US and thus are not able to provide any scores to some nodules. Therefore, there is a need for methods that provide comprehensive evaluation of thyroid nodules based on collectively exhaustive sets of US features. Several Thyroid Imaging Reporting and Data System (TIRADS) classification systems have been proposed over the last years with the aim of providing a systematic approach evaluating the cancer risks of thyroid nodules based on multiple US features. The newly developed TIRADS lexicon from the American College of Radiology (ACR) provides a set of standardized US imaging descriptors (visual semantic features) used in expert annotation-based scoring systems (TIRADS classifiers) to estimate the risk that a nodule is a cancer before biopsy. However, extraction of these qualitative features imposes additional burden on radiologists and is subject to intra- and interrater variability. Moreover, the scoring systems for nodule malignancy are often oversimplified due to their design for human use. Automated analysis of nodule properties by extraction of computational features from US images and estimation of the risks using machine learning based classifiers could help reduce the expert labor and eliminate the associated variability.

*These authors contributed equally to this work
In this work, we present a computational framework for automated cancer risk estimation from US images, which is based on analysis of a rich set of computational features using a random forest classifier (RF). Unlike existing TIRADS classifiers, the proposed framework does not require qualitative assessments from the expert radiologist. We validated the framework on a dataset of US images of cases with biopsy-proven diagnosis. Our proposed framework compares favorably to other methods and has potential value for computer-aided diagnosis to help decrease the high number of biopsies in patients ultimately found to have benign disease, while identifying those patients at risk of thyroid cancer.

Materials and Methods

Datasets

Ultrasound imaging data of patients that underwent thyroid nodule examination at Stanford Hospital from year 2010 to 2015 were collected retrospectively with the approval by the institutional review board (IRB). Our final dataset consisted of 47 malignant and 46 benign biopsy-confirmed nodules from 93 patients (74 females, 19 males; mean age 55.9±15.4 years). For each nodule, its principal transverse and longitudinal projection US images were included. Blinded to the diagnosis, an expert radiologist reviewed the images, outlined each nodule, and recorded descriptors of visual characteristics of nodules using the recently established ACR TIRADS consensus lexicon8. Viewing, outlining and annotation of the images was performed in the electronic Physician Annotation Device (ePAD)14 (Figure 1). The images were preprocessed to reduce the US-specific artifacts such as speckle using nonlocal means based speckle filtering15. The advantage of this filtering method over traditional smoothing is its ability to preserve the edges, which is crucial for reliable extraction of computational features.

Semantic features for radiologist-based malignancy risk estimation

We derive a set of ten semantic features directly from the radiologist’s annotations (Table 1). As reference malignancy risk estimators, we use existing expert annotation-based TIRADS classifiers. Using the ACR TIRADS lexicon, we reformulate and implement five such TIRADS classifiers as described in the works of Park et al.9, Kwak et al. in 201110, Kwak et al. in 201311, Zayadeen et al.12, and Russ et al.13. In their work, Park et al.9 used 12 US features to assess the risk of malignancy using linear regression, and define six TIRADS categories based on the estimated risk. Kwak et al. in 201110 distinguished eight US features suspicious of malignancy, which were incorporated into a logistic regression-based malignancy risk quantification and the count-based classification system. Kwak et al. in 201311 used five US features of malignancy to build their weighted sum based TIRADS scoring system. Zayadeen et al.12 proposed a scoring system based on the defined major and minor malignant features, and also benign features. Russ et al.13 describes French TIRADS, a five-tier scoring system based on five malignant and six benign features. ACR TIRADS lexicon provides terms sufficient to describe these major US features of thyroid nodules and thus all five TIRADS classifiers were implemented using our expert annotations.

Computational features for automated malignancy risk estimation

To describe appearance of nodules identified by the radiologist in a quantitative manner, we selected a rich set of computational features that encode the echogenicity, texture, margin and shape properties of thyroid nodules. Nodule echogenicity was expressed by nodule intensity features, i.e., intensity histogram and intensity statistics. Nodule composition and presence of echogenic foci was expressed by texture and intensity features: rotation-invariant local binary pattern, Gabor filter bank, gray level co-occurrence matrix based features, and intensity difference between the nodule and its surrounding tissue. Nodule margin was computationally characterized via edge sharpness and local area integral invariant descriptor statistics at multiple spatial scales. Nodule shape had the following computational counterparts: ellipsoid fit, compactness, and roughness features. Nodule halo and peripheral calcifications were quantified by local intensity features, specifically by intensity histogram over the nodule margin. Although some of the semantic features, such as extrathyroidal extension, cannot be characterized easily from nodule outline alone, the edge sharpness features can be used as a surrogate, since the edges are expected to be blurred at the boundary portion where the thyroid capsule is invaded by the nodule\textsuperscript{16}. Overall, 480 computational features were collected.

Classification

We formulate the automated malignancy risk estimation as a posterior probability of malignancy learned by a machine learning classifier on an annotated training dataset. For both radiologist-annotated semantic features and computer-derived computational features, we trained an RF classifier to predict whether the nodule is benign or malignant. Classification by RFs consists of creating an ensemble of decision tree (DT) classifiers, each learned on a subsample of the original training dataset, and predicting the outcome by averaging responses across the DTs. The subsamples are drawn with replacement and also consist of randomly selected features. The RFs are characterized by the number of grown trees and the depth of the trees (equivalent to the number of leaves) in the DTs.

We chose RF because it generally has superior performance in medical image analysis\textsuperscript{17} and bioinformatics research\textsuperscript{18}, and it also has several additional desirable properties: 1) RFs can handle situations when the number of features are considerably higher than the number of data samples and do not require explicit dimensionality reduction as some other methods, 2) they can work with both categorical and continuous features and their combinations, and 3) they provide a probabilistic output. Therefore, in formulation of RF classification as discriminating benign vs malignant nodules, we will use the malignancy probability as the risk estimate.

\textbf{Figure 1} Example of annotation of a thyroid nodule on a transverse US image using the ePAD image viewing and annotation tool.
Evaluation

We used five expert scoring systems, or TIRADS classifiers, as reference malignancy risk estimators. The annotations provided by the radiologist were transformed into a mineable feature set consisting of binary and categorical predictors. Overall, 10 semantic and 480 computational features were used to train RF classifiers (RF-Semantic and RF-Computational). Leave-one-out hyperparameter tuning and model fitting was performed. Within each fold, the minimal number of the leaves in the decision trees were selected by searching among values \{2,5,10,20\}, while the number of trees in the forest was fixed to value 50 across all folds. The RFs were trained on the biopsy-confirmed diagnoses of the nodules in two-label formulation, i.e., benign vs malignant.

We measured the predictive performance of the classifiers using receiver operating characteristic (ROC) curves built on the malignancy scores as predictions and nodule malignancy indicator as reference labels. As a quantitative evaluation metric, we used the corresponding values of area under the ROC curve (AUC), which is an estimate of the probability that, for the randomly selected malignant nodule and randomly selected benign nodule, their scores will be in the correct order, i.e., the malignant nodule will receive a score higher than the benign nodule.

Results

The performance summary of the five TIRADS and the two RF classifiers is demonstrated in Figure 2 using ROC curves. For TIRADS classifiers, performance in terms of AUC was AUC=0.73 for Park et al.\(^9\), AUC=0.72 for Kwak et al.\(^{2011}\), AUC=0.81 for Kwak et al.\(^{2013}\), AUC=0.76 for Zayadeen et al.\(^{12}\), and AUC=0.77 for Russ et al.\(^{13}\). The proposed computational framework (RF-Computational) achieved AUC=0.70 and its semantic counterpart (RF-Semantic) provided AUC=0.75 (Figure 2). As expected, the classifiers that rely on radiologist annotation performed better than RF based on computational features alone, however, the performance was still comparable, which can also be noticed in Figure 2 as the ROC curves are at a close proximity to each other.

To study the clinical relevance of the methods, we analyzed their behavior at the highest true positive rate, or sensitivity. We recorded the number of correctly identified benign nodules, i.e., true negative count, in the absence of misidentified malignant nodules, i.e. false negative count close to zero. An ideal classifier would correctly identify all benign nodules without missing any malignant nodules, thus resulting in the number of true negatives equal to the number of benign nodules while having false negative count as zero. The results on our dataset for all the implemented classifiers are summarized in Table 2. Although at non-zero missed malignancies (FN=1,2 or above) the TIRADS classifiers achieved higher number for spared benignities, implementation of such rules in practice
would result in a decrease of benign nodule biopsies at the cost of misdiagnosis of patients with cancer (FN>0). Only the RF classifiers were able to provide a positive number of true negatives with no false negatives, which is the number of biopsies that could be avoided at no cost to patients with malignancies.

**Discussion**

In this work, we presented a computational framework for evaluating thyroid nodules (benign vs. malignant) on US images, with performance comparable to that of expert annotation-based classification systems. The malignancy estimation performance with respect to the biopsy-confirmed diagnosis for our framework was 0.70 in terms of AUC, which was lower but comparable to performance of the classifier based on expert-annotated semantic features (AUC 0.75) and to values obtained by the expert annotation-based TIRADS classifiers (AUC ranged from 0.72 to 0.81). Comparability in terms of classification performance shows potential of such computational features to enhance or perhaps even replace annotation by radiologists, which is laborious, expensive and prone to intra- and interrater variability.

The clinical relevance of the classifiers as a potential pre-biopsy malignancy risk estimator was further analyzed in terms of the number of unnecessary biopsies that could have been avoided, i.e., nodules correctly identified as benign, at the minimal levels of misidentified malignancies. In our experiments, the proposed computational framework achieved the highest number of correctly identified benign nodules (5 out of 46) in the absence of missed malignancies (values in italics in Table 2). Although the TIRADS systems we compared our system against could identify more benign cases, they did so with more misidentified malignancies. Another disadvantage of TIRADS classifiers in this respect is the limited control over the threshold for benign nodule selection. This is due to the oversimplified rules that lay foundation to such qualitative classification systems and resulted in small number of possible thresholds, e.g. five nodule malignancy scores in the work by Park et al. As can be seen in Table 2, only the RF classifiers provided thresholds for all the analyzed missed malignancy (false negative) counts.

Although some prior work has been done in thyroid cancer diagnosis using computational features derived from ultrasound images, the studies were limited to considerably smaller datasets (20 patients). More recently, Wu et al. have shown that their framework of radiologist-annotated semantic features and machine learning classifiers can provide results comparable to that of expert malignancy scoring. However, to the best of our knowledge, our work is the first to demonstrate a framework of computational features and a machine learning classifier having a performance comparable to expert classification. Our computational framework could serve as a basis to develop computer-aided diagnosis tools that ultimately could help reduce the high number of unnecessary biopsies in patients with benign nodules.

Thyroid cancer diagnosis currently relies on cytopathological analysis, which is invasive and carries risks of bleeding, infection and potential damage to adjacent structures. Identifying patients who have low risk for cancer is important to avoid such unnecessary health risks and decrease societal healthcare costs. Recent attempts to address the issue by introducing more reliable pre-biopsy cancer risk estimation using standard-of-care US images are based on radiologist-
annotated standard descriptors, which are laborious to collect and subject to inter- and interrater variability\textsuperscript{21}. Ultrasound is invaluable to noninvasive characterization of thyroid nodules; however, current guidelines are limited to recording a limited number of US feature of the nodules\textsuperscript{8}. By computing a rich set of features from these images, our proposed framework maximizes the use of the information available in the images. The use of the computer-aided diagnosis tools that are based on frameworks similar to ours could improve the management of thyroid nodules and result in decreasing the number of unnecessary biopsy or surgical risks, while more appropriately directing care in patients who actually need more invasive management.

A limitation of this study was the use of only two principal projections, transverse and longitudinal, for extraction and analysis of semantic and computational features. Although the selection of these projections is standard in practice to evaluate nodule properties such as shape and size, the use of multiple image frames from the ultrasound exams could better other US features and will be analyzed in future work. Obtaining consistent US features is also challenged by the variability in positioning the transducer by the operator; an extended study with multiple operators to study inter- and intra-rater variability can give more insight on robustness of certain features and limitations of others. An additional limitation of our work was the use of a single radiologist for determining the semantic features, though that radiologist is an academic expert. Future studies assessing the impact of inter-reader variation in assessments among experts on our results could be helpful.

**Conclusion**

In this paper, we presented a computational framework for estimating the risk of cancer in thyroid nodules by analysis of US images. The framework computes a rich set of computation features in the US images and estimates the malignancy probability using random forest classifier. Performance of the framework in terms of AUC was lower but comparable to that of five baseline expert radiologist annotation-based TIRADS classifiers. Given that our framework does not require qualitative assessments from the expert radiologist, it could reduce the effort required to evaluate these images and reduce variation in practice. In addition, the number of biopsies that a classifier could help to avoid without missing any malignancies was the highest for our framework. Our results confirm the feasibility of computer-aided diagnosis systems for thyroid cancer risk estimation. Such systems could provide second-opinion malignancy risk estimation for clinicians and ultimately help decrease the number of unnecessary biopsies and surgeries.

**Abstract**

The effectiveness of a clinical decision support (CDS) program encouraging clinicians to record patient’s Body Mass Index (BMI) and document appropriate follow-up plans is evaluated. Test (4,987 practices, 33,445 clinicians) and control groups (881 practices, 6,316 clinicians) were selected using stratified random sampling. Three CDS alerts for BMI screening and follow-up based on evidence based clinical quality guidelines were displayed at the point of care in a cloud-based EHR. The effectiveness of the CDS program was measured over 4 months by tracking recorded BMI and documented follow-up plans. Over the program, BMI recording increased minimally and documentation of follow-up plans increased 5-fold (p=0.05) compared to the control group. The overweight test group patients (18-64yo) gained less weight (p=0.06) than the control group and underweight patients gained more weight (p<0.01) during the program period. Outcome studies with longer follow-up periods are needed to further confirm positive outcomes.

**Introduction**

According to the Centers for Disease Control and Prevention (CDC), more than one-third (36.5%) of U.S. adults are obese¹. Obesity prevalence in the United States (U.S.) is on the rise and is expected to reach 42% of the population by 2030². Obesity is a risk factor for conditions including heart disease, stroke, type 2 diabetes, and certain types of cancer, some of the leading causes of preventable death²,³. Various institutions including the National Institutes of Health (NIH) and CDC have provided guidelines to help classify weight based on Body Mass Index (BMI)⁴,⁵. Anyone with a BMI between 25 and 29.9 would be classified as overweight and anyone with a BMI over 30 would be classified as obese⁴. In 2003, the U.S. Preventive Services Task Force recommended that primary care practitioners (PCPs) screen all adults for obesity and offer behavioral interventions and intensive counseling to affected individuals⁶. However, practice guidelines alone have failed to elicit appropriate clinician behavior⁷. Studies have shown that CDS systems improve clinical practice in preventive care and computer-assisted drug ordering and dosing systems⁸. While various studies have been done to test the effectiveness of CDS in management of high blood pressure, diabetes care, and asthma care⁸,⁹, there have been a limited number of studies that evaluate the effectiveness of a weight management CDS on clinician behavior and patient outcomes¹⁰.

A manufacturer of a chronic weight management treatment sponsored this CDS program for BMI screening and follow-up on the Practice Fusion EHR platform (PF-EHR). Our goals were to first measure the effectiveness of the CDS programs and second to find any evidence of improvements in patient outcomes associated with the CDS programs. The PF-EHR is cloud-based with 30,000 active practices in all 50 states facilitating over 5M office visits per month representing 6.7% of US ambulatory care. This study evaluates the impact of the weight management CDS program on clinician behavior and patient outcomes.

**BMI Clinical Decision Support Program Development**

For this study, three computer-based CDS alerts were implemented based on evidence-based clinical guidelines and quality measures¹¹. The CDS logic implemented is represented below (Figure 1).
Figure 1. CDS Alert logic

The first alert ("BMI not recorded") prompted clinicians to record BMI for patients age 18 years or older who did not have a recorded BMI in the prior 6 months (Figure 2).

Figure 2. Screenshot of alert: BMI not recorded.

For patients who did have a BMI recorded during the prior 6 months, the second alert ("Overweight, document follow-up plan") identified patients aged 18-64 whose most recent BMI recording during the prior 6 months was >= 25 and patients of age>65 years with BMI >=30 and prompted clinicians to document a weight loss plan (Figure 3).

Figure 3. Screenshot of alert: Overweight, document follow-up plan

The third alert ("Underweight, document follow-up plan") identified patients aged 18-64 whose most recent BMI recording during the prior 6 months was <18.5 and patients of age>65 years with BMI <23 and prompted clinicians to document a weight gain plan (Figure 4).
In the PF-EHR, BMI is auto-calculated when height and weight are documented in the vitals area of the patient chart, so for this study, BMI documentation equates to documentation of height and weight. In addition, documentation of a BMI related follow-up plan was counted when a clinician indicated in the assessment area of the patient chart that they performed one of two follow-up plans: “Calculated BMI above normal parameters and a follow-up plan was documented” or “Calculated BMI below normal parameters and a follow-up plan was documented”. The list of follow-up plans that clinicians could choose from were BMI follow-up plans available in the PF-EHR as a structured data associated to SNOMED concepts: weight controlled education (procedure), nutrition counseling, nutrition supplement (dietary) therapy, peripherally acting anti-obesity drug, counseling about physical activity (exercise), referral to weight maintenance regimen service, bariatric operative procedure (surgery), and next appointment.

The CDS logic for all three alerts excluded pregnant women, patients who received palliative care, refused BMI measurement, were in an urgent or emergent medical situation where time was of the essence and to delay treatment would jeopardize the patient’s health status, or any other reason documented in the medical record by the clinician explaining why BMI measurement was not appropriate during the timeframe.

**Measuring Effectiveness**

Test (4,987 practices, 33,445 clinicians) and control groups (881 practices, 6,316 clinicians) were selected prior to the program using a stratified random sampling method at the practice level. Eligible practices (5,871) were chosen based on history of patients meeting the CDS alert criteria (previous patients with BMI recorded and previous diagnosis of obesity). Practices were then stratified on all combinations of the following: tertiles of number of active patients per practice, tertiles of total visits by patients, tertiles of BMI values, tertiles of counts of BMI Screening/Intervention/Assessments, tertiles of visits by patients diagnosed with obesity, tertiles of number of MDs and NPs per practice and specialties (PCPs (Family Medicine, Internal Medicine, and General Practice), Obstetrics and Gynecology, Endocrinology), geographic region (West, Southwest, Midwest, Southeast, and Northeast). 15% of practices from each stratum were randomly selected for inclusion into the control group (strata combinations with less than 5 practices were combined and randomly sampled). The remaining practices comprised the test group.

Non-parametric Mann-Whitney tests were performed for continuous parameters and Chi-squared tests for categorical parameters to evaluate test and control group similarity. High p-values indicated that the control group adequately represented the test group (total visits by patients with a BMI captured (p=0.99), count of BMI follow-up plans documented (p=0.95), patients aged 65+ with low BMI (p=0.94), patients aged 65+ with normal BMI (p=0.88), visits by patients diagnosed with obesity (p=0.58), specialty (p=0.72), number of MD/NP clinicians per practice (p=0.99), number of active patients per practice (p=0.86)).

Test and control practices were monitored through a baseline period from 8/1/2014 to 11/30/2014 and through the CDS alerts program period from 12/1/2014 to 3/31/2015. CDS alerts were not shown to the control group, however visits where the CDS criteria were met were recorded for comparison. Percentage of visits for BMI recorded for visits where alerts shown (test group)/alerts should have shown (control group) were calculated and compared for the program period. The study did not continue past 4 months due to changes of the BMI documentation user-interface on the PF-EHR platform which changed the conditions of the study.

**Results**

During the 4 month program period, of the 39,761 clinicians in our program (33,445 test, 6,316 control), 11,123 clinicians were alerted. The alerted clinicians saw 1,154,304 distinct patients (981,155 test, 173,149 control) over 3,226,031 visits (2,766,603 test, 459,428 control). "BMI not recorded" was displayed to 8,856 clinicians and 285,947 patients, over 779,508 visits. Overall, percentage of visits with recorded BMI were equivalent between the test and control group (53.0% vs 53.6%, p=0.36, Figure 5).
However, for the subset of visits that were shown (test group) or were eligible for (control group) the "BMI not recorded" alert, there was a significantly higher percentage of visits with recorded BMI in the test group than the control group (27.9% vs 12.1%, p < 0.01, Figure 6).

"Overweight, document follow-up plan" was displayed to 10,018 clinicians, attributed to 837,721 patients over 2,713,986 visits. 9.8% of alerted patients (82,170 patients) had a follow-up plan documented in the program period. Documentation of follow-up plan for overweight patients increased by a factor of 5 for most of the program period compared to the baseline period in the test group (Figure 7). A smaller factor increase was observed in the test group between 12/11/14 and 1/11/15 attributed with a decrease of office visits during the winter holiday. The control group had no change BMI documentation of follow-up plan for BMI between the baseline and program period.
“Underweight, document follow-up plan” was displayed to 7,036 clinicians, attributed to 92,309 patients over 311,382 visits. 7.7% of alerted patients (7160 patients) had a follow-up plan documented in the program period. Documentation of follow-up plan for underweight patients increased by a factor of 5 for most of the program period compared to the baseline period in the test group (Figure 8). A smaller factor increase was observed in the test group between 12/11/14 and 1/11/15 attributed with a decrease of office visits during the winter holiday. The control group had no change BMI documentation of follow-up plan for BMI between the baseline and program period for the control group.

Figure 8. Percent of visits with follow-up plan documented by week alerted with "Underweight, document follow-up plan"
Overall percent of visits with documented follow-up plans for abnormal BMI increased in the test group in the program period compared to the baseline period (1.24% vs 0.29%, p<0.01). The control group showed no difference in percent of visits with documented follow-up plans (0.26% vs 0.22%, p=0.80, Figure 9).

**Figure 9.** Percent of visits with documented BMI follow-up plan by week.

Weight control education (procedure), nutrition counseling, and nutrition supplement (dietary) therapy were the top three Follow-up plans documented (Table 1).

Patient Outcomes:

Differences in patient BMI recorded at the start of the program and the end of the program were examined for patients with visits that were alerted and that had at least one BMI recorded between 12/1/2014 and 12/31/2014 and at least one BMI recorded between 2/1/2015 and 3/31/2015. The first BMI recorded between 12/1/2014 and the last BMI recorded between 2/1/2014 and 3/31/2015 were compared.

Table 2 compares the impact of follow-up plans during the four-month follow-up period between the test and control groups. While the patients (18-64 years) in the test group did not lose weight, there is weak evidence that they gained less weight during the follow-up period than the control group (p=0.06). There was no significant difference in weight change for patients 65+ (p=0.40). While underweight patients (18-64 years and 65+) gained significantly more weight than those in the control group (p<0.01, p=0.02).

Discussion

Though we observed a small increase in BMI recorded for visits that received the “BMI not recorded” alert, the overall percentage of visits with a documented BMI did not change significantly. This suggests that the “BMI not recorded” alert is not as effective at a population level. However, the significant increase in percentage of documentation of follow-up plans indicate that follow-up plan alerts were effective in altering clinician behavior. Our study had a few limitations. Firstly, the follow-up period was relatively short. Although the follow-up period was short, we did see improved patient outcomes. Further studies with a longer follow-up periods are needed to confirm the positive outcomes. Secondly, test and control groups were chosen based on practice criteria. Future studies controlling better for patient demographics characteristics (such as more granular geography, age, socioeconomic characteristics, genomic traits, and co-morbidities) would provide additional insight on patient outcomes.

Conclusion

CDS systems are increasingly being adopted by the medical community to help clinician compliance with evidence based guidelines and best practices with the intent of improving patient outcomes. This study has shown that CDS systems can be an effective tool to help clinicians follow weight management clinical guidelines and improve patient outcomes.

Abstract
The Veterans Healthcare Administration (VHA) is developing a civilian referral system to address specialty access issues to VHA healthcare. Homeless women Veterans may not have the resources to navigate referral systems when travel to VHA Medical Centers (VAMCs) is limited, especially for family planning needs. Recent Texas legislation restricted funding to civilian, publically-funded family planning clinics, limiting comprehensive services. This study’s goal was to assess geographic availability of VAMCs and family planning clinics for homeless Texan women Veterans. We identified 3,246 Texan women Veterans, age 18-44y with administrative homelessness evidence anytime between 2002-2015. Significant clusters of homeless women Veterans were near VHA facilities, yet mean travel distance was 24.1 miles (range 0-239) to nearest family planning clinic compared to 82.6 miles (range 0.8-316.4) to nearest VAMC. Community clinics need ongoing civilian funding support if the VHA is to rely on their geographic availability as a safety net for vulnerable Veterans.

Introduction
Women Veterans are the fastest growing population of Veterans Health Administration (VHA) eligible users, nearly doubling in the past decade and numbering more than 2 million in 2015. \textsuperscript{1,2} Women Veterans who access care in the VHA are a vulnerable population with a high prevalence of medical and mental health comorbidities \textsuperscript{1,3}, military sexual trauma experiences \textsuperscript{4}, and have a 4-fold increased risk of homelessness compared to the civilian population \textsuperscript{5}. In order to meet the unique needs of this growing population, the VHA prioritized expansion of comprehensive primary care that includes reproductive health care by a single, women’s health provider.\textsuperscript{6} This comprehensive care should include family planning services but may require travel to an urban, Veterans Healthcare Administration Medical Center (VAMC) for more advanced services, such as insertion of an intrauterine device (IUD), due to provider availability or training.\textsuperscript{7} To avoid this travel barrier, the VHA is increasingly developing policies to partner with healthcare providers closer to Veterans’ homes.\textsuperscript{8} This community referral process (Veterans Choice Program) can be challenging for Veterans to utilize. They must first make contact with a VHA provider through a VAMC or Community-Based Outpatient Clinic (CBOC), obtain a referral for non-VHA or “Choice” care, wait for an authorization process, and then wait until an appointment is scheduled with an eligible civilian provider. Unfortunately, this practice only works if trained civilian providers are geographically accessible to meet the Veterans’ needs.

Homeless women are at increased need for family planning services, due to elevated risks for sexual trauma and infections (STIs), unintended pregnancy, and adverse outcomes, such as preterm birth.\textsuperscript{9,13} Women Veterans are at greater risk for homelessness than civilian women due to the prevalence of military sexual trauma (MST), unemployment, disability, poor overall health, and anxiety disorders or post-traumatic stress disorder.\textsuperscript{14} Homeless women Veterans are highly reliant upon the VHA and, unlike Veterans with more resources, may not be able to overcome travel barriers or the logistics of the “Choice” referral process to access family planning services-especially for more time-sensitive needs, such as access to emergency contraception or STI treatment. Additionally, they are less likely to have public or private insurance to access non-VHA care through civilian healthcare providers, thus publically-funded family planning clinics are their safety net for services. Publically-funded clinics typically rely upon Title X federal funding, payments from Medicaid insurance plans, and state-funded family planning waivers, with federal policies requiring all qualified providers remain eligible to participate in care funded
by these federal programs. Recent political challenges to this healthcare infrastructure have progressed in several states and at a national level and Texas became the first state to enforce a string of legislative initiatives beginning in 2011 that drastically impacted publically-funded family planning clinics. These initiatives excluded Planned Parenthood clinics from federally funded programs, diverted family planning funds to other government programs, and shifted funds from comprehensive family planning providers to those with limited service abilities. By 2015, 25% of publically-funded Texas family planning clinics had closed. Additionally, clinics offering comprehensive contraceptive services, including IUD placement, decreased from 71% to only 46% of those remaining, and Medicaid-funded childbirths had risen.

In order for the VHA to ensure the family planning needs of women Veterans are met, an assessment of safety net services, especially in rural settings where VAMCs are not accessible and many high-risk women Veterans reside, needs to be completed. Texas is an extreme example with several years of data on the impact of restrictive funding changes for these clinics. Some of these same changes, such as exclusion of Planned Parenthood clinics from Medicaid funding and limiting Medicaid and Title X coverage, are being considered at a national level as part of the debate over U.S. healthcare coverage. These changes would further limit Veterans from seeking care outside the VHA, even when VHA clinics are geographically distant for impoverished Veterans. Therefore, the objectives of this study were to assess the geographic availability of VAMCs and publically-funded family planning clinics for homeless Texan women Veterans through information visualization tools. This work is a necessary first step to develop geographic interventions to improve gender-specific care within the VHA or guide policies for non-VHA care, as each region will likely have unique needs.

Methods
The University of Utah Investigational Review Board and the Research and Development Committee at the Veterans Administration Salt Lake City Health Care System approved this study.

We identified women Veterans in the state of Texas with administrative evidence of homelessness at any time ("ever-homeless") who accessed the VHA between fiscal years (FY) 2002-2015 using a national VHA research database of administrative and clinical data managed by the Veteran’s Informatics and Computing Infrastructure (VINCI). We included only women Veterans age 18-44y in birth cohorts for each fiscal year. Homelessness was identified through International Classification of Diseases, Ninth Revision (ICD-9) codes, Homeless Care stop codes, or treatment specialty codes. In reality, the exact moment a Veteran becomes homeless is known only to the Veteran or those close to them. They come to the attention of the healthcare system when they have been identified as being homeless by a provider and coded in administrative data based on statements by the Veteran regarding housing instability or an interest in VHA homeless services that are available to those experiencing homelessness. This method of identifying homelessness among Veterans using administrative data has been validated and has been peer-reviewed and published by the Office of Inspector General of the US Department of Veterans Affairs and VHA researchers. Thus, in this study, we use administrative data to identify those women Veterans who are experiencing homelessness and have been noted as such in VHA electronic data.

Demographic variables included age at entry into VHA services, marital status, race/ethnicity, and religious affiliation. Military characteristics included branch of service, combat exposure, and results (positive or negative) of screening for a history of military sexual trauma (MST) in VHA. While MST status was not routinely screened for, or reliably captured, in structured data until 2004, Veterans who accessed care prior to 2004 were screened at follow-up encounters.

We defined the geographic “residence” of the homeless women Veteran’s last known zip code reported at the VHA site where the homelessness designation was made. For women with only post office box (PO Box) numbers, we assigned the associated zip code as their “residence”, as the PO boxes were assumed to be in close proximity to where the homeless women Veterans were staying. The population density of homeless women Veterans per zip code were plotted on a map with locations of VAMCs. The geographic distribution of all 18-44-year-old women Veterans using county-level counts from the National Center for Veterans Analysis and Statistics of women veterans were used as map background.

Travel distance was measured first as the number of drive miles between the Veteran’s “residence” zip code and the nearest Texas VAMC. Drive distance was calculated as miles using a 2010 network of roads and using the “Closest Facility” method in the Network Analyst extension of ESRI’s ArcGIS software suite. To visualize the change in availability of publically-funded family planning clinics before and after the exclusion of Planned Parenthood, we mapped all available Texas Planned Parenthood Clinics, as of 2010, using publically available county-level data.
from the Guttmacher Institute. To capture currently available (March 2017) publically-funded clinics that provide family planning services, we used publically-available data from the Texas Health and Human Services “Healthy Texas Woman” website and searched by zip code under “Find a Doctor”. We then geocoded these clinic addresses. Travel distance was calculated in the same manner as for distance to VAMCs, measured as the number of drive miles between the Veteran’s “residence” zip code and the nearest currently available clinic according to the Texas Health and Human Services website. Some clinics did not appear appropriate for homeless women Veterans, i.e. high school and teen health clinics, and were censored from analysis.

As the stage of Texas is geographically large with the bulk of the population clustered in several relatively urban areas, we used a local spatial statistic (Cluster and Outlier Analysis (Anselin Local Moran’s I), part of the spatial statistics extension for ESRI’s ArcGIS software suite) to identify zip codes that had non-random similarity and dissimilarity count values (both high and low values) of homeless women veteran as compared to neighboring zip codes. Results were expressed as Z scores, with high values indicating similarity with neighboring zip codes and low Z scores indicating dissimilar values, and as p-values. We also applied a false discovery rate correction to account for multiple testing dependency and spatial dependency (gives a more conservative answer). The method also classifies features that have statistically significant values according to how different their Z Score values.

Cluster: High are features with neighbors that have similarly high values, and High Outlier are features that have high values near neighbors with low values.

As the real-world travel burden (or the experienced conceptualization of space) is based on road travel distance rather than linear distance, we compared each zip code count value of homeless women veterans to its closest 30 neighbors where the neighborhood was defined as road distance. The reason for this approach is that while two points (an origin and a destination) can be linearly very close, actual travel may be much farther (and sometimes much farther) if a bona fide barrier (such as a mountain, valley, or river) prevents an approximate straight drive between the origin and destination. We reasoned, therefore, that a street network conceptualization of space was a more appropriate for comparing places.

We then mapped these analysis values to compare the results to the proximity of VHA facilities and to the countywide count of all women veterans of childbearing years. While CBOC VHA facilities do not routinely provide specialty family planning services, such as IUD placement, veterans who visit these facilities can be identified as being homeless or be referred for non-VHA/Choice care, and therefore we wanted to see if these facilities were also near significant clusters of homeless women veterans.

Results

We identified 41,747 women Veterans nationally with administrative evidence of homelessness who had accessed the VHA between FY2002-2015. We then limited the cohort to state of Texas zip codes only, resulting in 3,246 homeless Texan women Veterans for analysis. The majority (35%) was in the age group 18-34 years at time of entry into the VHA during the study period. Those included were most likely to have served in the army (59%) and had low combat exposure (10%). Most (48%) identified as African American and non-Hispanic (85%). The homeless women Veterans also had a high prevalence of being positive for military sexual trauma screening (39%).

Homeless women Veterans were frequently co-located in areas of high population density for all reproductive age women Veterans in Texas. High countywide counts of women veterans were located in counties with large cities, such as Dallas, Fort Worth, Houston, Austin, San Antonio, Corpus Christi, and El Paso. (Figure 1)

![Figure 1. Map: Geographic distribution of homeless women Veterans in relation to all reproductive age women Veterans and Veterans Healthcare Administration Medical Centers](image)

The mean distance from Texas Zip Codes to VAMCs was 82.6 miles (range 0.8-316.4). Counties with the greatest travel distance were in the far west near El Paso and far south near Brownsville, both along the Rio Grande River and sharing a national border with Mexico. (Figure 2)
We completed a cluster and outlier analysis for statistically significant clusters of homeless women veterans by zip code in relation to all reproductive age women veterans (represented in Figure 1 as shaded counties) and VHA Facilities. “Cluster: High” represents a statistically significant count near other features with high values, and “High Outlier” represents a statistically significant count near other features with low values. Homeless women veterans tended to be clustered around VA facilities (both VAMC and CBOC) in counties that had general high counts of women veterans. Of Texas’ 2,629 Zip codes, 90 (almost all in relatively urban areas) were classified as “Cluster: High” and three were “High Outlier” (two in El Paso and one in Houston), representing 1,286 (40%) of the 3,246 homeless women veterans. While there was no overall clustering of homeless women veterans in El Paso, there were two zip codes with in the city of El Paso with counts high enough to be considered statistical outliers. Notably, the headquarters for the active Army base, Fort Bliss, is in El Paso. (Figure 3)
The number of publically-funded family planning clinics decreased starting in 2011, following the exclusion of Planned Parenthood Clinics from funding sources, and other clinics were added as funding recipients, even though they do not provide comprehensive family planning services. To represent these changes, we explored the drive distances from zip codes to current publically-funded family planning clinics (as of March 2017) and also show the count by county of formerly funded 2010 Planned Parenthood Clinics. As of March 2017, homeless women Veterans have a mean drive distance of 24.1 miles (range 0-239) to the nearest publically-funded family planning clinic. In particular, Planned Parenthood Clinics formerly had a heavy concentration in the far south, which now require some of the longest driving distances for women to access care at currently funded clinics. (Figure 4)
Discussion

In order to overcome access barriers to specialty care, the VHA is increasing the focus on community civilian partners to meet the healthcare needs of the Veteran population. High-risk, homeless women Veterans may not be able to navigate the often complex process to access this option, yet they still need the same civilian healthcare safety net that non-Veterans use, especially for family planning services. Women with a history of military or lifetime sexual trauma and homeless women are vulnerable populations at increased risk for repeat sexual trauma. The high prevalence of MST in this study population highlights the needs for access to reproductive healthcare. In using Texas as an example of the impact of restrictive legislative family planning policies, we found publically-funded family planning clinics are more geographically accessible than VAMCs for homeless women Veterans. Unfortunately, these clinics do not routinely provide comprehensive family planning service, especially in more rural areas, as funding changes limit services, close clinics, and uproot affiliated healthcare providers. Ongoing assessments of comprehensive Texas family planning services found clinics were able to serve 54% fewer clients between 2011 and 2021-2013. In a similar comparison to our results, closure of Texas abortion clinics resulted in increased one-way travel distance for women from 22 miles to 85 miles with additional out of pocket expenses and reported difficulty in clinic access. Public or private insurance coverage and non-VHA/Choice benefits will not increase access, when trained providers are not geographically available to accept the coverage. Additionally, the most socio-economically disadvantaged women will not be able to access coverage options, as many of the same states with the most restrictive Medicaid eligibility requirements are also states without family planning waivers or national family planning Title X clinic funding to fill gaps for uninsured women.

National VHA priorities include improved access to healthcare for women and homeless Veterans, and family planning services are an essential component of preventive healthcare. Despite these commitments, many women Veterans currently bypass VHA services due to lack of availability of gender-specific care, confusion regarding VHA eligibility and travel distance to the nearest VHA facility. Longer drive time is also associated with attrition from VHA health care in women Veterans, identifying a continued need for improvement in service provision.
VHA policies and priorities attempt to standardize healthcare services and quality across the nation. Despite these goals, there are vast geographic differences for Veterans to access publically-funded, civilian services between “conservative” states like Texas and more “liberal” states such as California, where family planning services and providers are abundant due to MediCal coverage and Title X funded clinics. As the nation weighs conservative changes to federal family planning funding and restructuring of the entire VHA referral system, the adverse outcomes seen in vulnerable Texan women and the resultant impact on our women Veterans needs to be considered.

We acknowledge several limitations of this study. The use of structured data to identify homelessness among women Veterans may lead to misclassification of their true homelessness status. We also looked at any housing instability (ever homeless), instead of a limited timeframe around homeless designation. Even though homelessness is not typically a constant over many years, many socio-economic stressors pre-date and persist beyond the administrative capture of homelessness and would likely result in the need for healthcare safety net clinics. We made the assumption that homeless women Veterans who cannot access care at a VAMC would also have challenges in accessing a non-VHA/Choice referral allowing for clinical coverage outside of publically-funded clinics. The VHA will pay for transportation for many Veterans who are eligible for this benefit, dependent upon level of disability or service-connection, but the Veteran again needs to navigate the system to access this coverage option. The current clinic mapping does not include homeless clinics that may offer some free family planning services, but previous literature shows family planning options are highly variable and limited in these settings.

Conclusions

In summary, homeless women Veterans represent the most vulnerable subset of women Veterans at greatest risk for adverse reproductive outcomes. Current restrictive funding changes have limited the safety net services of publically-funded family planning clinics in the state of Texas, despite the improved geographic availability of these clinics over VAMCs. As national efforts are underway to establish civilian care as the “cure” to access issues within the VHA, the impact of civilian funding changes in Texas on the availability of family planning services and providers for women Veterans need to be considered. The current push to exclude Planned Parenthood clinics from federal funding will increase the unmet need of comprehensive family planning services nationwide, including for our vulnerable homeless women Veterans.

Quantifying the Impact of Trainee Providers on Outpatient Clinic Workflow using Secondary EHR Data

Isaac H. Goldstein2, Michelle R. Hribar, PhD1, Sarah Read-Brown2, Michael F. Chiang, MD, MA1,2

1Medical Informatics & Clinical Epidemiology, and 2Ophthalmology
Oregon Health & Science University, Portland, OR

Abstract

Providers today face productivity challenges including increased patient loads, increased clerical burdens from new government regulations and workflow impacts of electronic health records (EHR). Given these factors, methods to study and improve clinical workflow continue to grow in importance. Despite the ubiquitous presence of trainees in academic outpatient clinics, little is known about the impact of trainees on academic workflow. The purpose of this study is to demonstrate that secondary EHR data can be used to quantify that impact, with potentially important results for clinic efficiency and provider reimbursement models. Key findings from this study are that (1) Secondary EHR data can be used to reflect in clinic trainee activity, (2) presence of trainees, particularly in high-volume clinic sessions, is associated with longer session lengths, and (3) The timing of trainee appointments within clinic sessions impacts the session length.

Introduction

Outpatient healthcare clinics face ongoing pressures to see more patients in less time due to concerns about the accessibility and cost of healthcare.1,2 Significant challenges can impede outpatient clinic efficiency including increased patient demand with limited clinic resources, ad-hoc scheduling methods, increased clerical burdens and possible negative effects of the introduction of electronic health records (EHRs).3–6 Given these pressures and challenges, methods to study and improve clinical workflow are becoming ever more significant. In previous studies, we developed methods to improve clinic workflow through secondary use of EHR timestamps and discrete event simulation.7,8 These results showed how EHR timestamps adequately approximated clinic workflow timings for use in large scale simulations. In this study, we make use of EHR timestamps in order to address an important unanswered question: the impact of trainee providers on academic outpatient clinic workflow.

In its Common Program Requirements, The Accreditation Council for Graduate Medical Education (ACGME) states that “The specialty education of physicians to practice independently is experiential, and necessarily occurs within the context of the healthcare delivery system”.9 Despite this commitment to train within the health care system, there are few studies on graduate medical education’s impact on outpatient clinics, and many have been small in size and have had conflicting findings. For example, two studies found trainees improved workflow by shortening patient wait times,10,11 while a different study found trainees lengthened appointment times.12 More recently, we conducted a large scale investigation of the relationship between presence of trainees and outpatient appointment length and found that appointments with trainees were significantly longer than appointments without trainees (Goldstein, IH et al. IOVS 2017 58: ARVO E-Abstract 5060). Spurred on by the high demand for emergency physicians and the association between emergency department crowding and adverse health outcomes, a number of research groups have quantified and refined the impact trainee providers have on the workflow of emergency departments.13–15 Some groups found trainees are associated with both length of stay and the number of patients who leave without being seen, while others have found the association was negligible.16–18

This sparse and conflicting literature leaves many unanswered questions about the relationship between trainees and outpatient clinic workflow. This study utilizes EHR data to quantify the impact of residents and fellow trainees on half-day clinic sessions in an outpatient ophthalmology clinic. Our results show that trainees can impact the overall length of clinic sessions significantly, with implications for secondary use of EHR data, clinic efficiency, and provider reimbursement models.
Methods

This study was approved by the Institutional Review Board at Oregon Health & Science University (OHSU).

Study Environment

OHSU is a large academic medical center in Portland, Oregon. The department of ophthalmology includes over 50 faculty providers who perform more than 115,000 outpatient examinations annually. The department provides primary eye care, and serves as a major tertiary referral center in the Pacific Northwest and nationally. Typically, the department has 15 residents and 10 fellows per academic year.

EHR Dataset

For our study, we identified “stable faculty providers” who worked at OHSU for at least 6 months before and after the study period. This minimized bias from providers with growing or shrinking clinical practices. Providers who did not have a standard clinical practice, who did not use the EHR, who had a small number of appointments with trainees (less than 3), or who had only appointments with trainees were excluded. Demographics for study providers and trainees (gender, age, and ophthalmic sub-specialty) were gathered using publicly-available data. We queried check in and check out times, as well as the primary billing code, from OHSU’s clinical data warehouse (EpicCare; Epic Systems, Verona, WI).

Determining the involvement of a trainee in patient encounters is not straight forward given that there isn’t a standard method for recording when trainees participated in encounters. For the purposes of this study, we considered trainees to be involved in the appointment if there was a record in the EHR encounter. This record can appear in several areas; we used audit log entries as markers for trainee activity. We measured the time that trainee providers used the EHR during each patient appointment, while the patient was checked in. A trainee was considered present for an appointment if they used the EHR for more than two minutes during the patient’s appointment (sometimes called trainee appointments in this paper). Appointments were excluded if they were missing either a check-in or checkout time, if there was a non-physician trainee present, or if there were two of the same kind of trainee present. The final exclusion criteria eliminated 50 appointments and focused our data on common workflows with physician trainees.

From this data set of appointments, we aggregated the encounter data into half-day clinic sessions. Session length, the dependent variable in our models, was calculated as the first patient check-in time of the session subtracted from the last patient checkout time of the session. A trainee session was defined as a half-day clinic session with more than one patient appointment in which a trainee was present. Because volume is a big determinant of the length of a clinic session we included patient volume as a factor in our model. To simplify analysis, we categorized clinic sessions as low, medium, and high. A low patient volume session was defined as one with ≤6 patients, a medium patient volume session was defined as one with 7-14 patients, and a high patient volume session was defined as one with >14 patients.

Data Validation

To validate our method of using audit log entries to determine the presence of a trainee in an appointment, we (SRB) conducted a thorough manual chart review of 50 appointments, and determined whether or not a trainee was present for the appointment if one or more of four criteria were met:

1. Attestation: The provider specifically affirmed they reviewed the activity of a trainee provider.
2. Revision History: The chart’s revision history showed activity by a trainee provider during the exam.
3. Edited Exam Element: The chart showed a trainee provider edited exam elements.
4. Signature: A trainee provider signed the note following the exam.

We then compared the study’s method for determining the presence of trainees, as well as each of the four criteria individually, to the results of this chart review. We further tested the robustness of our method of using 2 minutes of audit log activity by creating new data sets with adjusted time cutoffs and comparing them to the original.

Exclusions

Because we are studying the effect of trainees on regularly scheduled clinic sessions, we excluded sessions whose patient volume was in the bottom quartile for that session’s provider. These low volume sessions typically represent limited clinic sessions (e.g. a few post-op appointments on a non-clinic day). Since some of our analysis involved
dividing clinic session into quartiles, we excluded all sessions with fewer than four appointments. Finally, we 
excluded one outlier session with a session length of 16 hours, which was due to an invalid checkout time.

Data Analysis
To analyze the impact of trainees on session length, we constructed multiple linear and linear mixed models with 
interacting terms. Models were used to analyze the impact on session length of: (1) the presence of trainees in a 
session (2) the percentage of trainee appointments in a session (3) the length of trainee appointments, and (4) the 
timing of trainee appointments. For the linear mixed models without interacting terms, p-values were obtained 
through type II Wald chisquare tests, for those with interacting terms, multiple comparisons and the Holm-
Bonferroni method were used. For all tests, significance was defined as p<.05. All data processing and statistical 
calculations were conducted in R
, models were constructed via lme4, p-values were calculated via the Anova 
function from the car package, and the glht function from the multcomp package.

Table 1. Characteristics of faculty ophthalmology providers, residents and fellows.* Demographic information for the providers and trainee 
providers, as well as summary statistics for the study appointments and sessions.

* Providers were identified based on having worked at the study institution for 6 months before and after the study period.
† Age and length of practice are calculated based on the beginning of the study period Jan 1, 2014.
‡ Because of rounding, the percents do not add to 100
§ Trainee appointments have either residents, fellows, or both. Note the number of trainee appointments is the not the sum of the resident appointments and the 
fellow appointments, as some appointments have both. The total number of trainee appointments was 10635
ǁ Trainee Sessions have two or more resident or fellow appointments per session. Note the number of trainee sessions is the not the sum of the resident 
and the fellow sessions, as some sessions have both. The total number of trainee sessions was 1557

The time period of this study was from January 1, 2014 to December 31, 2014. Data regarding attending faculty providers are shown in Table 1. There were 33 faculty attending providers who met study inclusion criteria. These 
faculty providers had 3,764 half-day clinic sessions which met study criteria, of which 1,557 were trainee sessions.
In total 12,247 appointments and 2,197 sessions were excluded.

Low volume sessions had on average 5 appointments, medium volume sessions had on average 10 appointments, high volume sessions had on average 19.8 appointments. Low volume trainee sessions had on average 3.4 trainee appointments, medium volume trainee sessions had 5.2 trainee appointments, and high volume trainee sessions 9.8 trainee appointments. In this study, 39.4% of providers were female, and the median age was 44.0 years. Twelve different ophthalmic sub-specialties were represented, with the largest numbers in glaucoma, pediatrics, and retina (N=4 each).

During the calendar year, there were 10 Post Graduate Year (PGY) 2 and PGY-3 residents, 9 PGY-4 residents, and 23 fellows. As our data are from the calendar year 2014, these numbers represent two different classes of trainee providers: the 2013-2014 year, and the 2014-2015 year.

Validation and robustness of trainee identification method

Table 2 shows the validation results of comparing our method of using audit log entries to manual chart review. Of the methods tested, only this study’s method based on audit log entries had a sensitivity score of 1, it also was the only method with a specificity score less than 1, with a score of .97. In addition to validating our method, we also wished to test its robustness. To this end we created two additional data sets, one where a trainee was present if for more than one minute a trainee used the EHR during the exam (>1), and another where a trainee was consider present if for more than three minutes a trainee used the EHR during the exam (>3), and compared the number of appointments with trainees, number of sessions with trainees, and model impact of the presence of trainees on session length to those of the study’s data set (>2), shown in Table 3. As the definition was loosened or restricted, the appointments and sessions with trainees increased and diminished predictably, with >3 having the largest difference in trainee appointments with an 8.6% decrease compared to >2. Notably, for all three data sets, the model impact of the presence of trainees on session length (discussed below) was significant, and the size of the impact was similar.

Association of presence of trainees and session length

Figure 1 summarizes the session data regarding the association of presence of trainees with session length, and shows the spread of session lengths for trainee vs. non-trainee sessions, grouped by patient volume to help eliminate differences due to the number of patients seen at the clinic. For each category of patient volume, the median session length for trainee sessions is larger than the median session length of non-trainee sessions. To see when the presence...
of trainees produced a significant difference in session length, we must also consider the effect of providers on this difference. We constructed a linear mixed model where half-day clinic sessions were the input and session length the output, the fixed effect was the presence of trainees, the random effect was providers. This model showed that trainee sessions were associated with an increase of 10.3±2.4 minutes compared to non-trainee sessions (p<.001). To further analyze this effect, we added patient volume as an interacting fixed effect along with the presence of trainees. This more detailed model showed that high volume sessions with trainees were associated with an increase in session length of 21.0±3.9 minutes (p<.001), but the association was not significant for medium and low volume sessions.

**Association of percentage of trainee appointments and session length**

---

**Figure 1: Distribution of trainee and non-trainee session lengths.** Boxplots of session length, grouped by volume and presence of trainees. In all Categories, session length varies greatly, though the median session length of sessions with trainees is larger than the median session length of sessions with no trainees.

**Figure 2: Percent trainees versus session length.** We compared the percent of a session’s appointments which were trainee appointments to session length. For all volume groups, as the percentage of trainee appointments increases, so too does average session length. Trend lines are significant with p<.001. Thin lines are 95% confidence intervals.
We next analyzed the association between the amount of trainee activity and clinic session length. Figure 2 displays the session data regarding this association with sessions grouped by their volume label. All three trend lines were significant, with low volume sessions seeing an increase of 3.5±.7 minutes per 10% increase, medium volume sessions seeing an increase of 2.8±.5 minutes per 10% increase, and high volume sessions seeing an increase of 2.8±.8 minutes per 10% increase.

To test this further, we developed another linear mixed model with the percentage of trainee appointments as the fixed effect, and the individual providers as the random effect. This model showed that the percentage of trainee appointments was associated with an additional .86±.4 minutes per 10% increase (p<.03). When this model was expanded to take patient volume per half-day clinic session into account, the impact of the percentage of trainee appointments was significant for high patient volumes, with an impact of an additional 2.1±.6 minutes per 10% increase (p<.004).

**Trainee appointment length**

Next, we investigated how the length of trainee appointments affected clinic length. To assess this, we used a ratio of a session’s average trainee appointment length compared to the session’s provider’s average appointment length for appointments from sessions with no trainees. Table 4 shows the results of our linear mixed models: the ratio and patient volume are interacting fixed effects and the providers are the random effect. Overall, an increase in the ratio was associated with a significant increase in session length of 7.1±.5 minutes per 10% increase, with the greatest increase for high volume sessions. This association was significant for all patient volumes (p<0.001).

**Trainee appointment timing**

Finally, we analyzed the association of the timing of trainee appointments and session length. For these tests, we divided each session into quartiles (roughly representing each hour of the session) and labeled each appointment with the quartile when it occurred.

As described above, low volume trainee sessions had on average 3.4 trainee appointments, medium volume trainee sessions had 5.2 trainee appointments, and high volume trainee sessions 9.8 trainee appointments. Keeping this in mind, the first conditions we developed were based on patient volume, and tested whether it mattered when a corresponding number of minimum trainee appointments occurred. For example, there were on average 5.2 trainee appointments in each medium volume session, meaning at least one quartile had 2 trainee appointments. Thus one condition tested was “two or more trainee appointments in the 1st quartile.”

Our only significant result from these tests was from testing the conditions “3 or more trainees in the nth quartile” among high volume sessions (N=1068). To test these conditions we created a model where the fixed, independent effects were the true/false conditions “3 or more trainees in the 1st, 2nd, 3rd or 4th quartile” and the random effect was patient volume. The only condition which proved to be significant was “3 or more trainees in the 1st quartile”, which was associated with an increase in session length of 27.8±6.0 minutes (p<.001).

Moving from absolute numbers of trainees, we examined a variety of conditions concerning the percentage of overall trainee appointments that occurred in a particular quartile of the clinic. For these conditions we used the full data set and a model with a true/false rule interacting with patient volume as the fixed effects, providers as the random effect. Our analysis showed that for high volume sessions, meeting the condition that 60% of their trainee appointments were in the first half of the session was associated with an increase in session length of 10.4±3.2 minutes (p<.002).

*Reported as minutes per 10% increase in trainee appts.

Table 4: Association of the ratio of average trainee appointment time to average provider non-trainee appointment time with session length. For trainee sessions we looked at the ratio between the session's average trainee appointment length and the session's provider's average appointment time from sessions with no trainees. As the ratio increases in size, session length also increases, both overall and for all patient volumes. P-values were calculated via Wald type II chi squared tests and multiple comparisons and the Holm-Bonferroni method.
Lastly, we tested the condition “One or more trainees in the last quartile.” The model was constructed similarly to the previous one, using the full data set and patient volume as an interactive term. For high volume sessions, meeting this criteria was associated with an increase of 20.1±3.7 minutes (p<.001), for medium and low volume clinic sessions there was no significant difference. When volume was not included in the model, meeting this criteria was associated with an increase in session length of 12.1±2.4 minutes (p<.001).

Discussion

There were three key findings from this study: (1) Secondary EHR data can be used to reflect in-clinic trainee activity, (2) presence of trainees, particularly in high-volume clinic sessions, can be associated with longer session lengths, and (3) the timing of trainee appointments within clinic sessions is associated with session length.

The first key finding is that EHR data can be used to reflect in-clinic trainee activity. For this paper we determined that a trainee was present for a patient appointment if for more than two minutes a trainee provider used the EHR during the appointment. When we tested this method for sensitivity and specificity, both scores were extremely high (Table 2). While manually reviewing a patient’s revision history proved to be nearly as sensitive and more specific, our method is considerably faster. Though some form of automation could be developed to review revision history, this would be somewhat cumbersome, and given the success of our method, we believe it to be a good choice for this kind of analysis.

While numerous papers have been written using EHR data to answer clinical questions, and a robust literature of time motion studies analyze clinic workflow, few studies have used big data repositories of EHR data to address issues of clinic workflow. It is possible that one of the reasons so few studies considering the relationship between trainees and workflow in outpatient clinics exist because determining when trainees see patients by any other means is a prohibitively resource intensive endeavor. Our study provides one way to address this issue.

The second key finding is that presence of trainees, particularly in high volume clinic sessions, can be associated with longer session lengths. Overall, the presence of trainees in a half-day clinic session was associated with a ten minute increase in session length. However, once volume was included into the model, this association was only significant for high volume clinic sessions (sessions with more than 14 patients), which were about 20 minutes longer. Additionally, our study found that, for high volume sessions, as the percentage of appointments seen by trainees increases, so too does session length, suggesting that not only the involvement of trainees, but the degree of the involvement can affect session length.

While we found on average that appointments with trainees are longer than appointments without trainees, this is certainly not always the case. We were interested in how much the length of a trainee appointment was related to session length, but wanted to account for the fact that trainee appointments are not always longer than non-trainee appointments. Thus, we developed the ratio of a session’s average trainee appointment length to the session’s provider’s average non-trainee appointment length, to focus in on what happened as the length of trainee appointments became significantly longer than non-trainee appointments. Our results found that, for all patient volumes, as this ratio increased so too did session length (Table 4).

To our knowledge, there has been little research on the relationship between trainees and session length. One paper used simulations to predict that trainees would shorten both appointment time and session length, however the simulation was never corroborated with collected data. We believe our large scale-retrospective study gives a more accurate sense of the relationship between trainees and session length. Our results are also consistent with our previous study concerning trainees and outpatient clinic efficiency, which found that appointments with trainees are on average longer by 25 minutes, and that in some cases even appointments where no trainee was present from a trainee session may have longer appointment times (Goldstein, IH et al. IOVS 2017 58: ARVO E-Abstract 5060). We hypothesized this was because trainees were introduced as an additional step in the workflow of an appointment, leading to lengthened times and sometimes resource bottlenecks, which would also contribute to longer session lengths.

The third key finding is that timing of trainee appointments within clinic sessions is associated with session length. One goal of this study was to investigate not only if it mattered whether trainees were present during a clinic session,
but also if it mattered when they saw patients. In total we found three conditions concerning the timing of trainee appointments that, when met in high volume clinic sessions, led to increases in session length of 20-30 minutes. Our study found that concentrating trainee appointments in the first half of the session (in particular the first quarter) led to longer session lengths, probably caused by workflow bottlenecks created due to longer appointment times (Goldstein, IH et al. IOVS 2017 58: ARVO E-Abstract 5060). Our study also found session length increased when trainee appointments were concentrated in the last quarter of the session, this is probably because longer appointment times at the end of the day push back the final checkout time, and thus lengthen the session.

Together, these key findings tell us that trainees can be associated with a significant negative impact on clinic efficiency, and that this impact is affected by a variety of factors concerning trainee involvement, activity, and timing. While it seems unlikely that clinics could change the way trainee providers are involved in appointments due to educational factors, these findings at least help academic providers better understand how trainees affect their clinic workflow.

With MACRA, the United States is continuing to transition toward “value-based” models of provider reimbursement, which are based on a combination of quality and cost of care. Key findings 2 and 3 highlight a structural characteristic of academic outpatient clinics that should perhaps be considered as reimbursement models are refined, because presence of trainees is associated with increased time – and therefore lower efficiency. Specifically, our results suggest that, due to the presence of trainees academic outpatient providers see fewer patients in a given period of time than non-academic outpatient providers.

Limitations

There were several study limitations that should be highlighted. (1) There is a great deal of variance associated with clinic session length that is not associated with trainees. This most likely is why so many of the rules we tested failed, notable ones included: the percentage of trainee appointments in any given quartile of the clinic session, the number of trainee appointments in quarter four, and the lack of trainee appointments in quarter four. The fact that we could not establish significance for these factors does not speak to whether or not they are actually important factors in determining session length, simply that we were unable to do so with our data set and models. Further research seems warranted to help correct for this variance. (2) It is worth noting that we calculated session length using appointment checkout times, which may not be correct due to staff delays. This may also contribute to some of the variance in our models. (3) Finally, this study only considers appointments where trainees used the EHR as part of their involvement, there are training activities that do not involve the EHR which our study fails to take into account. Other research modalities would seem to be necessary to address limitations 2 and 3.

Conclusion

We have shown that secondary EHR timestamp data may be applied to arrive at important and timely conclusions about the impact of trainees on clinic workflow. Findings from this study demonstrate that presence of trainees is associated with longer clinic session lengths, and may have implications for clinical care, medical education, and policymaking regarding provider reimbursement.

Inferring Clinical Correlations from EEG Reports with Deep Neural Learning

Travis R. Goodwin, MS, Sanda M. Harabagiu, PhD
The University of Texas at Dallas, Richardson, TX, USA

Abstract

Successful diagnosis and management of neurological dysfunction relies on proper communication between the neurologist and the primary physician (or other specialists). Because this communication is documented within medical records, the ability to automatically infer the clinical correlations for a patient from his or her medical records would provide an important step towards enabling health care systems to automatically identify patients requiring additional follow-up as well as flagging any unexpected clinical correlations for review. In this paper, we present a Deep Section Recovery Model (DSRM) which applies deep neural learning on a large body of EEG reports in order to infer the expected clinical correlations for a patient from the information in a given EEG report by (1) automatically extracting word- and report-level features from the report and (2) inferring the most likely clinical correlations and expressing those clinical correlations in natural language. We evaluated the performance of the DSRM by removing the clinical correlation sections from EEG reports and measuring how well the model could recover that information from the remainder of the report. The DSRM obtained a 17% improvement over the top-performing baseline, highlighting not only the power of the DSRM but also the promise of automatically recognizing unexpected clinical correlations in the future.

Introduction

Diagnosing and managing neurological dysfunction often hinges on successful communication between the neurologist performing a diagnostic test (such an Electroencephalogram or EEG), and the primary physician or other specialists. In 2005, Glick et al. studied malpractice claims against neurologists and found that 71% of the claims arose from “an evident failure of communication by the neurologist” and that the majority of the claims resulted from deficient communication between the neurologist and the primary physician or other specialists. In addition, Glick et al. found that 62.5% of claims included diagnostic errors and that 41.7% involved errors in “ordering, interpreting, and reporting of diagnostic imaging, follow-through and reporting mechanisms.” It is expected that these types of errors could be reduced, and communication could be improved by developing tools capable of automatically analyzing medical reports. Moreover, a recent Institute of Medicine Report advocated the need for decision-support tools operating on electronic health records for primary care and emergency room providers to manage referral steps for further evaluation and care of persons with epilepsy. Specifically, the ability to automatically extract and analyze the clinical correlations between any findings documented in a neurological report and the over-all clinical picture of the patient, could enable future automatic systems to identify patients requiring additional follow-up by the primary physician, neurologist, or specialist. Furthermore, systems capable of automatic analysis of the clinical correlations documented in a large number of reports could ultimately provide a foundation for automatically identifying reports with incorrect, unusual, or poorly-communicated clinical correlations mitigating misdiagnoses and improving patient care. It should be noted, however, that automatically identifying incorrect, unusual, or poorly-communicated clinical correlations has two critical requirements: (1) inferring what the expected clinical correlations would be for the patient and (2) quantifying the degree of disagreement or contradiction between the clinical correlations documented in a report and the expected clinical correlations for the patient. In this initial study, we focus on the first requirement by considering the clinical correlation sections documented in EEG reports.

The role of the clinical correlation section is not only to describe the relationships between findings in the EEG report and the patient’s clinical picture, but to also explain and justify the relationships so as to convince any interested health care professionals. Consequently, the clinical correlation section of an EEG report is expressed through natural language, meaning that the clinical correlations documented in the clinical correlation section are qualified and contextualized through all the subtlety and nuance enabled by natural language expression. For this reason, while it might appear sufficient to simply extract individual findings or medical concepts from the clinical correlation section, describing and justifying the clinical correlations requires producing coherent natural language. This requirement makes inferring the expected clinical correlation section from an EEG report a challenging problem because it requires not only identifying the correct clinical correlations, but also expressing those correlations through natural language which is by the content of the EEG report as well as the neurologist’s medical knowledge and accumulated experience.

In this paper, we present a novel Deep Section Recovery Model (DSRM) which applies deep neural learning on a large body of EEG reports in order to infer the expected clinical correlations for a patient based solely on the natural language content in his or her EEG report. The DSRM was trained and evaluated using the Temple University Hospital (TUH) EEG Corpus by (a) identifying and removing the clinical correlation section written by the neurologist and (b) training the DSRM to infer the entire clinical correlation section from the remainder of the report. At a high level, the DSRM can be viewed as operating through two general steps:
Step 1: word- and report-level features are automatically extracted from each EEG report to capture contextual, semantic, and background knowledge; and

Step 2: the most likely clinical correlation section is jointly (a) inferred and (b) expressed through automatically generated natural language.

Our experimental results against a number of competitive baseline models indicate the generative power of the DSRM, as well as the promise of automatically recognizing unusual, incorrect, or incomplete clinical correlations in the future. It should be noted that although we evaluated the DSRM by recovering the clinical correlation sections from EEG reports, the model automatically extracts its own features based on the words in a given report and (clinical correlation) section. Consequently, we believe the DSRM could be easily adapted to not only process addition types of medical reports, but to also to infer and generate medical language for other purposes, e.g., generating explanations for CDS systems, providing automated second opinions, and assessing and tracking documentation quality.

Background

The Deep Section Recovery Model (DSRM) presented in this paper was originally envisioned as part of a larger project to design an automatic patient cohort retrieval system (operating on natural language) for EEG reports. This system assigns different weights or importance to each section in an EEG report, with the clinical correlation section being the most important. Unfortunately, we found that as many as 1 in 10 EEG reports were missing a clinical correlation section. In previous work, we designed a binary classification model for automatically inferring the over-all impression (normal or abnormal) for an EEG report. This model was extended and adapted to produce natural language, forming the basis for the DSRM presented in this paper.

As a natural language generator, the DSRM incorporates advances from Natural Language Generation, Machine Translation, and Automatic Summarization. We briefly review each of these topics below.

Natural Language Generation. Natural language generation (NLG) is an area of study on how automatic systems can produce high-quality natural language text from an internal representation. Traditionally, NLG systems rely on a pipeline of sub-modules including content selection – determining which information the model should generate – and surface realization – determining how the model should express the information in natural language. These systems typically require supervision at each individual stage and cannot scale to large domains. In health care, NLG has traditionally focused on surface realization through a number of applications, including generating explanations, advice, or critiques in expert systems, as well as generating explanatory material for patients. These systems largely rely on templates and rule-based mechanisms for producing natural language content. By contrast, the DSRM jointly performs content selection (via latent feature extraction) and surface realization (using a deep neural language model) without requiring predefined rules or templates.

Machine Translation. Perhaps the most ubiquitous application of NLG, machine translation has been an active area of research for the last 50 years. While the earliest systems were largely rule-based, statistical machine translation (SMT) systems have become the focus of the field. Statistical machine translation systems typically rely on gold-standard word or sentence alignments between parallel texts in a source and target language and use machine learning to train models which can automatically translate between them. More recently, the advent of deep learning has enabled the design of systems which jointly learn to align and translate. The canonical work by Bahdanau et al. introduces the notion of neural attention, which allows the model to learn how words in the target language should be aligned to words in the source language without supervision. The DSRM extends this idea by incorporating an attention layer to learn the association between words in the clinical correlation section and those in the rest of the report.

Automatic Summarization. Automatic summarization systems can be typically divided into two categories: extractive summarization systems, which aim to select individual words or sentence from a document and “stitch” them together to form a summary, and abstractive summarization systems which consider structural and/or semantic information to produce a summary that can contain words not mentioned in the document. It has been shown that extractive summarization may not be sufficient for health care needs; rather, abstract summarization efforts should be preferred. Fortunately, as with SMT, advances in deep learning have allowed allowed summarization systems to learn an internal or embedded representation of a document which can be used as the basis for NLG using so-called Sequence-to-Sequence models. Consequently, the DSRM model adapts the notion of abstractive summarization and combines and extends Sequence-to-Sequence models with the attention mechanisms used by SMT systems.

Data

The experiments reported in this paper use the Temple University Hospital (TUH) EEG Corpus with a standard 3:1:1 split for training, validation, and testing sets. The TUH EEG Corpus is the largest publicly available collection of EEG reports and the first...

The publicly released collection which includes both the raw EEG signal data as well as the EEG report associated with each EEG session. The EEG reports were authored according to The American Clinical Neurophysiology Society (ACNS) guidelines for writing an EEG report which stipulate that all EEG reports should contain (a) an introduction, (b) a description of the EEG recording, and (c) an interpretation regarding the normality or abnormality of findings as well as a correlation to the patient’s overall clinical picture. In the TUH EEG Corpus, the introduction was typically divided into three sections: (1) the Clinical History section indicating the age and gender of the patient as well as a brief history of any medical conditions which may affect the EEG recording; (2) the Medications section which consists of a comma-separated list of any medications the patient is regularly taking that could influence the EEG recording; and (3) the Introduction section itself which describes the setting of the EEG, the configuration of electrodes, the patient’s state of consciousness, whether the patient had been fasting, and any other pertinent information about the EEG setting. The description of the EEG recording was represented by the Description section which provides a “complete and objective” list of any notable findings including details about all waveforms in the record as well as a description of the patient’s background electro-cerebral activity. The neurologist’s interpretation was documented in two sections in the TUH EEG Corpus: (1) the Impression section in which the neurologist documents whether the EEG recording indicates normal or abnormal brain activity as well as – particularly in the cast of abnormal brain activity – a list of the most important findings that lead to this conclusion; and (2) the Clinical Correlation section in which the neurologist ties the findings in the report to the over-all clinical picture of the patient. Table 1 provides an example of each section from the TUH EEG Corpus.

Figure 1: Simplified Architecture of the Deep Section Recovery Model (DSRM).

Inferring the Clinical Correlation Section

When writing the clinical correlation section of an EEG report, the neurologist considers the information described in the previous sections, such as relevant clinical history or notable epileptiform activities, as well as their accumulated medical knowledge and experience with interpreting EEGs. This type of background knowledge is difficult to capture with hand-crafted features because it is rarely explicitly stated; rather, it is implied through the subtlety, context, and nuance afforded the neurologist by natural language. Consequently, to approach this problem, we present a deep neural network architecture which we refer to as the Deep Section Recovery Model (DSRM). Illustrated in Figure 1, the DSRM consists of two major components:

- the **Extractor** which learns how to automatically extract (a) feature vectors representing contextual and background...
knowledge associated with each word in a given EEG report as well as (b) a feature vector encoding semantic, background, and domain knowledge about the entire report; and

- the Generator which learns how to use the feature vectors extracted by the Extractor to produce the most likely clinical correlation section for the given report while also considering the semantics of the natural language it is generating.

In order to train and evaluate the DSRM, we identified all EEG reports in the TUH EEG Corpus which contained a CLINICAL CORRELATION section and removed that section from the report. The model was trained to recover the missing clinical correlation section in the training set and evaluated based on the clinical correlation sections it inferred for reports in the test set. In the remainder of this section, we describe (1) the natural language pre-processing steps applied to the data, (2) the mathematical problem formulation, (3) the Extractor, (4) the Generator, (5) how the parameters of the model are learned from the training set, and (6) how the learned parameters are used to infer the most likely clinical correlation section for a (new) EEG report.

**Natural Language Pre-processing**

Before applying the Deep Section Recovery Model, we pre-processed each EEG report with three basic natural language processing steps: (1) sentence boundaries were identified using the OpenNLP* sentence splitter; (2) word boundaries were detected using the GENIA tokenzer, and (3) section boundaries were identified using a simple regular expression search for capitalized characters ending in a colon. These three pre-processing steps allowed us to represent each section of an EEG report as a sequence of words in which the symbols ⟨s⟩ and /⟨s⟩ were used to indicate the start and end of each sentence, ⟨p⟩ and /⟨p⟩ were used to indicate the start and end of each section, and ⟨d⟩ and /⟨d⟩ were used to indicate the start and end of each report.

**Problem Formulation**

In order to formally define the problem, it is necessary to first define the vocabulary as the set of all words observed at least once in any section (including the clinical correlation section) of any EEG report in the training set. Let V indicate the size or number of words in the vocabulary. This allows us to represent an EEG report as a sequence of V-length one-hot vectors corresponding to each word in the report, i.e., $R \in \{0,1\}^{N \times V}$ where $N$ is the length or number of words in the report. Likewise, we also represent a clinical correlation section as a sequence of V-length one-hot vectors; in this case, $S \in \{0,1\}^{M \times V}$ where $M$ is the number of words in the clinical correlation section. The goal of the Deep Section Recovery Model is to infer the most likely clinical correlation section for a given EEG report. Let $\theta$ be the learn-able parameters of the model. Training the model equates to finding the values of $\theta$ which assign the highest probabilities to the gold-standard (neurologist-written) clinical correlation sections for each EEG report in the training set; formally:

$$\theta = \arg\max_{\theta'} Pr(S|R; \theta')$$

(1)

We decompose the probability of a particular clinical correlation section being produced for a given EEG report (i.e., correctly identifying and describing the clinical correlations in the report) into two factors:

$$Pr(S|R; \theta) \approx Pr(e,h_1,\ldots,h_N|R; \theta) \cdot Pr(S|e,h_1,\ldots,h_N; \theta)$$

(2)

where the first factor is implemented by the Extractor and the second factor is implemented by the Generator.

**The Extractor**

The language in the clinical correlation section is intended to relate findings and observations described in the previous sections of the record to the over-all clinical picture of the patient. Consequently, in order to automatically produce the clinical correlation section, the goal of the Extractor is to automatically (1) identify important neurological findings and observations (e.g., “background slowing”), (2) identify descriptions of the patient’s clinical picture (e.g., “previous seizure”), and (3) determine the inferred relationship(s) between each finding and the clinical picture as described by the EEG report or implied by medical knowledge and experience (e.g., “observed epileptiform activity is consistent with head trauma”). It should be noted that the length and content of each EEG report varies significantly throughout the collection, both in terms of the sections included in each report as well as the content in each section. Moreover, when producing an EEG report, each neurologist writes in a different style, ranging between terse 12-word sections to 600-word sections organized into multiple paragraphs. Consequently, the role

*https://opennlp.apache.org/*
of the Extractor is to overcome these barriers and extract meaningful feature vectors which characterize semantic, contextual, and domain knowledge. To address these requirements, we implemented the Extractor using the deep neural architecture illustrated in Figure 2. The Encoder relies on five neural layers to produce feature vectors for each word in the report \((h_1, \cdots, h_N)\) as well as a feature vector characterizing the entire report \((e)\):

- **Layer 1: Embedding.** The role of the embedding layer is to embed each word in the EEG report \(R\) (represented as a \(V\)-length 1-hot vector) into a \(K\)-length continuous vector \(r_i^{(1)}\) (where \(K \ll V\)). This is accomplished by using a fully connected linear projection layer, \(r_i^{(1)} = R_i W_e + b_e\), where \(\{W_e \in \mathbb{R}^{V \times K}, b_e \in \mathbb{R}^{1 \times K}\} \in \theta\) correspond to the vocabulary projection matrix and bias vector learned by the Extractor.

- **Layer 2: Bidirectional Recurrent Neural Network.**
  Layer 2 implements a bidirectional recurrent neural network (RNN) using two parallel RNNs trained on the same inputs: (1) a forward RNN which processes words in the EEG report in left-to-right order and (2) a backward RNN which processes words in the EEG report in right-to-left order. This allows the forward RNN to extract features capturing any short- or long-range contextual information about each word in \(R\) provided by any preceding words in the EEG report (e.g. that “slowing” is negated in “no background slowing”). Likewise, the backward RNN extracts features capturing any short- or long-range contextual information provided by successive words in the EEG report (e.g. that “hyperventilation” described in the introduction section may influence the inclusion of “spike and wave discharges” in the EEG impression or description sections). Formally, the forward RNN maps the series word embeddings \(r_1^{(1)}, \cdots, r_N^{(1)}\) to a series of “forward” word-level feature vectors \(r_1^{(2)}, \cdots, r_N^{(2)}\), while the backward RNN maps \(r_1^{(1)}, \cdots, r_N^{(1)}\) to a series of “backward” word-level feature vectors \(r_1^{(2b)}, \cdots, r_N^{(2b)}\). In our model, the forward and backward RNNs were implemented as a series of shared Gated Recurrence Units\(^{22}\) (GRUs)*.

- **Layer 3: Concatenation.** The concatenation layer combines the forward and backward word-level feature vectors to produce a single feature vector for each word, namely, \(r_i^{(3)} = \left[ r_i^{(2)}, r_i^{(2b)} \right] \) where \([x; y]\) indicates the concatenation of vectors \(x\) and \(y\).

- **Layer 4: \(2^{nd}\) Bidirectional Recurrent Neural Network.** In order to allow the model to extract more expressive features, we use a second bidirectional RNN layer. This layer operates identically to the bidirectional RNN in Layer 2, except that the word-level feature vectors produced in Layer 3, i.e., \(r_1^{(3)}, \cdots, r_N^{(3)}\), are used as the input to the bidirectional RNN (instead of \(r_1^{(1)}, \cdots, r_N^{(1)}\) used in Layer 2). Likewise, the memory states produced in Layer 4 are denoted as \(f_2\) and \(b_2\), corresponding to the forward RNN and the backward RNN, respectively. Unlike the bidirectional RNN used in Layer 2, we use the final memory of the forward RNN (i.e. \(f_2\)) as the report-level feature vector \(e\) which will be used by the Generator.

- **Layer 5: \(2^{nd}\) Concatenation.** As in Layer 3, the second concatenation layer combines the forward and backward word-level features vectors produced in the previous layer. In the case of Layer 5, however, we used the resulting feature vectors \(h_1, \cdots, h_N\) as the word-level feature vectors which will be provided to the Generator.

* A GRU is a block of coordinated sub-layers in a neural network which learn to transform an input vector (e.g. \(r_i^{(3)}\)) into an output vector (e.g. \(r_i^{(2f)}\) or \(r_i^{(2b)}\)) by maintaining and updating an internal memory state. The memory state used in the forward RNN is denoted by \(f_1\) while the memory state used in the backward RNN is denoted by \(b_1\).
The Generator

The role of the Generator is to generate the most likely clinical correlation section for a given EEG report using the feature vectors extracted by the Extractor. It is important to note that because the clinical correlation sections vary both in terms of their length and content, the number of possible clinical correlations sections that could be produced is intractably high \( (V_{\text{MAX}} \) where \( V_{\text{MAX}} \) is the maximum length of a clinical correlation section). Consequently, we substantially reduce the complexity of the problem by modeling the assumption that each word in the clinical correlation section can be determined based solely on (1) the word-level feature vectors \( h_1, \ldots, h_N \) extracted by the Extractor, (2) the report-level feature vector \( e \) extracted by the Extractor, and (3) any preceding words produced by the Generator. This assumption allows us to define the probability of any clinical correlation section, \( S' \), having been produced by a neurologist for a given EEG report (i.e., the second factor in Equation 2) as:

\[
Pr(S'|R) = \prod_{j=1}^{M} Pr(S'_j|S'_{j-1}, \ldots, S'_1, e, h_1, \ldots, h_N; \theta)
\]  

To compute Equation 3, we designed the Generator to act as a type of Recurrent Neural Language Model (RNLM) which incorporates a Recurrent Neural Network (RNN) to produce one word in the clinical correlation section at-a-time while maintaining and updating an internal memory of which words have already been produced.

![Diagram of the Generator's architecture](image)

**Figure 3:** Detailed Architecture of the Generator under (a) Training and (b) Inference Configurations.

To improve training efficiency, the Generator has two similar but distinct configurations: one for training, and one for inference (e.g., testing). Figure 3 illustrates the architecture of the Generator under both configurations. The primary difference between each configuration is the input to the RNN: when training, the model embeds the previous word from the gold-standard clinical correlation section (e.g., \( S'_j \)) to predict \( S'_j \) while during inference the RNN operates on the embedding of the previously generated word (e.g., \( S'_{j-1} \)) to predict \( S'_j \). The Generator produces the natural language content of a clinical correlation section for a given EEG report using four layers (with the preliminary embedding layer in the training configuration acting as an extra “zero”-th layer):

- **Layer 0: Embedding.** The embedding layer, which is only used when the Generator is in training configuration, embeds each word in the gold-standard clinical correlation section \( S_j \) (represented by \( V \)-length 1-hot vectors) into an \( L \)-length continuous vector space, \( s_j^{(0)} \), where \( L \ll V \). This is accomplished by using a fully connected linear projection layer, \( s_j^{(0)} = S_j W^{(0)} + b^{(0)} \) where \( (W^{(0)} \in \mathbb{R}^{V \times L}, b^{(0)} \in \mathbb{R}^L) \in \theta \) correspond to the vocabulary projection matrix and vocabulary bias vector learned by the Generator.

- **Layer 1: Concatenation.** The first layer used in both configurations of the Generator is a concatenation layer which combines the embedded representation of the previous word with \( e \), the report-level feature vector extracted by the Extractor, \( s_j^{(1)} = [s_j^{(0)}, e] \) where \([x,y]\) indicates the concatenation of vectors \( x \) and \( y \) and \( s_0^{(0)} \) is defined as a zero vector.

- **Layer 2: Gated Recurrent Unit.** The second layer used by both configurations is a Gated Recurrent Unit (GRU). The GRU allows the model to accumulate memories encoding long-distance relationships between each produced word of the clinical correlation section,
We evaluated the performance of the Deep Section Recovery Model (DSRM) using the Temple University Hospital EEG Corpus\textsuperscript{5}.

In order to improve the quality and coherence of natural language produced by the Generator, an attention mechanism was introduced. The attention mechanism allows the Generator to consider all of the world-level feature vectors $h_1, \ldots, h_N$ produced by the Extractor for the given report, and learns the degree that each word in the EEG report influences the selection of (or aligns with) $S_j^\prime$; formally:

$$s_j^{(3)} = \sum_{i=1}^{N} \alpha_{ij} h_i$$

such that $\alpha_{ij}$ is an alignment vector used in the alignment model $\beta_{ij}$ which determines the degree that the $i^{th}$ word in the EEG report $R$ (represented by $h_i$) influences the $j^{th}$ word of the clinical correlation section $S_j^\prime$ (represented by $s_j^{(2)}$).

The role of the fourth layer is to combine the result of the previous attention layer with the result of the GRU in Layer 2, i.e., $s_j^{(4)} = s_j^{(3)} + s_j^{(2)}$.

In order to measure the probability of each word $S_j^\prime$ being produced for the given EEG report, we use a final softmax projection layer to produce a vocabulary-length vector $s_j^{(5)}$ in which the $v^{th}$ element indicates the probability that $S_j^\prime$ should be generated as the $v^{th}$ word in the vocabulary. $s_j^{(5)} = \text{softmax}(\langle V \rangle W_j + b_j)$ where softmax($x$) = \frac{\exp(x_v)}{\sum_{v=1}^{V} \exp(x_v)} and $v \in [1,V]$. This allows us to complete the definition of Equation 3:

$$Pr(S_j^\prime = v|S_{j-1}^\prime, \ldots, S_1^\prime, e, h_1, \ldots, h_N; \theta) = s_j^{(5)}$$

Training the Deep Section Recovery Model

Training the Deep Section Recovery Model (DSRM) is achieved by finding the parameters $\theta$ which are most likely to produce the gold-standard clinical correlation sections for each EEG report in the training set $T$. Formally, we model this by minimizing the cross-entropy loss between the vocabulary-length probability vectors produced by the model ($s_j^{(5)}$) and the one-hot vectors corresponding to each word in the gold-standard clinical correlation section ($S_j^\prime$).

$$L(\theta) \propto \sum_{(R,S) \in T} \left[ \sum_{j=1}^{M} \left[ s_j^{(5)} \log S_j + (1 - s_j^{(5)}) \log(1 - s_j^{(5)}) \right] \right]$$

The model was trained using Adaptive Moment Estimation (ADAM)\textsuperscript{24} (with an initial learning rate $\eta = 0.001$).

Inferring Clinical Correlations

Given $\theta$ learned from the training set, the clinical correlation section $S$ can be generated for a new EEG report $R$ using the inference configuration illustrated in Figure 3b. In contrast to the training configuration in which $S_j^\prime$ is selected using the previous word from the gold-standard clinical correlation section ($S_{j-1}^\prime$), during inference, the model predicts $S_j^\prime$ using the word previously produced by the model ($S_{j-1}^\prime$). It is important to note that, unlike training, we do not know the length of the clinical correlation section we will generate. Consequently, the model continually generates output until it produces the END-OF-SECTION symbol $\langle /p \rangle$. Thus, the length of the inferred clinical correlation section $M$ is determined dynamically by the model. When inferring the most likely clinical correlation section, it is necessary to convert the vocabulary probability vectors $s_1^{(5)}, \ldots, s_M^{(5)}$ to one-hot vocabulary vectors $S_j^\prime$ that can be directly mapped to natural language.*

Experiments

We evaluated the performance of the Deep Section Recovery Model (DSRM) using the Temple University Hospital EEG Corpus\textsuperscript{5} (described in the Data section) using a standard 3:1:1 split for training, validation, and testing sets. The performance of our model was compared against four baseline systems:

1. **NN:Cosine.** In this nearest-neighbor baseline, we represented each EEG report as a bag-of-words vector. This baseline infers the clinical correlation for a given EEG report by copying the clinical correlation associated with the EEG report in the training set whose bag-of-words vector had the least cosine distance to the bag-of-words vector representation of the given EEG report.

*Let $\delta_j = \text{argmax}(s_j^{(5)}); S_j^\prime$ is defined as the one-hot vector in which the $s_j^{(5)}$ value is 1 and all other values are zero.
2. NN:LDA. In the second nearest-neighbor baseline, we represented each EEG report as a latent topic vector which was computed by applying Latent Dirichlet Allocation\(^*\) to the EEG reports in the training set. This allowed us to infer the clinical correlation for a given EEG report by copying the clinical correlation associated with the EEG report in the training whose topic-vector representation has the least Euclidean distance to the topic-vector representation of the given EEG report.

3. DL:Attn-RNLM. The first deep-learning baseline considers a recurrent neural language model\(^2\) (RNLM) using the standard attention mechanism operating on the embedded word-representations of a given EEG report. This baseline closely resembles the DSRM if the Extractor component were removed.

4. DL:Basic-S2S. The second deep-learning baseline uses a standard Sequence-to-Sequence\(^\dagger\) model without attention. This baseline closely resembles the DSRM if word-level feature vectors (i.e., \(h_1, \ldots, h_N\)) were not extracted and only the report-level feature vector is considered by the Generator.

**Implementation Details**

Our model and the two deep learning baselines were implemented in Tensorflow* version 1.0. For all deep learning models, we used a mini-batch size of 10 EEG reports, a maximum EEG report length of 800 words, a maximum clinical correlation section length of 60 words, 200-dimensional vectors for word embeddings, and 256 hidden units in all RNNs based on a grid search over the validation set.

**Experimental Setup and Results**

Evaluating the quality of automatically produced natural language (such as the inferred clinical correlation sections) is an open problem in the natural language processing community. Consequently, to quantify the quality of the clinical correlation sections inferred by all four baseline systems as well as the DSRM, we considered standard metrics used to evaluate machine translation, automatic summarization, and speech recognition.

We measured the surface-level accuracy of an automatically inferred clinical correlation section in two ways: (1) the Word Error Rate\(^2\) (WER) which measures how many “steps” it takes to transform the inferred clinical correlation section into the gold-standard clinical correlation section produced by the neurologist, where steps include (a) insertion, (b) deletion, or (c) replacement of individual words in the inferred clinical correlation; (2) the Bilingual Evaluation Understudy\(^2\) (BLEU) metric which is a commonly used analogue for Precision in language generation tasks. The surface-level completeness of each inferred clinical correlation section was measured using the Recall-Oriented Understudy for Gisting Evaluation\(^2\) (ROUGE), a commonly used analogue for Recall (i.e. Sensitivity) in language generation tasks. Finally, we measured the surface-level coherence between individual words or the semantics of multi-word expressions. For example, if the gold-standard clinical correlation contains “absence of epileptiform features”, then the excerpt “no epileptiform activity” would have BLEU-2 and ROUGE-2 scores of zero and a WER of 2 despite the fact that both excerpts express the same information. Consequently, these surface-level metrics should be interpreted as strict lower-bounds on the performance of each evaluated system.

Table 2 presents these results.

It can be seen that the DSRM achieved the best over-all performance. Moreover, it can be observed that the Attention Decoder (DL:Attn-Decoder) achieved the second-best performance. The Basic Sequence-to-Sequence model (Basic-S2S) as well as the Cosine and LDA nearest neighbor approaches achieved comparable, but only moderate performance. The high performance of the DSRM compared to the Basic S2S model indicates the importance of incorporating attention, allowing the model to discover latent relationships between words in the EEG report and each word in the clinical correlation section. Moreover, the improvement in performance shown by the DSRM compared to the Attention Decoder indicates that the clinical correlation cannot be generated

Discussion

In order to analyze the automatically inferred clinical correlation sections produced by the DSRM, we manually reviewed 100 randomly selected EEG reports from the test set by comparing the inferred clinical correlation sections to the gold-standard clinical correlation sections written by the neurologists. The over-all quality of the inferred clinical correlation sections was assessed using the Likert scale illustrated in Table 4, with the DSRM obtaining an average score 3.491, indicating that the inferred clinical correlation sections are generally accurate, but may contain minor additional erroneous information or have minor omissions.

Table 3 illustrates the inferred clinical correlation as well as the gold-standard clinical correlation section for three EEG reports in the test set. Example 1 illustrates an example of a correct, but incomplete inferred clinical correlation section. Both the inferred and gold-standard clinical correlation sections agree that (1) no epileptiform discharges were observed, and (2) that a repeat EEG focusing on extensive sleep is needed. However, the gold-standard clinical standard includes additional details about asymmetry and asymmetry of wicket activity which the DSRM omitted.

Example 2 illustrates an inferred clinical correlation section which accurately expresses the diffuse disturbance of cerebral function. However, the inferred clinical correlation section additionally indicates a “severe underlying encephalopathy” which was not expressed in the gold-standard clinical correlation section. Moreover, the inferred clinical correlation section attempts to correlate the findings with the patients “renal failure, and acute, and/or metabolic processes” and indicates that these findings should be correlated with imaging. While these inclusions highlight the model’s ability to accumulate knowledge across the large corpus of EEGs in the training set in order to simulate experience, they also demonstrate that the model occasionally struggles to determine which information is (or is not) relevant.

The inferred clinical correlation illustrated in Example 3 illustrates a relatively rare (15% of reviewed EEG reports) but significant error: contradiction within the inferred clinical correlation sections. While the first sentence (incorrectly) states that the EEG does not suggest metabolic encephalopathy, the second sentence indicates that it does. This error strongly suggests that the performance of the model could be improved by developing and incorporating a more sophisticated loss function: the average cross-entropy loss (shown in Equation 5) considers each individual word in the inferred clinical correlation equally; thus, the incorrect inclusion of “not” in the first sentence has a very small impact on the loss despite it inverting the meaning of the entire sentence.
Conclusion

In this paper, we have presented a deep learning approach for automatically inferring the clinical correlation section for a given EEG report, which we call the Deep Section Recovery Model (DSRM). While traditional approaches for inferring clinical correlations would require hand-crafting a large number of sophisticated features, the DSRM learns to automatically extract word- and report-level features from each EEG report. Our evaluation on over 3,000 EEG reports revealed the promise of the DSRM: achieving an average of 17% improvement over the top-performing baseline. These promising results provide a foundation towards automatically identifying unusual, incorrect, or inconsistent clinical correlations from EEG reports in the future. Immediate avenues for future work include (1) considering more sophisticated loss functions which incorporate contextual and semantic information and (2) an in-depth study and evaluation of metrics for qualifying the degree of disagreement between a given clinical correlation section and the inferred or expected clinical correlation section.

Abstract

Exploring relationships between admission variables and outcome using regression models has been the focus of Traumatic Brain Injury (TBI) research. Although practical and well established, these approaches do not evaluate interactions between predictors. We therefore applied a set-theoretic logical analysis to the Corticosteroid Randomization after Significant Head Injury (CRASH) trial database. Complete data analysis of 6945 patients demonstrated 9 different configurations of admission variables were sufficient for favorable outcome in 87.5% of all cases and explained 57% of favorable outcomes (moderate disability or good outcome). We also evaluated the contrasting configurations for unfavorable versus favorable outcome. Results are largely in line with findings of previous studies however the influence of age fell behind GCS components, which is unexpected. Specifying a combination of admission parameters that are likely to translate into a given clinical outcome is appealing from a clinician’s perspective therefore our results have considerable translational value.

Introduction

Traumatic Brain Injury is a significant source of morbidity and mortality. TBI-related disability is quoted to be 5.3 million in the United States4 and 7.7 million in the European Union old member state5. Furthermore TBI affects younger population (<45 years), which contributes to the devastating impact on society. Prognostic models have given increasing insight into predictor importance highlighting patient age, motor response and imaging findings as the most influential predictors of outcome6. These findings helped tailor our assessment protocols and pointed out the variables that should be gathered for clinical trials7. In the past, TBI studies have investigated both multi-variable and single-variable models to assess the prognostic strength of variables on TBI outcome8-10. Multi-variable models8-10 focus on development and assessment of the combined effect of multiple variables on the outcome, while single-variable approaches focus on assessing the prognostic strength of one particular variable9. More recently machine-learning methods such as Bayesian Networks have been applied to TBI databases, which proved to be an appealing way to formalize intuitive as well as unexpected associations between variables7.

Model specification for multi-variate approach using regression, often rely on the inherent assumption that each variable has an independent effect on the outcome11. It is known that these techniques assess the net effect12 of a set of variables on an outcome and are not generally concerned with configurations and interaction of variables. For understanding complex biological conditions, the interactions between variables needs to be studied in a multi-dimensional manner.

In reviewing the methods that assess the effect of multiple variables on TBI outcome, we note that the mainstream techniques are marked by limitations in expressing the interactions between variables, and the role of these interactions in predicting the outcome. This means that in these techniques, the data is assumed to have just one ready answer for the magnitude of a variable’s effect on the outcome. When interaction terms are not modelled adequately, the accuracy of estimates in regression approaches can be affected by model misspecification11. If interaction terms are not modelled, the effect of individual independent variables are likely to be over-estimated.

Modeling interactions in a multi-variate analysis is not a straight forward task. Starting from single variables, all possible combinations of variables need to be investigated. Depending on the number of variables, multiple models can be generated and the validation of these models is non-trivial. Conventional statistical methods, cannot account for situations in which only specific combinations of variables reveal their impact on the outcome (conjunctural causation) or all paths that lead to an outcome need to be simultaneously uncovered (equifinality). These methods also
fall short in explaining situations in which a given combination of variables contributes to the presence of an outcome but at the same time is irrelevant for the absence of that outcome (causal asymmetry).

Despite the depth and breadth of recent investigations, there is limited generalized knowledge to model the complex interaction of variables and the prognostic value of these interactions in TBI. In this study our goal is to systematically investigate these interactions. While considering that the predictors of favorable outcome in TBI are not necessarily the negation or reversal of predictors of unfavorable outcome, we study the interaction of variables causative to this asymmetry, in a multi-dimensional, multi-variate manner.

Set-theoretic logical analysis methods can detect recurring causal patterns, and are well suited to help us explore a configurational model of TBI outcome. For this, we apply the method of Qualitative Comparative Analysis (QCA) which unlike statistical approaches, can address the three important phenomenon of conjunctural causation, equifinality and causal asymmetry inherent in modelling the concept of configurations. The general assumption behind the configurational approach applied here is that the interaction or combinations of different predictor variables can explain the difference in outcome classes. Hence, in comparison to statistical approach like regression that provides an estimate of impacts of the study variable on outcome in a specified model, rather QCA allows a study factor to participate in difference configurations affecting the outcome.

The paper proceeds as follows: First we briefly cover the background on TBI and the current state of research in this area and will introduce the explanatory variables included in our study. Next, we explain the analytical framework behind our study, followed by the research design. We then present the QCA results and offer a more substantive interpretation of risk patterns before concluding the paper with an assessment of the predictive power of the model compared to that of a simple logistic regression model followed by a discussion.

**Prognostic Models and Predictor Variables in TBI**

The International Mission for Prognosis and Analysis of Clinical Trials in TBI (IMPACT) set forth three prognostic models with different levels of complexity, using well-known predictors (age, Glasgow Coma Motor Score, and pupillary reactivity), computed tomographic characteristics (CT classification and traumatic subarachnoid hemorrhage), secondary insults (hypoxia or hypotension) and laboratory values on admission (Hb and glucose)\(^5,6,8\). These models can predict 6-month outcome in patients with severe or moderate TBI with good discriminative ability based on the Area Under Curve (AUC).\(^7\) Assessment and validation of these widely accepted prediction models on different cohorts has been the focus of many investigations. Externally, the IMACT models were validated against the Corticosteroid Randomization after Significant Head Injury (CRASH)\(^8\) trial findings. The CRASH trial included 10008 cases of patients with traumatic head injury within 8 hours of clinical assessment from 239 hospitals in 29 countries.

We’ve based our current study on the clinically relevant variables from previous studies by IMPACT and CRASH researchers who have identified age, motor score and imaging abnormalities as important predictors of clinical outcome in TBI\(^6,8,7\). Study variables include demographics, injury characteristics, computed tomography (CT) findings and Glasgow Outcome Scale (GCS, motor, verbal response and eye opening). Outcome measure were dichotomized as death or severe disability at 6 months.

From the 10008 cases in the CRASH dataset, about a third had one or more missing values and were omitted from our analysis. Our analysis is therefore based on the 6945 cases that had no missing values. Table 1 describes the characteristics of patient data in the CRASH dataset. The missing CT findings were responsible majority of the excluded values in the study (2191 of the 10008 patients, 21.9%). For the majority of these patients (2063) a CT brain was not performed at all whereas only 128 had one or more imaging findings not recorded in the dataset. We considered multiple imputations of missing data, which would technically be difficult to interface with the subsequent analysis. Furthermore previous studies with the CRASH trial dataset found no difference between imputed and complete datasets. We therefore choose to undertake a complete data analysis rather than imputing missing values. Another consideration regarding the dataset was the better early outcomes (14 days) for high-income countries, compared low-middle income regions. The 6 month outcomes (used in our study) were however similar between income regions.

Qualitative Comparative Analysis

The method of Qualitative Comparative Analysis (QCA) carries potential for analysis of complex dependencies in configurational data\(^\text{2}\). Ragin describes QCA as “an analytic technique designed specifically for the study of cases as configurations of aspects, conceived as combinations of set memberships”\(^\text{17}\). A configuration is a combination of variables that consistently produce (i.e. are sufficient for) the outcome\(^\text{9}\).

At its core, QCA is based on ideas from the field of logic synthesis\(^\text{30}\) to obtain the minimal Boolean sum-of-products (SOP) formulas that fully represents a given truth table of variables. The truth table lists all logically possible combinations of the variables based on the dataset included in the study.

The core algorithm in QCA, the Quine-McCluskey\(^\text{20-21}\) algorithm, was established in 1950s and used for minimization of Boolean logic formulas to find the smallest, logically valid combination of variables that have the largest coverage over all cases under investigation. The minimization process is based on repeatedly applying three laws of logic: 1) absorption (e.g. \(x_1.x_2 + x_1.x_2' = x_1\)), 2) idempotency or redundancy (e.g. \(x_1 + x_1 = x_1\)), and 3) the law of excluded middle (e.g. \(x_1 + x_1' = 1\)).

The Quine-McCluskey algorithm like any other logical analysis method is not concerned with the empirical validity of the formulas that are being discovered. It is the role of the analyst to design a valid foundation for analysis and then to assess the empirical validity of the findings. After listing all variables in a truth table, the analyst needs to select the threshold at which sufficient evidence for the outcome is defined. For example, if the analyst wants to uncover all combinations of variables that lead to a certain outcome 85% of the time, the sufficiency score needs to be set to 85%.

All combinations of conditions that meet this threshold are then included in further analysis. The analyst can also define the minimum number of occurrences of a certain combination for it to be included in the study. This gives the analyst the choice to include for example all combinations that appeared at least twice for favorable outcome.

The parameters of fit in QCA are consistency and coverage\(^\text{15}\). These parameters assess how consistently a combination of conditions appears in the data and the degree to which the findings cover or explain the dataset.

Steps of Analysis

For analysis, we used fsQCA\(^\text{22}\), a software developed by Ragin\(^\text{15}\) for configurational analysis. An implementation of QCA in R\(^\text{22}\) was also used for replication and comparison. The steps are schematically shown below (Figure 1).

![Figure 1. The 6 Steps in our analysis](image)

Variable Selection and Dimensionality Reduction

Since the computational cost of an exact multivariate logical analysis increases according to the number of variables included in the study, the algorithms used with these methods cannot process a large number of variables. The predictor variables in TBI dataset are nominal and multi-valued. When flattened, the total number of variables in the truth table sums up to 36 (including the outcome variable,). An exact analysis of 35 variables and one outcome requires 1.8 Petabytes of memory and could not be analyzed on conventional lab computers at the university. (6th Generation Intel® Core™ i7-6700T Processor (8M Cache, up to 3.60 GHz), 12GB Memory, 1TB hard drive). For this reason, we need to select the most informative variables and consider increasing the granularity of multi-value variables by merging multiple sub-categories.
Results
We employed the binary decision tree algorithm RPART\(^4\), which is an implementation of Classification and Regression Trees\(^5\) (CART) in R, to identify the most informative variables and the cut off point for each multi-level variables. We pruned the resulting decision tree using two different complexity parameters (0.001 and 0.01) and evaluated the predictive power of the resulting models based on the Area Under Curve (AUC). Table 2 compares the AUC of the two models with that of the original CRASH dataset. DeLong\’s test was used to formally compare the ROC curves for the different models.

The 11-var model showed no significant different (Delong p values >0.05) compared with the original model (non-binarized dataset). The alternative hypothesis was that the true difference in AUC is not equal to 0. Even though the dataset represents the same population, the paired ROC test is not applicable for comparing the ROC curves of the binarized models with that of the original model since the models are very different and are deemed to be unpaired by the built-in glm (general linear model) algorithm in R. At AUC 0.8175, the 9-variable model has a higher AUC than sensitivity based (AUC 0.8149) and specificity based (AUC 0.8132) models reported in earlier studies\(^6\). The Delong p-value for the 9-var model is less than 0.05 showing a more significant difference to the AUC of the original model compared to the 11-var model.

We test two models. The first model includes the 9 most informative variables based on the application of RPART, and the second model includes only 7 variables. Variable importance ranking for the two models is given in Table 3.

Comparative Analysis Using QCA
The first step in an exact analysis of a dataset using the configurational approach is to construct a truth table of variables. Each case in the CRASH dataset will correspond to a row in truth table. A truth table represents a binary tree in which every input variable takes either a zero or one for value. The truth table for our dataset is constructed by replacing for each label \(i\) in variable \(x\) the \(i^{th}\) label of \(x\) with a new variable \(x_i\). This means that multi-level variables are flattened into binary variables by expanding column wise. Given that our dataset includes 6945 cases, and in QCA terms this represents a Large-N analysis, it is unlikely that we can find perfectly sufficient causal combinations. We tested multiple levels and decided to set the sufficiency threshold\(^7\) to 70%. The inclusion cut off point is kept at 1, meaning a single occurrence of a combination is enough to include it for further analysis.

Raw coverage (RC), unique coverage (UC) and consistency (CONS) are the parameters of fit and assess how consistently a combination of conditions appears in the data and the degree to which the findings cover or explain the dataset\(^8\). The dashes (-) in the result tables mean that presence or absence of the variable does not matter for the outcome of that configuration.

Analysis of the 9-Var Model
As shown in Table 4, 67.8% of the Configurations for favorable outcome with a consistency of 84.9% could be explained by 40 combinations. The top 6 configurations for favorable outcome based on this model are reported. The first four conditions cover more cases in the dataset based on their RC and UC. Table 5 shows top 6 configurations for unfavorable outcome.

Analysis of the 7-Var Model

Since variable importance ranking of hmt and sah are the lowest in the rankings of our classification tree, we removed these two variables to evaluate the resulting configurations without them. The AUC of the 7-var model is 0.811 (95% CI: 0.8136-0.8334 (DeLong)). At DeLong’s p-value 9.474E-04 compared with the original model, the ROC curves of the two models were significantly different. It was found that 57.2% of the cases with favorable

With a raw coverage of 0.48, the configuration of row 1 in Table 6 explains the highest number of favorable outcomes covered by the total model (2740 cases), capturing the configuration “patients (below 45), with motor (localizes OR follows commands) AND pupils (both reactive) AND mds (no) AND obt (no).” This means that regardless of the value of eye and verbal, with 86% consistency, any configuration that matches row 1 results in favorable outcome. On the other hand, 44.5% of the cases of unfavorable outcome with a consistency of 83% could be explained by 20 combinations. Due to space limitation, we only report the top 8 configurations in Table 7 below.

With a raw coverage of 0.48, the configuration of row 1 in Table 6 explains the highest number of favorable outcomes covered by the total model (2740 cases), capturing the configuration “patients (below 45), with motor (localizes OR follows commands) AND pupils (both reactive) AND mds (no) AND obt (no).” This means that regardless of the value of eye and verbal, with 86% consistency, any configuration that matches row 1 results in favorable outcome. On the other hand, 44.5% of the cases of unfavorable outcome with a consistency of 83% could be explained by 20 combinations. Due to space limitation, we only report the top 8 configurations in Table 7 below.

Note: Withdrawal or less means: withdrawal or abnormal flexion or extension or no response for Motor Response assessment.
With a raw coverage of 0.2, the configuration of row 1 in Table 7 explains the highest number of unfavorable outcomes covered by the total model; capturing the configuration "patients who are 45 and above with eye = (no response) AND verbal = (incomprehensible sounds or no response)."

Predicting Outcome with QCA

To evaluate the usefulness of the 7-variable QCA model, we compared its ability to predict the TBI outcome with that of a simple binary logistic regression (Logit) model:

\[
P(\text{TBI outcome}) = \text{Logit}(\beta_0 + \beta_1 \cdot \text{age} + \beta_2 \cdot \text{eye} + \beta_3 \cdot \text{motor} + \beta_4 \cdot \text{verbal} + \beta_5 \cdot \text{pupils} + \beta_6 \cdot \text{oblt} + \beta_7 \cdot \text{mul} )
\]

where \(P\) is the predicted probability of TBI outcome based on the assumption of linear relationship between the variables. The purpose of using this simple model for comparison is to show the difference between the results of a conventional additive model with that of QCA. The two models are based on very different assumptions. The linear logistic regression model assigns a weight to all independent variables and is additive in nature. The QCA model takes patterns of interactions between variables into account and outputs multiple combinations.

We compared the predictive power of the two models based on the number of true positives and false negatives they predict as well as their overall prediction accuracy. The results are shown in Table 10. Precision reports the percentage of correct predictions that the model makes. Recall reports the fraction of positive predictions that are truly positive. Accuracy of the model is the percentage of all true predictions from the number of predictions the model makes. One main difference between the two models is that the Logit model generates one model for the whole dataset, but the QCA only explains patterns in a fraction of the dataset.

### Table 10. Predicting favorable outcome in TBI in CRASH dataset

<table>
<thead>
<tr>
<th>Model</th>
<th>Precision</th>

<th>True Positive Rate</th>
<th>False Positive Rate</th>
</tr>
</thead>
<tbody>
<tr>
<td>7-var QCA favorable</td>
<td>2394/2790 = 0.857</td>
<td>2394/4182 (2790)</td>
<td>0.857</td>
<td>0.133</td>
</tr>
<tr>
<td>7-var QCA unfavorable</td>
<td>1232/1483 = 0.830</td>
<td>1232/2763 (1483)</td>
<td>0.830</td>
<td>0.169</td>
</tr>
<tr>
<td>7-var Logit favorable</td>
<td>0.755</td>
<td>3608/4182</td>
<td>0.881</td>
<td>0.447</td>
</tr>
<tr>
<td>7-var Logit unfavorable</td>
<td>0.735</td>
<td>1591/2763</td>
<td>0.553</td>
<td>0.317</td>
</tr>
</tbody>
</table>

* Favorable outcome = Moderate Disability or Good Recovery  
** Unfavorable outcome = Death or Sever Disability at 6 Months

If precision and recall for the two models are calculated based on the number of cases that they claim to explain, the QCA model benefits from higher accuracy:

\[
\text{Accuracy of the QCA model} = (2394+1232) / (2790+1483) = 0.848
\]

\[
\text{Accuracy of the Logit model} = (3684+1527) / (4182+2763) = 0.750
\]

However, when we evaluate the predictive power of each model on the full dataset, the Logit model demonstrates a better precision and recall than the QCA model in predicting outcome, but suffers from higher false positive rates for both cases of unfavorable and favorable outcome. These results highlights the advantages of using QCA particularly when variables that affect outcome positively do not necessarily have reverse effect when they are removed, hence enabling us to highlight the possible asymmetries in the way individual variables can influence the outcome through their participation in configurations.

For the 9-var model, the cases of favourable outcome that QCA did not cover totals 215 different combinations, and for cases of unfavourable outcome that number is 174. For the 7-var model, the numbers are 79 and 59 respectively. Some of these non-covered cases are single occurrences of the configuration of variables that could not be factored with other configurations.
Discussion

Our study demonstrated a different approach to evaluating predictors of clinical outcome in TBI. With methods of QCA we established multiple configurations for admission variables that are predictive of favorable versus unfavorable outcome. Most of the findings are intuitive, young age (<45), good neurological condition and lack of CT abnormalities are in keeping with favorable outcome. Whereas older age, poor neurological condition and CT findings such as mass effect or traumatic subarachnoid bleed are suggestive of an unfavorable outcome. These results are in line with previous studies, however an unexpected finding was that on formal variable importance ranking using RPART age fell behind the GCS components as well as pupillary response. This is further traceable in several of the configurations (1-3 Table 5) for unfavorable outcome where age does not appear. A further finding in our study is the dichotomization values for admission variables which we established using a binary decision tree algorithm (RPART). Binary adaptation of clinical features is appealing to clinicians because it simplifies patient assessment particularly in the emergency setting. We have demonstrated that collapsing multi-level variables into binary does not impact model performance when maintaining the full set or most of variables present in the original model (Table 2). Consequently, a binary model can potentially inform a simplified assessment protocol without substantial loss of clinical information.

The configurational asymmetric models uncovered through the application of set-theoretic methods such as QCA, make these methods appealing when there is a possibility of interactions between variables. Comparative analysis with QCA is receiving increasing attention among researchers from a variety of disciplines such as social science24, business and economics25-30, management and organization31, education32, and health policy research33, 34.

For analyzing the CRASH dataset with QCA, we made the models more parsimonious by removing some variables since the complexity of the dataset does not allow us to apply the exact procedure of QCA to the full dataset, or even the 11-var dataset. As a limitation, we forced the multi-level variables into dichotomies based on their first split in the classification tree. This first split is considered to be most informative for contrasting outcomes, however, with more granularity we might find different and possibly better results. These binary models however showed similar performance to models built with multi-level variables. A translational value of our findings is that the configurations of admission variables can be regarded as “typical” patient scenarios that are strongly predictive of a clinical outcome.

Conclusion

A configurational, asymmetric model of TBI outcome is investigated. We have demonstrated that the dichotomization of admission variables can provide basis of simplified assessment protocols that can usefully implemented in small centers for example without specialist capacity. From a clinician’s perspective is also useful to be presented with a set of “typical” scenarios that are suggestive of favorable versus unfavorable outcome. We evaluated the predictive power of a simple logistic regression model and a QCA model using the CRASH dataset. The Logit model demonstrates a better precision and recall than the QCA model in predicting outcome, but suffers from higher false positive rates for both classes of unfavorable and favorable outcomes. The QCA model only explains patterns in a fraction of the dataset while the Logit model attempts to cover the whole dataset. We are currently investigating a new heuristic based on logic synthesis and network analysis methods to overcome the inherent limitation in QCA in terms of the number of variables and the complexity of the dataset while automating the inclusion of interaction terms to develop minimal models that are maximally predictive.

Abstract

Information technologies have transformed healthcare delivery and promise to improve efficiency and quality of care. However, in-depth analysis of EHR-mediated workflows is challenging. Our goal was to apply process mining, in combination with observational techniques, to understand EHR-based workflows.

We reviewed nearly 76,000 event logs from 15 providers and supporting staff, and 142 patients in a pre-operative setting and we inspected 3 weeks of interviews and video observations. We found that on average 44 minutes were spent per patient interacting with the EHR, 55% of the time of the patient visit was spent by personnel interacting with the EHR and for over 5% of the time personnel used or reviewed paper-based artifacts. We also discovered the handover-of-care network and compared frequency of interactions between personnel.

This study suggests that applying process mining in combination with observational techniques has vast potential for informing Mayo Clinic in the forthcoming EHR conversion.

Introduction

Current health information technologies (HIT), such as electronic healthcare records (EHRs), aim to improve healthcare delivery through increased access to patient information and better organization. However, recent HIT implementation and use have yielded mixed results in different clinical settings. Problems with EHR integration with existing clinical work processes impact workflow. This has resulted in extending the time required to complete tasks and has also resulted in the development of workarounds which can result in adverse events that compromise patient safety or quality of care delivered. With these new problems arising, we need a meaningful way to record and analyze clinicians’ interactions with HIT. This need coincides with Mayo Clinic’s interest to collect and analyze current workflow on clinician’s interactions in order to facilitate a large-scale EHR conversion.

In advance of an upcoming enterprise wide conversion to a converged EHR, the Mayo Clinic launched the ROOT (Registry Of Operations and Tasks) project, which aims to understand EHR-mediated workflows and clinician-HIT interaction. Surgical settings have been prioritized as the testbed for this project. Surgery is one of the most clinical and resource intensive activities in health care, constituted by multiple care transitions and a high incidence of adverse events. A main goal of the ROOT project is to create a repository of current high-definition snapshots of clinical and informational workflows at Phoenix, AZ, Rochester, MN, Jacksonville, FL, and in the Mayo Clinic Healthcare System before the transition to a new EHR.

Process mining techniques describe a family of a-posteriory automatic analysis techniques that exploit event logs, which record information about the sequences (traces) of events (activities) executed using electronic information systems. While process mining has been extensively used in business management, medical process mining is a relatively newer research field. In our prior research, which laid the methodological foundation for this work, we investigated variations in clinicians’ EHR workflow by integrating quantitative analysis of patterns of users’ EHR-interactions with in-depth qualitative analysis of user performance. This paper summarizes preliminary outcomes from the ROOT project resulting from observations, interviews, video ethnography and process mining analysis at the pre-operative (PreOp) setting at Mayo Clinic Hospital, Phoenix, Arizona.

Objectives

The objective of this study was to employ an integrative methodological approach leveraging process mining, observations, interviews and video ethnography, to understand patient workflows, clinical workflows, and interactions of personnel with electronic systems at the PreOp setting of one of the Mayo Clinic facilities. Four questions were posed to guide this research: Can we validate observed handover-of-care based on PreOP personnel’s sequential
interactions with patient cases?; How much time do personnel spend in electronic information systems?; How much time do personnel spend on documenting and/or reviewing data using paper based artifacts vs. electronic systems?; Is there a correlation between care paths followed and the time spent in the PreOp by different patient groups?.

Methods

We integrated outcomes of clinical observations, interviews or video ethnography with process mining techniques to increase our study sample and, in some cases, validate outcomes. The interviews, observations and videos guided the process mining and helped us to identify relevant questions to be answered by process mining techniques in order to better understand clinical and patient workflows. In turn, the process mining can be used to discern the distribution of patterns evident in our workflow.

For this study, two different teams collaborated to carry out different data gathering techniques and analysis.

Observations, Interviews and Video Ethnography

The first team conducted mixed-method data collection on-site over a 3-week period in 2016. Data collection methods included semi-structured interviews and multiple observational techniques to surface specifics about all roles and activities performed in PreOp. In this paper, we refer to the following set of methods collectively as “observational techniques”: shadowing, video ethnography using hand-held video camera and Morae™ video capture. Morae™ software is used for usability studies and it records user activity with no interruption to the user’s work. Using a webcam, it was also used to record audio of participants verbalizing their thoughts and video recording of the participant’s hands and desk space. Participants were asked to think-aloud as they performed HIT-based tasks to reveal activity, goals and cognitive processing, and allow for retrospective analysis.

The mixed-method approach was used by the team to identify, describe and validate the clinical workflow components and processes. The study presented here, draws on a subset of this analysis for an in-depth description of patient flow, personnel, and personnel’s coordination processes integral to efficient patient flow.

Process Mining Analysis

The second team was responsible for collecting and analyzing, using process mining techniques and tools, the event logs generated at the PreOp during two days that the first team was on-site. The team had access to nearly 76,000 event logs generated during the selected days. For those days, there was a daily average of 15 providers and supporting staff, and 71 patients.

The event logs mainly captured actions performed within the Cerner SurgiNet environment. SurgiNet is the EHR application used for tracking cases in the perioperative settings (i.e. pre-op, intra-op and post-op) and for most perioperative documentation. In addition, when applications outside the EHR system such as Synthesis, Smart Template Wizard, Schappt Book and Outlook email were launched, there were few if any event logs created.

![Figure 1: All of the attributes provided in a Cerner event log are split into two rows. The columns of interest in the first row provide the ending timestamp of the event (End Date, End Time), duration of the event (Elapsed Time), name of software function that triggered the event (Timer Name) within an information system (Exec Name), and the identifier of the provider (User Name) using the software. The second row contain the identifier of the patient (Metadata 1) that is related to the event and additional information regarding the software’s function (Subtimer).](image-url)

Each row in the log file was considered to be an event. Each event in the log file included 16 attributes: 1) End Date: date of the log file event; 2) End Time: accurate to the second when the log file event was completed; 3) Node Name: networking information; 4) Timer Name: high-level description of the log file event; 5) Elapsed Time: amount of time in seconds for the system to execute the log file events; 6) Pass: unknown; 7) Exec Name: name of the execution software; 8) Process ID: unknown; 9) Thread ID: unknown; 10) Username: provider identifier; 11) Client PC: workstation identifier; 12) Client IP: networking identifier; 13) Fail Code: unknown; 14) Subtimer: additional background regarding the log file event; 15) Result Count: unknown; 16) Metadata 1, 2 and 3: may contain a patient identifier; the patient identifier is not related to the patient medical record number or any other identifier that could be used to re-identify the patient. We provide in Figure 1 an example of an event in a log file. From all the information...
contained in the log files the most relevant for process mining analysis was end date and time, elapsed time, timer name in conjunction with the subtimer, username (provider identifier) and the metadata (patient identifier).

The Mayo Clinic also made available an event log dictionary that provided, for each potential event log that could be collected, a description of its interpretation. To better understand and associate users’ behavior and clinical workflow, the second team reviewed selected portions of the Morae™ video recordings and closely collaborated with the first team to generate the results reported here.

Morae™, Microsoft Excel, Java, and Disco™ were used for preprocessing and cleaning the EHR event logs. While the process mining analysis presented in this paper is based on two of the observed days, the full data set of Morae™ video recordings and researchers’ observations, were reviewed for log event analysis.

In Excel, event logs were sorted based on date and time. Files were converted from .csv to .xls format. The .xls files were then cleaning using a Java program. Once the files were cleaned, they were manually merged with Excel. Files were merged according to days so that multiple personnel were all in the same file. This organization allows for the process mining analysis to be done from either the personnel or patient perspective.

Once the .xls files were organized by days, they were imported into Disco™ and exported as XES ProM files. Disco™, a processing mining and automated process discovery software, was used for additional data cleaning and file conversion. The resulting XES files were imported to ProM for analysis. ProM is an open-source, free software, considered the “de-facto” process mining software. It contains hundreds of plug-ins (algorithms) for process mining analysis. Several ProM plug-ins were used to further refine the dataset for analysis and produce visualizations.

**Results**

First, we present outcomes from the application of observational techniques, in particular descriptions of PreOp personnel roles and responsibilities, patient-based workflows and personnel’s coordination process integral to patient flow in PreOp. Then, we build on those outcomes to apply process mining techniques to address three relevant questions posted by the observational team: Can we validate observed handover-of-care based on PreOP personnel’s sequential interactions with patient cases?; How much time do personnel spend in electronic information systems?; How much time do personnel spend on documenting and/or reviewing data using paper based artifacts vs. electronic systems?; Is there a correlation between care paths followed and the time spent in the PreOp by different patient groups?.

**Personnel and their interactions, captured through observational techniques**

PreOp relies on a number of personnel and roles to ensure safe patient care delivery and timely preparation for surgery. Roles specific to PreOp include the health unit coordinator (HUC), patient care associate (PCA), pre-operative nurse (RN), float nurse (Float RN), Desk nurse (Desk RN), and Team Lead (TeamLead RN).

HUCs are non-clinical staff who are stationed at the check-in desk in the Surgery Waiting Room. For patients arriving to the hospital on their day of surgery, the HUC station is their first stop. The HUC facilitates communication between patient’s family and clinicians during the patient’s perioperative care (i.e., pre-op, intra-op and post-op). For example, the HUC is responsible for notifying the Desk RN when the patient has arrived in the Surgery Waiting Room.

The PCA is the patient’s second point of contact in PreOp. PCAs guide the patient from the Surgery Waiting Room to the patient’s PreOp room, orient the patient to the room, and collect some of the patient’s vital signs measures (written on paper). For some patients, PCAs may help with surgery preparation activities. PCA’s do not use HIT in support of patient care.

Each day, RNs are assigned two PreOp Rooms and are responsible for ensuring the Nurse Assessment, preparatory care and associated documentation are complete for each patient assigned to those rooms. Activities include: validate the patient and surgical procedure, activate anesthesia, surgery and nursing orders, reconcile medications, administer medications, validate procedure and signature on the informed consent document, validate presence of a recent history and physical note is documented, ensure pre-operative testing is completed, coordinate outside resources, complete assessment questions with the patient (e.g., neurological assessment), collect patient contact information and post-surgery transportation plans and others. The RN’s last activity for each patient, is to complete a face-to-face verbal handoff to members of the patient’s surgical team, who then transport the patient to the operation room.

Each day, several nurses fill the role of Float RN. Unlike RNs, Float RNs are not assigned to rooms or patients. Instead, they provide assistance to the RN as needed. The assigned RN is responsible for the RN Assessment and required pre-operative documentation. Therefore, the Float RN will assist with non-documentation activities allowed by their training (e.g., place IV catheter and administer IV fluids).

The Desk RN and TeamLead RN roles are each filled daily by a nurse who is more experienced in the unit. The Desk RN manages patient flow through the PreOp unit and day-of-staffing schedules. Responsibilities include, assign patients to PreOp Rooms with consideration to the RN’s workload and the patient’s scheduled surgery start time,
identify patients who may not be prepared for the scheduled surgery start time and communicate with the surgical team (e.g., the patient arrives late to the unit), and coordinate patients and PreOp staff in response to emergent changes to the surgery schedule (e.g., contact patients to notify of change). Experience is important because the Desk RN needs to anticipate changes to the surgery schedule (e.g., based on a surgeon’s anticipated efficiency in prior procedures, the surgeon is likely to ask for a patient to be prepared of surgery earlier than scheduled) and resource constraints (availability of RNs and Float RNs). The TeamLead RN role is typically filled by one experienced RN. When this RN is not working, another experienced RN fills this role. Otherwise, the TeamLead RN’s daily responsibilities are similar to a Float RN where they assist PreOp RNs with safe and timely preparation of the patients for surgery.

*Patient-based workflow, captured through observation techniques*

Table 1 provides a schematic summary of observed patient-workflow in terms of patient’s physical location in PreOp setting, personnel involved in patient care, artifacts used (paper-based or electronic) and SurgiNet perioperative tracking status. The patient’s first interaction with the PreOp unit, is at the Surgery Waiting Room on the hospital’s second floor. Prior to this, upon arriving at the hospital, the patient checks in at the Admission Desk. In the Surgery Waiting Room, the patient checks in with the HUC at the check-in desk. Patients are asked to arrive two hours before their scheduled surgery. To inform other PreOp personnel that the patient has arrived, the HUC uses Perioperative Tracking in SurgiNet. Specifically, the HUC changes the patient’s tracking status to “Arrival Waiting Room”.

The Desk RN monitors the Perioperative Tracking display, which most often remains displayed on one of the person’s desktop monitors. When the Desk RN sees the indication that the patient is in the Waiting Room, the Desk RN retrieves the patient’s prepared chart from a file rack behind him/her, which holds prepared paper charts (PC) for all surgical cases planned for the day. The Desk RN interacts with the Perioperative Tracking display at SurgiNet to select the room and to type the name of the RN assigned to that patient case. To make the room assignment, the Desk RN views PreOp RN staff and the availability of their assigned rooms. The room number is also written on the front of the patient’s chart and on a small purple paper attached to the chart. PreOp RN staffing and their assigned rooms are viewed and managed on a locally-developed screen view, Staff Scheduler, that is always displayed on the Desk RN’s second desktop monitor.

### Table 1. Observed correlation of patient’s physical location in PreOp setting, personnel involved in patient care, artifacts used (paper-based or electronic) and SurgiNet perioperative tracking status.

</tbody>
</table>

When a chart becomes available in the file rack, a PCA picks up the chart on her way to get the patient. The PCA meets the patient in the Surgical Waiting Room and guides the patient to the assigned PreOp room. On the way, they
stop at a scale and measure to get the patient’s height and weight, which the PCA records on the purple paper. To signal to the Desk RN that the patient is on the way to a room, the PCA takes a patient identification sticker off the chart and leaves it with the Desk RN. This triggers the Desk RN to change the patient status in Perioperative Tracking display in SurgiNet from “Arrival Waiting Room” to “In PreOp”. The patient is placed in the PreOp room one or two hours before the surgery.

In the PreOp room, the PCA collects additional patient vital signs (e.g., blood pressure, temperature, etc.). To signal to the RN when the patient is in the room, the PCA moves the rolling table in the room to the hallway just outside the room, and places the patient chart on the table. Before entering the room, the RN will often get the patient’s paper chart from the table and access patient data in the PowerChart to assess pre-operative care needs and initiate processes, such as activating surgical, anesthesia and nursing orders. The duration, number and type of system interactions the RN performs to complete the Nurse Assessment, preparatory care and associated documentation for each case, are affected by a number of factors, such as the patient’s acuity, surgical service and surgical procedure.

When finished with the RN Assessment and pre-operative care and the patient is ready to go to the operating room, the RN changes the patient’s Perioperative Tracking status in SurgiNet to “RN Assess Comp”. If the patient would like to see family who are waiting in the Surgery Waiting Room, the RN changes the patient’s status in SurgiNet to “Family” to signal to the RN when the patient is in the room. The HUCs monitor their Perioperative Tracking display for the brown “Family” status. When they see this, a HUC guides the family to the patient’s room. Upon returning to their desk, the HUC removes the “Family” status event from the Perioperative Tracking display, which returns the display back to the message “RN Assess Comp”.

After the RN completes a face-to-face verbal handoff with members of the patient’s surgical team, they transport the patient to the assigned operating room for surgery. On their way past the Desk RN, one of the surgical team members drops off the purple card with the Desk RN. This transfer of the purple card is used to signal to the Desk RN that the patient is leaving the PreOp unit. After several minutes have passed and the patient’s Perioperative Tracking status reads “In Surgery”, the Desk RN removes “In PreOp” from the patient’s tracking list. Of note, the purple card has the patient’s vital signs on it that were hand-written by the PCA. The Desk RN is responsible for entering these data into the patient’s chart in PowerChart.

Provider and patient-based workflows captured through process mining

Using a combination of process mining techniques, and outcomes from observational data collection we endeavored to answer four questions relevant for workflow analysis:

1. Can we validate observed handover-of-care based on PreOP personnel’s sequential interactions with patient cases?

We examined how an analysis of team interactions using the event logs compares to the above observational-based description of patient-based workflow. To achieve this, we created a sequential visualization and performed a social-network analysis of the event logs where team interactions are measured by personnel’s sequential access to a patient chart. For example, in the sequence of events associated with a patient chart, if there is an event associated with the HUC followed by an event associated with the Desk RN, then the sequential visualization would show a dot associated to a HUC preceding a dot associated to the Desk RN role, and the social-network analysis would identify a HUC-to-Desk RN interaction for this patient case.

We used the dotted chart PROM plug-in to automatically discover and visualize the sequence of personnel’s interactions for each patient case for Days 1 and 2. Dotted chart for Day 2 is shown in Figure 2. Of note, each row is for a single patient and the dot colors are associated to the personnel’s role. The HUC and the Desk RN usually generate the first event log for each patient. These events are often followed by an RN. This is consistent with the observed workflow.

The handover-of-work social network PROM plug-in provides an alternative visualization of team interactions on Days 1 and 2, in which the role-to-role interactions with SurgiNet are visualized as a relative probability. The event logs were filtered to contain four events types that best represented user interactions with SurgiNet for patient documentation or information review activities. These four events were among the 15 most-frequently occurring events for both Days 1 and 2. For example, “Build SDL” event represents personnel clicking check boxes on the screen when completing documentation or reviewing information, and “Load Set Events” event represents personnel changing the PreOp tracking status of the patient. The other two events, “Display Plans” and “Start Chart Search” indicate that the provider/staff has accessed a patient’s care plan and chart, respectively.

In Figure 3, the social network of handover-of-work analysis shows that generally all the roles reciprocate handover-of-work to one another, except for the TeamLead RN who only interacts with the Desk RN. The most common hand-offs occurred from the HUC-to-Desk RN and then back and forth between the Desk RN and the RNs (i.e., Desk RN-to-RN and RN-to-Desk RN). The next most common interactions occurred from the Desk RN–to-HUC, back-and-forth between the HUC and the RNs (i.e., HUC-to-RN and RN-to-HUC). Also, consistent with
observations there were fewer event logs generated by float RNs as they generally assist with non-documentation related care.

Figure 2: Dotted chart for Day 2. The x-axis is divided into hours of the day and each row represents a patient. The colored dots represent log file events from all the type of providers in PreOp. The colors are based on provider roles.

Figure 3: The social network of handover-of-work shows that generally all the roles reciprocate handover-of-work to one another except for the Team Lead RN only hands-off work to the Desk RN. The most common hand-offs occur from the HUC-to-Desk RN and then bi-directionally between the Desk RN and the RNs. Circle size correlates to the number of event logs associated with the role—a larger circle size indicates that role generated a larger number of event lows. Arrow thickness correlates to the number of interactions. A larger arrow indicates that interaction occurred more frequently when compared to other interactions.
2. How much time do personnel at PreOp spend using electronic information systems?

To answer this question, two things had to be quantified for each patient: a) how much time personnel spent in electronic information systems, and b) how much time personnel spent with a patient.

After manually reviewing event logs, we found that SurgiNet was almost exclusively the executed program recorded in the provided event logs. There were few events outside SurgiNet. For example, on Day 1, there were only 40 events of ~38,000, or 0.1%, not associated with SurgiNet. Two other programs identified, other than SurgiNet, were Smart Template Wizard and Schappt Book. We were not able to interpret these events, as they did not coincide with the Morae video capture. On the other hand, using Morae video recordings, we could associate an event from Day 2 labeled “web launch” with the launch of Synthesis. Synthesis is a home-grown system to facilitate the navigation of the EHR. It offers users a single, integrated view of information from many disparate sources. This log file event occurred an additional 11 times on Day 2 and only once on Day 1. These other “web launch” events from Days 1 and 2 did not coincide with Morae™ video recordings; therefore, we could not assess if this event name always referred to the user accessing the Synthesis system. Also, there were instances in the Morae™ video recordings where users launched other systems or tools, such as web browsers or email, and these events were not identifiable in the event logs. As a result, we concluded that event logs do not sufficiently identify when users access electronic systems outside SurgiNet; therefore, the event logs could not be analyzed to measure the amount of time personnel spent on other clinical information.

To quantify how much time personnel spent in electronic information systems, we assumed that all activity in the event logs was attributed to time spent using SurgiNet. We analyzed the amount of time the personnel spent in the system per patient by generating patient-centered workflows using ProM. The data from Days 1 and 2 was visualized from the patient perspective with the dotted chart PROM plug-in (Figure 4). From the 142 identified patients we selected a subset of 60 patients. For instance, we removed patients when we identified that personnel spent less than 15 minutes interacting with the information systems to review information of that patient. For the given example, the assumption was that the personnel were accessing patient charts for individuals not scheduled for the surgery that day. For each of the 60 patients we created the corresponding dotted chart and we discovered that the average amount of time a RN spent interacting the patient’s chart using SurgiNet was 44 minutes. On average the time the patient spent in the PreOp room, excluding time in the waiting room and waiting time for surgery, was 3 hours and 33 minutes and 27.2% of that time was spent by personnel accessing SurgiNet.

Figure 4: Dotted chart of Day 1. The x-axis is divided into hours of the day (4:00am to the end of the day is displayed) and each line represents one of the 77 patients. Each colored dot represents one of the 39,363 log file events from all the personnel and the colors are based on 274 unique even types. For instance, dark purple represents events where the doctor read clinical notes and light green corresponds to an ICU band load.
The time spent by personnel with a patient could be different from the time spent in electronic information systems. To quantify the time spent by personnel with a patient we excluded event logs generated by HUC, Desk RN and other personnel to eliminate variability in patient arrival times with respect to the PreOp schedule. The dataset was reduced to only include RNs and patients for whom we had Morae video recordings available, which was 6 patient cases. For that subset, total time in the system was found looking at the difference between the first event log from the RN and the last event log from the RN with respect to the patient of interest. This was assumed to closely represent the amount of time a patient spent in a PreOp room before being wheeled into surgery and did not include time spent in the waiting room. For the patient of interest, activity groups associated to the RN role were defined as two or more events that occurred within close temporal proximity to each other. Gaps of 5 minutes or more in the event logs indicated the beginning of a new activity group. The start time from the first event log in an activity group was subtracted from the end time of the last event log from the same activity group, to determine the total amount of time the RN spent reviewing/updating patient information in SurgiNet. The duration of each activity group was considered an approximate representation of the time the RN spent using SurgiNet, which was then compared to the total time in the system. We found that the average amount of time a patient spent in the PreOp Room, excluding time in the waiting room and waiting time for surgery, was 2 hours and 12 minutes. One hour and 12 minutes (55%) of that time was attributed to RNs using SurgiNet to record information relevant to the patient’s clinical case.

3. How much time do personnel at PreOp spend on documenting and/or reviewing data using paper based artifacts?

In Question 1, we used event logs to quantify the amount of time a patient is in PreOp and amount of time personnel use the computer-based artifact, SurgiNet. Morae™ video analysis was required to identify how much time personnel spent per patient reviewing and/or documenting with paper artifacts. The RN spent an average of 6 minutes and 40 seconds using paper-based artifacts per patient, which accounted for 5.2% of the average total time a patient is in PreOp. The remaining time (40%) was not spent using paper-based artifacts or interacting with SurgiNet.

4. Is there a correlation between care paths followed and the time spent in the PreOp by different patient groups?

In our case, patient groups could be defined in terms of several factors, such as the patient’s acuity, surgical service and surgical procedure. By filtering the event logs based on common PreOp patient tracking events described in Figure 1 (e.g., those associated with check-in and check-out events), it is possible to estimate how much time a patient spent in the PreOp unit. The amount of time each patient spent in PreOp was determined by first visualizing the filtered event logs (i.e., a sub-set that only contains the event type associated with tracker status update events for the patients with the dotted chart analysis), see Figure 4. The data was cleaned to only include personnel and patients for whom we had Morae video analysis available. Then the dotted chart plug-in was used to extract the time spent in PreOp in the same fashion that was done to find the amount of time personnel were in SurgiNet as in Figure 4. While we could estimate the care paths and time spent by patients at PreOp, correlating them with the patient’s clinical case requires a manual review of the patient’s chart, which is outside the scope of the methodological approaches chosen for the ROOT project. Therefore, while very relevant, this question remains unanswered.

Discussion

The application of process mining into healthcare is a relatively new, but growing area of research. Zheng et al investigated user’s interaction with an EHR by uncovering hidden navigational patterns in EHR event logs. They identified repeated feature access in successive action sequence. Various patterns deviated from optimal clinical management pathways. Kannampallil et al used event logs to compare the information-seeking strategies of clinicians in critical care settings. Specifically, they characterized how distributed information was searched, retrieved and used during clinical workflow. They found that there are costs (e.g., effort, time and cognitive load) associated with particular strategies. In our prior work, process mining was applied to characterize clinician’s patterns of information gathering. Kaufman et al. proposed the novel use of process mining techniques in combination with qualitative methods to help discover, analyze and visualize records of human computer interactions to lead to improved EHR designs. Applying similar methods, Furniss et al. found that participants’ EHR-interactive behavior was associated with patient case complexity, preferred information sources, and EHR default settings.

A 2016 review by Rojas et al. found 74 papers associated with the use of process mining in healthcare domains. In 2013 a review of the state of the art by Mans et al. indicated that only 40 publications referred to the use of process mining in real clinical contexts. From those, only one publication focused on the use of process mining in the context of PreOp processes. The review surfaced the five questions that are most frequently asked when process mining techniques are used in the healthcare context: Q1) What are the most commonly followed paths and what exceptional paths are followed? Q2) Where are the bottlenecks in the process? Q3) Is there compliance with external and internal guidelines? Q4) Are there any differences between care paths followed by different patient groups? Q5) What are the roles and social relationships between medical staff?. Besides the questions addressed in the Result section, the ROOT project also attempted to answer frequently asked questions Q1-Q5. A central goal of our research
was to apply a hybrid methodology for addressing similar questions. Below we explain in detail successes and challenges encountered trying to answer those questions. We also describe how questions that could not be fully addressed in this study can be investigated in future research.

Questions Q1-Q3: unfortunately, the event logs available in the ROOT project were created to quantify performance measurements. This constraint makes it difficult to accurately infer the clinical context of the related workflow activities. Therefore, applying process mining techniques to the available event logs did not lead to answering questions Q1-Q3.

Question Q4: the research teams wanted to know if there was a correlation between the care paths followed and the time spent in PreOp by different patient groups. Understanding patient’s clinical case would require having access to the patient’s chart. The ROOT project did not envision review of the patient’s medical records, and therefore we could not answer this question.

Question Q5: We successfully answered this question by validating results from observational techniques with the discovered handover-of-care (Figure 3). Consistent with observations, the social network shows that generally the roles reciprocate handover-of-work to one another except for the Team Lead RN who only hands-off work to the Desk RN. In addition, we compared the frequency of interactions between role types. The most common hand-offs occur from the HUC-to-Desk RN and then bi-directionally between the Desk RN and the RNs. This analysis could be replicated considering individual personnel or groups of personnel.

In the process of trying to answer frequently asked questions Q1-Q5 the ROOT project encountered some limitations:

- **Event logs were created for performance analysis and not for workflow analysis:** we only had access to event logs being recorded for tracking the performance of electronic information systems (e.g., system response time). Example: time required to load a new screen, time required to register a click in a box in a screen, time required to close a screen, etc. The event logs that we had access to did not contain the level of granularity and event types needed to answer some relevant clinical workflow questions posted by the research team, or to answer the four questions chosen in the Objective section using only process mining techniques. It would have been desirable to have access to event logs related to personnel activities as described in the observed provider-based and patient-based workflows. Example: check-in, assessment, upload vital signs, etc. What we have learned will help to better identify the type of event logs that we wish to collect in the new EHR ecosystem to better understand and discover clinical workflows and to guide workflow improvements.

- **Lack of access to event logs from all electronic information systems used:** We only had event logs from a single information system used in PreOp unit, the EHR-based SurgiNet system. While it was the primary system used for patient documentation and coordination activities in this setting, RNs referenced other information systems to complete key patient care activities. In addition, when applications outside the EHR system such as Synthesis, Outlook, Smart Template Wizard and Schappt Book were launched, there were few if any event logs created. As a result, we could only approximate the total time personnel spent with all HIT systems (Question 1). We are in the process of understanding the implications of these limitations.

- **Lack of access to patient’s medical records:** because the ROOT project has been framed as a quality improvement research, we had no access to EHR data for the observed patients. Access to this information could have provided additional insights on the discovered patient-based workflows.

The challenges and successes encountered while answering the questions described in the Result section and questions Q1-Q5 helped the ROOT team to identify lessons learned:

- Access to event log dictionaries was a very valuable initial resource to help interpreting logs
- Review of observational data could be time consuming but essential to further interpret event logs and outcomes from process mining. The need to access to observational data is based on the limitation that event logs available for the ROOT project were created for performance analysis, instead of for workflow analysis.
- Mine both patient-centered and provider-centered workflows provided complementary insights for the clinical workflow analysis.
- Understand differences between the type of events captured through the enterprise, as oppose to the type of desirable events could guide future event log capturing.

Conclusions and Future Work

The Mayo Clinic is embarking on a large-scale effort to standardize workflows across its four geographical clinical networks, and thus move from multiple disparate EHR platforms to a single EHR system.

Here we reported preliminary results that demonstrate the value of applying process mining techniques, in combination with observational techniques, to better understand clinical and electronic workflows before they
disappear due to the transition of Mayo Clinic to the new EHR. Most importantly, lessons learned on the limitations encountered during the process of mining existing log events to answer relevant workflow questions will guide future recommendations on type of information and levels of granularity required to be captured by log events to be generated by the new Mayo Clinic EHR.

We have conducted similar multi-method data collection observational techniques at four additional Mayo Clinic locations. In addition, we have completed and we are in the process of analyzing 35 interviews (21 of them involving leadership) across the enterprise. We plan to apply the methodologies described in this paper to answer similar questions, and to compare results between locations. Similarities and differences between identified workflows could inform the upcoming process of workflow standardization and future process improvements across the Mayo Clinic enterprise.

We suggest that determination of event types in system-generated event logs is made with consideration for clinical workflow analysis, such as for the goals of the ROOT project.

Abstract

Though several institutions offer hospitalized patients access to their medical records through acute care patient portals, no studies have assessed the potential impact of patients’ access to physicians’ notes through these systems. We employed a mixed-methods approach, including patient surveys, system usage log analysis, and qualitative interviews, to describe patients’ perspectives on receiving their clinical notes and usage of the clinical notes feature in an acute care patient portal. Patients visited the clinical notes feature more frequently and for longer durations than any other feature. In qualitative interviews, patients reported improved access to information, better insight into their conditions, decreased anxiety, increased appreciation for clinicians, improvements in health behaviors, and more engagement in care. Our results suggest that sharing notes with hospitalized patients is feasible and beneficial, although further studies should investigate the magnitude of benefit and explore the unintended negative consequences associated with increased transparency of clinical information.

Introduction

Increasingly, healthcare institutions offer inpatient access to the medical record through acute care patient portals. Several medical centers, including Brigham and Women’s Hospital, NewYork-Presbyterian Hospital / Columbia University, Michigan Medicine, the Ohio State University Wexner Medical Center, Northwestern Memorial Hospital, and the Veteran Affairs Medical Centers have trialed or currently maintain acute care patient portals. The Libretto Consortium is composed of five institutions that have implemented or plan to implement an acute care patient portal.

Acute care patient portals offer various features, including medical record viewing, patient-provider messaging, care plan and safety information, educational materials, and amenities such as food ordering. To our knowledge, no studies have evaluated the impact of a feature that enables inpatients to view their clinicians’ notes, despite evidence that most patients (over 90%) report wanting access to their complete medical record. In the outpatient setting, the OpenNotes consortium has enabled nearly 10 million patients to access their primary care physician’s office notes. Research suggests that OpenNotes increases patient satisfaction, trust and safety, and the project has attracted considerable media coverage.

Given the acceptance of OpenNotes in the outpatient setting and patients’ enthusiasm for increased transparency of their medical record, the expansion of note-sharing to the inpatient setting is a probable next step. To date, few data exist regarding the benefits and risks of inpatient note-sharing, because few institutions have embraced the practice. To address this gap, we designed a mixed-methods study to evaluate usage of a clinical notes feature in an acute care patient portal and describe inpatient perspectives regarding receiving their clinical notes.
Methods

Study Design

Using purposeful sampling, we recruited study participants from a single cardiac step-down unit at NewYork-Presbyterian Hospital / Columbia University Medical Center. Each participant received access to their hospital medical record via a previously described acute care patient portal. Participants accessed the portal using a hospital-provided iPad with internet. A new “Clinical Notes” feature provided participants with real-time access to all clinical notes written about them by either medical doctors or nurse practitioners. Patients maintained access to the portal throughout their hospital stay, even if moved to another unit. Each participant completed a survey as well as a semi-structured interview. Additionally, we recorded and analyzed system usage logs for each participant. The Columbia University Institutional Review Board approved the study.

Recruitment

Inclusion and Exclusion Criteria: We included adult patients admitted to the cardiac step-down unit. Although the portal offered information in both English and Spanish, we included only English-speaking patients because our clinicians write notes in English. We excluded patients with severe cognitive impairment or major psychiatric illness, patients unable to provide written informed consent, patients actively participating in another research study, and patients placed in contact isolation.

Recruitment Protocol: The research coordinator identified potential participants through discussion with attending cardiologists on the unit. The coordinator typically invited patients to participate within 1-2 days of admission. Patients agreed to provide survey data and to participate in an audio-recorded interview. After participants provided written informed consent, the coordinator conducted a brief training session to familiarize the participant with the iPad, the portal login procedure, and the portal layout. For the first five days following recruitment, the coordinator visited each participant daily to troubleshoot any issues with the network, iPad, or portal. After the first five days, the coordinator visited the participant twice weekly until discharge. For infection control purposes, the coordinator used antibacterial wipes to clean the iPad between participants.

Measurements

To collect participant demographics, assess technology literacy, and determine health literacy, we used our previously described patient survey. We used the Patient Activation Measure (PAM) to assess patients’ knowledge, skills, and confidence in managing their health and healthcare. To measure portal usage, we recorded each user action in a detailed system usage log.

A content expert used an iterative process to develop a semi-structured interview guide. Briefly, the content expert developed a preliminary five-question guide based on patient interviews from a separate study. Then, the content expert incorporated feedback from each study team member to develop the final interactive interview guide. The interview topics included general experience with the iPad and portal, and the usefulness, comprehension, emotions, and behavior changes associated with reviewing providers’ notes.

Data Collection and Management

The research coordinator (LVG) collected the patient survey and PAM responses at the time of recruitment. The semi-structured interview took place either two weeks after enrollment or one-to-two days before discharge. The research coordinator received training prior to interaction with participants and followed specific guidelines to ensure consistency of data collection. The coordinator continued enrollment until thematic saturation occurred, meaning participants discussed no novel themes.

Data Analysis

Quantitative: We conducted a descriptive analysis of the patient survey data, PAM data, and system usage log data in R Studio. For the purposes of comparison, we conducted a descriptive analysis of the age, sex, employment status, race, and ethnicity of all patients admitted on the cardiac step-down unit during the study period.
Qualitative: A professional service transcribed the audio-recordings of the interviews verbatim. Transcripts were imported into NVivo Version 11 (QSR International) for thematic analysis. The authors analyzed the transcripts in multiple steps using a qualitative descriptive approach to uncover common themes regarding patients' perspectives on receiving their medical record information, particularly their clinical notes. The analysis included three steps. First, two authors with training in qualitative methods (LVG, RMC) independently read each transcript, and defined codes in a dictionary for the remaining analysis. In addition to codes that emerged from the data, the dictionary included a priori codes based on the research questions, interview guide, and literature. Second, the two authors independently coded all transcripts using nodes corresponding to the coding dictionary. We conducted one round of inter-coder comparison queries in NVivo11. Kappa scores ranged from 0.74 to 0.94. The coders met to review, discuss, and arrive at consensus for the content coding. Third, additional experts reviewed codes for accuracy and to identify common themes. Themes emerging from four or more interviews were identified as common.

Rigor: One author (LVG) conducted all the interviews and confirmed the content of the audio recordings and transcripts to ensure accuracy. All authors reviewed the coding procedure to ensure dependability and credibility, and both coders stringently adhered to the coding procedure. To further enhance dependability and credibility, the coders shared an audit trail and notes on the application of each code with the research team to illustrate the process that led to their conclusions. The authors triangulated multiple sources with the interview data to confirm accuracy, including patients' comments through the portal and during daily visits.

Results

Study Population

Out of eleven patients approached to participate in the study, ten consented to and completed the study, including five congestive heart failure patients, four post-heart-transplant patients, and one post-kidney-transplant patient. The eleventh patient declined to participate due to feeling too ill. Participants spent an average of 13.3 days with access to the portal (range: 4-38). The mean age of participants was 49 years (range: 27-60), comprised predominantly of men (n=9). Table 1 compares the study participants' demographic characteristics with the overall demographics of the cardiac step-down unit. The study population was representative of the employment status, race, and ethnicity of the unit, but was more predominantly male and younger.

* Non-English Speakers excluded from study because cannot read notes
-- Data not available for the unit
Technology and Health Literacy: The majority of participants reported previously using the internet to look up health information (n=7). All participants reported previously using the internet through another device, and half reported previously using an iPad or another tablet. Three participants reported needing frequent help to read and understand hospital materials or medical information.

Patient Activation: The Patient Activation Measure (PAM), which assesses individuals' knowledge, skills, and confidence in managing their health and healthcare,\textsuperscript{18, 41-56} categorizes patients into four distinct levels of activation: (1) disengaged and overwhelmed, (2) becoming aware, but still struggling, (3) taking action, (4) maintaining behaviors and pushing further. The PAM categorized our study participants as level 2 (n=3), level 3 (n=6), and level 4 (n=1). The high level of activation is consistent with the selection of five participants as transplant candidates.

Portal Usage

Based on system usage log analysis, all ten patients accessed the portal independently, without the research coordinator present. Eight out of ten patients viewed their clinical notes. Patients logged in an average of 2.19 times per day (range 0.375-7.2). Patients typically accessed the portal in the morning, prior to rounds, or in the afternoon, when new test results or clinical notes tended to appear.

Patients navigated to the clinical notes feature most frequently, followed by the laboratory test results and the medications. Patients spent the longest time viewing the clinical notes feature (mean: 7.2 minutes, max: 34.1 minutes), compared to the laboratory test results feature (mean: 3.0 minutes, max: 31.4 minutes) and the medication feature (mean: 1.25 minutes, max: 20 minutes).

Usefulness of Clinical Notes

Participants spoke of reading clinical notes as an informational experience that supplemented their verbal communications with their physicians. Participants felt the notes allowed for communication outside of potentially intimidating or rushed one-on-one situations. One participant discussed how important the written information felt to him, because he felt overwhelmed in one-on-one situations:

"A lot of times, the docs say all this stuff. It's really intimidating. I don't always understand everything they're saying. I get an idea, if things are good or bad, or if they're concerned or not concerned. But this is a different kind of communication that I've never seen before. It's bringing everybody [the patients] in, putting us on the same page." [Pt.1]

Another participant discussed how important the written information felt, given the short amount of time devoted to verbal communication with his physician:

"On average, I get to spend about a minute-and-a-half with my doctor a day, and so when I go back after the doctor writes the report, I get a more detailed account. Although it's not a personal one-on-one, it at least comes from her mind that she has seen me and these are the more detailed things." [Pt.7]

Participants viewed notes as objective indicators of both their health condition and their progress while in the hospital. Multiple participants (n=3) used the metaphor of seeing information in "black and white" through the notes. The participants explained:

"It's different, when you see the note. It's like a report card, I guess. When you see it; it hits you a different way. It's not as emotional, it's more objective. And it's there. It's right there in black and white so you can totally track like, "Oh, I'm good, I'm good, I'm good, I'm in trouble, ok now I got back on my feet." So I find that that's very good information." [Pt.1]

"To be honest, I can't always believe the doctors. I think that sometimes they sweet-talk you, excuse me for saying that. They don't want you to stress, and it's not like they lied to you, but sometimes they don't tell you the whole truth." [Pt.7]
Participants expressed a sense of ownership over their data, and wanted access independent of plans to read or use it. One participant who did not view his clinical notes still wanted the notes to be available:

"Even though I didn’t look at them [the notes], it’s just nice to have them. You can’t go wrong with it. More information is always better. Maybe if I had gotten sick, maybe it would have been different, or if something had changed, I would have looked." [Pt.5]

Half the participants (n=5) asked for access outside the hospital, unprompted. One participant even offered to pay for outside access. Two patients reported photographing information in the portal on their personal devices, to avoid fees associated with requesting their medical record from the hospital after discharge. Multiple participants (n=4) expressed the desire to review notes from prior hospitalizations.

Comprehension and Insight

Participants spoke of clinical notes as "truth tellers" that improved their insight about their progress and condition. One participant, after reading his notes, asked for a family meeting:

"My sister and I didn't realize that what I'm going through is as bad as it is. Basically, reading the notes, we felt it [my condition] was more serious. For some reason we weren't getting that in the room. We needed to know what our goals are. Which direction we're heading and how we're going to get there." [Pt.9]

After the family meeting, the patients' care team involved the palliative care service, who arranged the participant's discharge to home hospice care.

For another participant, the notes offered clarity about his condition's severity, and encouraged him to consider destination left ventricular assist device (LVAD) surgery:

"I was walking up and down that hall, going to the bathroom on my own. I really thought I was going to be able to go home, without any drugs, the Milrinone, all that stuff. But then you look at the notes. And they say it's the total opposite. I can see why I need this [LVAD]. I was glad that the doctors made the best decision... Every patient that walks through that door wants the raw deal of what's going on with their health situation." [Pt.10]

Participants spoke about "getting on the same page" as their physicians. Multiple participants (n=4) felt more able to converse with their physician, either because of better insight about their condition or increased comfort around the care team. The participants explained:

"It's very, very useful, because from the note we [I and my family] know exactly what's going on. And when we talked to the doctor, we were able to ask questions, and we know what the doctor is saying." [Pt.8]

"[The notes] help me keep track of who everybody is and who has seen me recently. Today, this older doc came in. And I was comfortable enough to be like, “Do I have to do a blood test every day?” And he was like, “No. We don’t have to do that.” And he totally changed it for me. If I was uncomfortable with him, I would never have broached that topic." [Pt.1]

Two participants reported that the portal answered questions they might otherwise ask their physician:

"It's better because you don’t have to call [the doctor] to ask questions; you just go there [the notes] directly." [Pt.6]

All participants who read their clinical notes reported struggling to understand medical terms and acronyms, excepting one participant who had a Master's degree in a medicine-related field. One participant explained his struggle with interpreting acronyms:

"There were a lot of acronyms. Some of these acronyms, I knew what they were talking about just because I know my history... there were a lot of line items [e.g., HPI, PMH, ROS], that I didn’t really get. But the parts that I could read and make my way through - that seemed pretty evident - I would just read." [Pt.1]
Emotional Reactions

Multiple participants (n=4) reported that viewing their notes decreased their anxiety. No participant expressed concern that seeing the notes increased anxiety. The notes reduced anxiety by providing new information, verifying known information, and offering additional processing time:

"Humans can make mistakes and even the input to these computers can be wrong. But when she [the doctor] tells me one thing and it’s backed up with visual, it makes me feel a little bit better about it... and you feel more confident, seeing that at least whatever episode or what you felt was bothering you at the moment has been notated, and at least it’s on their radar." [Pt.7]

"A lot of people get scared by this stuff. They’re intimidated. They’re in the hospital. They’re scared. It’s tough when there’s a guy in a white coat with stethoscope and glasses. Standing on top of you and telling you, “your CBC level is blah-blah-blah.” It’s rough. This [reading the notes] is not as intense. It’s a nice filter. It's like reading the paper." [Pt.1]

Participants reported increased appreciation for and trust in their clinicians. Seeing the amount of documentation prompted appreciation for the work physicians devoted to patient care:

"I don’t really understand everything in the notes, but it’s really amazing to see everything that goes into my care. I don’t think I really appreciated how much gets done for me before." [Pt.3]

"When I read the notes, I feel that the doctors are following and that they care for you." [Pt.8]

"[The notes] grounded me in my whole being here. At first, I just want to get out of here. But when I got this, I was like, “Wait a minute, they’re doing all this work for me.” I really looked at all this. It kind of laid it out for me. And I was like, 'Maybe I should just settle in. Let them do what they got to do.' " [Pt.1]

"Sometimes there are just so many different things, and if your gout doesn't clear up, you feel like you're not being taken care of sometimes. But when you read in the note, 'pending talking to a gout doctor,' it makes you feel better. They're really trying to care for you." [Pt.7]

Health Behavior Change

Multiple participants (n=4) reported changing their health behaviors after reading the notes, including one participant who called a family meeting, and another who considered LVAD surgery, described above. Another participant began drinking the nutrition supplement (Ensure) that his nutritionist had prescribed:

"I started drinking the Ensure. Honestly, I never really gave it a shot before. It was just that my dad had to drink it when he was sick, so it bummed me out. But once I saw everything, I felt like, the nutritionist is trying and is giving me this food for a reason, so I should try too, and do what I can to make my numbers as good as they can be." [Pt.1]

Another participant reported feeling more likely to take his antihypertensive medications:

"When I saw that my weight went really down, that was an eye-opener. I mean, you know it, but then when you actually see it, it’s different. Maybe when I get out, I’ll be a little more careful." [Pt.3]

Participants described how reading the notes increased their ability to engage with their care, because the written information allowed for processing time to overcome anxieties:

"I was able to read it and then process it, and then when the doctor came in and talked to me, it was easier to talk about." [Pt.9]

"At first, to be honest, I was a little bit weirded out. I was so excited to get my heart. And I think of that moment, and it's just like 'do I really want to know any more?' But once I got into it, it was like a good book. You just want to
Patient Safety

Participants reported incidents where access to their information improved their quality of care. One patient noticed a medication error:

"This morning I saw the prednisone had fallen off [of my medication list]. I showed the nurse, who agreed with me that something wasn't right. She called the doctor, and within a minute-and-a-half the prednisone was back on [my medication list]. And within another minute-and-a-half, my nurse was back with the [prednisone] pill." [Pt.7]

Another patient noticed a low calcium level which needed correction after plasmapheresis:

"In the afternoon something happened. It was about my calcium level. I went to the nurse, and explained to her, the normal is between this and this, and I'm here. The nurse wasn't sure, so I said look, I'm going to show you [with the portal]. She [the physician] doubled my calcium supplement. She said since I will have more plasmapheresis, we need the calcium to be higher. So [the portal], it saved me." [Pt.8]

Upon reviewing the chart, the participant's physician deferred his plasmapheresis until his serum calcium level returned to normal.

Discussion

A rapidly growing literature documents the benefits of acute care patient portals. Research suggests that bedside access to information may increase patient safety and satisfaction. To our knowledge, ours is the first study to elicit inpatients' perspectives on receiving their clinical notes through an acute care patient portal.

Although only ten patients participated, our results suggest that patients may benefit specifically from inpatient note-sharing. In our qualitative interviews, patients reported better access to information, increased insight into their condition, increased appreciation for their clinicians, changes in their health behaviors, and medical error prevention. The system usage log data demonstrated that patients used the clinical notes feature more frequently and for longer durations than any other feature. We achieved these results in a complex clinical practice setting, with variations in patients' conditions and treatments as well as heterogeneity among clinicians in education, experience, and motivation to share notes.

The lack of common negative themes surprised the research team. We expected that note-sharing might increase some patients' anxiety. However, we did not find evidence of increased anxiety among our participants, but we did find evidence of decreased anxiety. Given the study design, we do not know whether response bias existed which led to this conclusion. However, an alternative explanation is plausible, that information in any form counteracts the uncertainty and disempowerment patients feel when hospitalized. This explanation is consistent with prior OpenNotes research.

One striking result was the intervention's apparent influence on health behavior change and hospital outcomes. In a sample of only ten patients, four reported significant changes to their health behaviors, and two reported preventing possible medical errors. This included one patient who changed his entire course of end-of-life care, and another who opted to pursue surgery. Because completing an interview allows patients to reflect on and verbalize changes, further research should explore whether note-sharing actually translates to increased illness understanding, medical knowledge, health behavior change, and error prevention.

Some clinicians fear that note-sharing may prompt mistrust, force unwelcome changes to documentation practices, require increased time with patients to alleviate concerns, and increase legal liability risk. In our study, physicians did not appear to change their documentation practices. Patients expressed surprise and gratitude at receiving their notes, and after reading them, voiced increased appreciation for and trust in clinicians. In some instances, patients reported answering questions using the portal rather than asking their physicians. Although the patients' perspective...
cannot serve as a proxy for the impact on clinicians, our results encouraged us to remain open-minded about note-sharing. Future research should identify the unintended consequences of inpatient note-sharing, and investigate the effects of note-sharing on consultation time.

Our study had several limitations. First, we enlisted patients from a single clinical unit in an urban academic medical center. Though our sample included only ten patients, we achieved thematic saturation. Consistent with the sample size, we introduced stringent criteria for identifying common themes, namely that the theme must exist in four or more interviews. Second, we did not select participants randomly. Although the attending cardiologists purposefully selected patients representative of the unit, a selection bias for younger, more technology literate patients existed. Third, the study used five transplant patients as participants. Transplant patients must demonstrate high engagement prior to receiving their transplants, and may exhibit more interest in their health care than other patients. To confirm our findings, this study should be repeated with randomly selected participants and a more generalizable patient population than transplant patients.

Conclusion

To our knowledge, this is the first study to assess hospitalized patients' perspectives about receiving their clinical notes through an acute care patient portal. In qualitative interviews, patients who read their notes described better insight into their medical conditions, better access to information, decreased anxiety, increased appreciation for their clinicians, improvements to their health behaviors, and engagement with medical decision-making. Although our patient population is too unique to draw broadly generalizable conclusions, our results suggest that further studies to explore the potential benefits and unintended consequences of inpatient note-sharing are warranted.

When synonyms are not enough: Optimal parenthetical insertion for text simplification

Yang Gu\(^1\), Gondy Leroy, PhD MS\(^1\), David Kauchak, PhD\(^2\)

\(^1\)University of Arizona, Tucson, AZ; \(^2\)Pomona College, Claremont, CA

Abstract

As more patients use the Internet to answer health-related queries, simplifying medical information is becoming increasingly important. To simplify medical terms when synonyms are unavailable, we must add multi-word explanations. Following a data-driven approach, we conducted two user studies to determine the best formulation for adding explanatory content as parenthetical expressions. Study 1 focused on text with a single difficult term (N=260). We examined the effects of different types of text, types of content in parentheses, difficulty of the explanatory content, and position of the term in the sentence on actual difficulty, perceived difficulty, and reading time. We found significant support that enclosing the difficult term in parentheses is best for difficult text and enclosing the explanation in parentheses is best for simple text. Study 2 (N=116) focused on lists with multiple difficult terms. The same interaction is present although statistically insignificant, but parenthetical insertion can still significantly simplify text.

Introduction

Text-based information plays an important role in patient education. Doctors send leaflets and instructions home with patients so they can adequately care for themselves. More than half of American Internet users independently search for health-related information online\(^1\). Therefore, it is essential that medical information be written in language simple enough to be correctly interpreted by patients. Changing the words and grammar of a text can achieve text simplification, and appropriate modifications will enhance readability and comprehension.

In our prior research, we found that term familiarity, as approximated by term frequency, is a reliable indicator of text difficulty\(^2\). Term familiarity can identify and rank terms by difficulty. By substituting familiar synonyms for difficult terms, we were able to decrease both actual and perceived difficulty. However, many medical concepts do not have simple synonyms. For example, a single word is not enough to understand “reactogenecity”; the reader needs to make the connection between three concepts: a medical product, its adverse reaction, and the anticipated nature of the adverse reaction. For such concepts, we must insert an explanation in the text. Enclosing the new text in parentheses is one of the most natural ways to insert relevant but discontinuous information into text. Previous research has found that adding explanatory content enclosed in parentheses simplifies text\(^3\)\(^4\); however, the best way to formulate and insert the new information has not been investigated.

This research contributes to a semi-automated text simplification system for writers, which will automatically identify difficult text and suggest options for simplification. The human writer can choose to accept, refine or reject system suggestions to create coherent text. We examine four factors that may affect simplification using parentheticals: the difficulty of the original text, whether to place a term or an explanation in the parentheses, the difficulty of the explanatory content, and the position of the difficult term in the sentence. We conducted one study to investigate those four factors in sentences that contain a single difficult term. In a second study, we examine the extent to which parallelism in the formulation of parenthetical expressions will impact simplification of texts with multiple difficult terms in a list.

Background

Useful Existing Models to Guide Simplification

The fields of psychology and linguistics have explored the reading and discourse comprehension process, and there are many models of text comprehension. Some of the more well-known models include the Construction-Integration Model\(^5\), the Landscape Model\(^6\), and the Resonance Model\(^7\). Every model differs in its assumptions and computational model, but they agree on how the comprehension process works on a high level. During reading, the text provides the reader with cues, such as words and punctuation. Readers search their long-term memory to give meanings to these cues and construct propositions. Comprehension occurs when the reader is able to make connections between the propositions. In text simplification, we can facilitate comprehension by modifying the cues, such as words and syntactic markers, which will help readers make connections.
Explaining Difficult Concepts

Discovering and collecting a consumer-friendly medical vocabulary has been an ongoing effort in the health and medical informatics community. For example, there have been several efforts to collect vocabulary through web mining or automatically generating simple explanations based on relationships in the UMLS Metathesaurus.

Synonym replacement is an intuitive, effective, and popular approach for lexical simplification, but it is not always possible. When no synonyms are available, explanations need to be inserted. Kandula et al. made the distinction between “definitions” and “explanations” for terms. A “definition” is a description of the terminology that aims to be correct, accurate, and precise. For example, the Wikipedia page for “reactogenecity” provides a definition from the NIH (National Institute of Health), which states “Reactogenicity events are adverse events that are common and known to occur for the intervention/investigational product being studied.” An “explanation” is a description that is more abstract but also more understandable to the reader. It should not introduce more difficult terminology. In a sentence about anthrax vaccines, we can explain “reactogenecity” as “known side effects from vaccines.”

Some automated text simplification systems employ explanation generation. For example, Eom, Dickinson, and Sachs designed a system for second language learners that allows users to upload text in one panel and show the sense-specific definition for a selected vocabulary in a side panel. Damay et al.’s SimText system first uses a thesaurus to look for synonym replacements for difficult terms and then appends a definition when synonyms are unavailable. Kandula et al.’s system specializes in the medical domain and also first searches for consumer-friendly synonyms to medical terms in the Open Access and Collaborative Consumer Health Vocabulary. When that is unavailable, they generated simple explanations using high-level relationships in the UMLS.

Simplification through Parenthetical Expressions

A natural way to introduce new content into text is with parenthetical expressions. A parenthetical expression is any expression embedded in a host expression that makes no contribution to the structure of the host and makes the host expression discontinuous. In written text, the expression can be enclosed using a variety of punctuation characters, such as brackets, dashes, or commas. For example, consider “He told John – his best friend from college – all about it.” While it introduces more information, the parenthetical expression also disrupts the structure of the original sentence. We are interested in appositive parenthetical expressions, which reformulate parts of the original host expression. The reformulation provides additional information about the concept in the host expression. In the context of text simplification, we only consider appositive parenthetical expressions enclosed by literal parentheses in written texts.

We have two options for formulating parenthetical expressions to simplify difficult words. The common approach is to insert the explanatory content as a parenthetical expression behind the target term, as in “local and general reactogenicity (known side effects from vaccines) are expected.” This can be easily automated. The reader expects the parentheses to signal an interruption to the flow and structure of the entire sentence, so the language of the explanatory content need not blend perfectly with the host expression. However, the reader needs to read the parenthetical expression to understand the concept.

Alternatively, we can incorporate the explanatory content into the text and state the obscure medical term in a parenthetical expression, as in “local and general known side effects from vaccines (reactogenicity) are expected.” In this formulation, it becomes apparent immediately after the modifier clause that the clause describes the side effects of medicine. The reader can comprehend this information faster with less strain on their memory. Most reading comprehension models agree that readers keep snippets of information in their working memory, which has an approximate limit of seven plus/minus two units of information. Therefore, making information comprehensible as early as possible, and avoiding long interruptions and divergences in the text that must be stored in working memory, can be advantageous for comprehension. However, directly inserting definitions into text will create cohesion issues, especially when definitions are long, like those of many medical terms.

Because adding definitions within parentheses is widely used in written English, this formulation has been adopted as the default for parenthetical insertions. Nonetheless, there is little empirical support that one formulation is superior to the other.

Study Objectives

The goal of our studies is to discover combinations of features that would influence and optimize simplification when parenthetical insertion is needed. The first study focuses on simplifying sentences with one difficult “target” term. We investigate the impact of the difficulty of the source material, the placement of the parentheses, the position...
in the sentence, and the difficulty of the explanatory content. The second study focuses on simplifying sentences with multiple target terms in a single list. We investigate the impact of the difficulty of the source material and the parallelism of the parentheses. The target terms always remain in the text, so readers can learn the difficult vocabularies in their medical texts.

Methods

We conducted two user studies on the effects of parenthetical insertion on simplification. The subjects were asked to read short passages and answer questions about the actual and perceived difficulty of the text. Subjects were recruited on Amazon Mechanical Turk (MTurk), an online service that allows human workers to complete small tasks for monetary compensation. We restricted the workers to being in the United States with 95% approval ratings on previous tasks. MTurk has been used for tasks ranging from survey completion, data annotation or tagging, to user studies; study results have been shown to be as reliable as those from traditional approaches\(^1\),\(^2\).

Study Instrument. Each study used 16 passages identified from 16 documents. Eight documents are Wikipedia articles about medical topics and eight are PubMed abstracts of studies on various diseases. To select the passages, sentences were randomly selected and manually checked for suitability based on the following criteria:

1. The sentence does not contain difficult terms other than the target term, which we will augment with parentheses. The target term can be defined sufficiently in one sentence or less, and a reasonable, simple explanation can be created based on the target term.
2. The sentence can be edited to satisfy all experiment conditions, i.e., the definition and explanation for the term can be incorporated into the text of the sentence with minimal editing. Study 1 also requires that the target term can be moved to the end of the sentence with only minor changes to the words in the sentence.
3. The sentence is preceded and followed by one or two sentences from the same document that provide context for the passage. The context does not contain difficult terms or difficult terms can be removed.

The following is a passage from the Wikipedia article on Anthrax with the target word “reactogenicity”:

“Vaccines against anthrax for use in livestock and humans have had a prominent place in the history of medicine. The French scientist Louis [...] All currently used anthrax vaccines show considerable local and general reactogenicity (erythema, induration, soreness, fever) and serious adverse reactions occur in about 1% of recipients.”

We removed or simplified other difficult words besides the target word and split up sentences to make the context easier to understand. We also ensured that we did not introduce misinformation about the topic in our modifications. The edited passage used in our study is:

“Vaccines against anthrax in humans and livestock have had a prominent place in the history of medicine. Considerable local and general reactogenicity are expected from all currently used anthrax vaccines for humans. Common reactions include soreness and fever, and serious adverse reactions occur in about 1% of recipients.”

We conducted all statistical analyses with SPSS Statistics 24 with standard settings.

Study 1: Single Parenthetical Insertion

Design

This study focuses on simplifying sentences with one difficult target term. We use a 2x2x2x2 full-factorial within-subjects experimental design with the following factors:

1. Types of text: Wikipedia and PubMed. We use the source of the text as a proxy for difficulty. The Wikipedia articles represent easier text, while the PubMed research abstracts represent more difficult text. Wikipedia articles may contain difficult vocabulary and content, but they are meant to be descriptive and informative. Research articles have a different writing style and assumption of the reader’s knowledge, but they are also an important resource for expert patients and caregivers. We want to investigate how localized simplification that targets one single difficult concept may impact a generally difficult piece of text differently from a text that is only difficult at that single point.

2. Placement of Explanatory Content: Inside Parentheses and Outside Parentheses. Explanatory content placed inside parentheses is commonly used and easy to automate, but the alternative is less disruptive to the flow of the sentence and the reading process. Table 1 provides an example of how factors 2, 3, and 4 combine to form sentences.
3. Difficulty of the Explanatory Content: Simple (explanation) and Difficult (definition). Definitions can be extracted from established domain resources and provide more comprehensive information. Explanations tend to contain simpler language. For each target term, we create a “definition” using definitions from the term’s Wikipedia page or from a dictionary. Then, the definition is shortened and simplified manually to create an explanation. We did not use a single resource such as UMLS or Wikipedia for definitions because some terms are not defined concisely or understandably to a layperson in any one place. Since our system is designed for writers, they can intervene to refine existing definitions.

4. Position in Sentence: Middle and End. Since parenthetical expressions introduce an interruption in the flow of the text, we consider where this interruption occurs. If we insert the parenthetical expression at the end of the sentence, the interruption may be less disruptive than if we insert it in the middle.

</table>

We evaluate simplification using the following metrics:

Actual Difficulty. Average accuracy on three multiple-choice questions about the content of the passage, which the subjects answer without the text present. One question specifically focuses on the meaning of the target term, which is most directly related to the parenthetical expression.

Perceived Difficulty. A 5-point Likert Scale (1 = Very Easy, 5 = Very Difficult) response to “How difficult would this passage look in a text” immediately after reading.

Reading Time. Time (in seconds) the respondents spent on the page containing the passage.

Procedure

Subjects recruited on MTurk were redirected to a survey on Qualtrics. We used Qualtrics’ randomization features to assign 8 passages to each subject. The subjects do not see more than one version of any single passage.

After reading each passage, subjects were taken to a new page with six questions. The first question asked about perceived difficulty. Then there were three multiple-choice questions about the content of the passage and an attention question. The final question always asks about the subject’s prior knowledge or experience with the condition: “How familiar are you with the topic of [topic of passage].” Response choices were: “I have never heard of it before,” “I have only heard of it in passing,” “I have studied it in detail for educational purposes,” “I know of someone with this condition,” or “I have (or have had) this condition.” We interpret scores of 1 or 2 (first two
options) as minimal or no knowledge of the condition and scores of 3 to 5 (last three options) as high knowledge, and use this metric to control for the impact of background knowledge on the results.

We also use an attention question to filter out respondents who have not read the passage. For example, for the earlier passage about Anthrax vaccines, we asked “Which word appeared in the passage?” To someone who read the passage, the correct answer is obvious among the choices: Anthrax, Arthur, Anthropology, and Antonym.

**Results**

We invited 56 MTurk workers to read and answer questions on 8 passages for compensation of $3 USD. We removed three subjects for having missed two or more attention questions and six subjects for spending an unreasonably long or short amount of time reading or answering the questions. Prior knowledge of the topic is significantly correlated with reading time (r = 0.102, p < 0.046), perceived difficulty (r = -0.212, p < 0.000), and actual difficulty (r = 0.1, p < 0.038), so we removed all responses from someone with high knowledge of the medical condition.

Table 2 summarizes the demographic characteristics of subjects whose responses were included in the analysis. The majority are under 40 years old. More than half have a bachelor’s degree and about one-quarter have a high school diploma. About three-quarters are white and most of the respondents speak only English at home. Females make up just about half of our respondents.

Table 3 summarizes the means for all experimental conditions. Actual difficulty is measured by accuracy, so lower scores denote more difficult texts. Consistent with conventional wisdom, inserting any explanatory material in any formulation reduces actual difficulty compared to the baseline condition, with a few exceptions for when difficult definitions are inserted into the text. For Wikipedia texts, the improvement from baseline is the largest when we insert simple explanations in parentheses at the end of the sentence ($t_{35} = 2.241, p < 0.034$). Other configurations do show improvement as well, though not statistically significant, though this may be due to the small number of responses we have in each condition.

When we aggregate data based on features of interest, we do observe significant interactions, though, some parenthetical formulations are more successful at simplification than others. The best formulation for Wikipedia passages (simple explanation inside parentheses at the end of sentences) yields significantly higher accuracy (i.e. easier documents) than the worst formulation (difficult explanation outside parentheses the middle of the sentence; $t_{31} = 2.242, p < 0.032$). Similarly, the best configuration for PubMed (explanation inside parentheses in the middle) is significantly different than the worst configuration (definition inside parentheses in the middle; $t_{30} = 2.236, p < 0.033$). It is important that we understand which combinations of features can affect the effectiveness of each formulation.

We performed a 4-way ANOVA on the experimental condition for actual difficulty, perceived difficulty, and reading time ($N = 260$). We exclude the baseline from this discussion because it does not contain any explanatory content.

**Actual Difficulty**: We found a main effect for the difficulty of explanatory content on the accuracy of the content questions ($f_{1,244} = 6.501, p < 0.011$). Readers presented with a technical definition correctly answered 62.6% of the content questions, while readers presented with the explanation achieved higher accuracy and were able to correctly answer 72.1% of the time. The difficulty of the explanatory content also has a significant effect ($f_{1,244} = 4.056, p < 0.045$) on the accuracy of the questions focusing on the meaning of the target term. Readers presented with a technical definition were able to correctly answer the question about meaning of the target term 56.4% of the time, while readers presented with the explanation were able to correctly answer 68.7% of the time.

Figure 1.A shows the significant interaction between placement of the parentheses and the source material of the text ($f_{1,244} = 5.759, p < 0.017$). If the text is from Wikipedia, adding explanatory content inside the parentheses (with the difficult term outside the parentheses) results in better accuracy than adding the new content outside the parentheses (with the difficult term inside the parentheses). However, if the text is from PubMed, which is more difficult and less familiar to the general audience, the results are reversed but the magnitude of change is much smaller. This suggests that the best approach for inserting new explanatory content into text depends on the difficulty, or at least type of text. Using the wrong approach could reduce comprehension and increase difficulty.

We also found a nearly statistically significant trend ($f_{1,244} = 3.633, p < 0.058$) showing a similar interaction between the placement of parentheses based on type of explanatory content. As seen in Figure 1.B, given a simple explanation, adding explanatory content inside parentheses resulted in a high retention of content compared to adding the explanatory content outside. However, given a technical definition, adding it inside parentheses resulted in lower retention compared to keeping the explanatory content outside of parentheses and integrated with the text.

![Figure 1](image-url)

**Figure 1. Interaction Effects from Placement of Parentheses and Difficulty of Source or Explanatory Content**
**Perceived Difficulty.** While perceived difficulty is significantly correlated with actual difficulty ($r = -0.243$, $p < 0.001$), we do not see a significant difference between individual experiment conditions and the baseline due to the small sample size. However, if we aggregate the data based on specific features, we find that the difficulty of the explanatory content has a significant effect ($f_{1, 244} = 4.053$, $p < 0.045$) on perceived difficulty. Readers presented with a technical definition report the average difficulty of the text as 3.143, while readers presented with a simple explanation report a lower difficulty of 2.860.

**Reading Time.** One concern is that retention of the text material would be influenced by the time spent reading it. In our experiment, we kept wording consistent between conditions as much as possible, only changing the position and placement of the target term and associated vocabulary. We ran correlations between our difficulty scores and reading time. We found that reading time is not significantly correlated with perceived difficulty ($r = -0.027$, $p < 0.666$), term question ($r = 0.083$, $p < 0.185$), and actual difficulty ($r = 0.042$, $p < 0.490$), which rules out reading time as an alternative explanation to the effects we observe in our data.

Table 3 shows two outliers for mean reading time of Wikipedia passages. Three subjects in the baseline condition took about six minutes each. Only the baseline condition had multiple subjects needing more than two minutes. This behavior can be explained by the subjects becoming confused by passages that were lexically simple (Wikipedia text) but incomprehensible without the explanatory content. The other outlier condition is caused by one single subject whose time pattern suggests he/she took a break during the experiment and returned later. This reflected plausible behavior of a subject who was committed to the task, so we retained the data. (We removed all data from subjects who took multiple long breaks). Without this subject, the mean reading time is 36.547 seconds.

**Study 2: Multiple Parenthetical Insertions**

**Design**

Study 2 focuses on the cases where there are several target terms that form a list in a sentence to understand whether using parallel parentheses insertion, which would provide structure to the text, simplifies the text. Based on the results from Study 1, position of target terms in the sentence is not considered, and we use only explanations. We also included a baseline condition containing the original sentence. We use a 2x3 full-factorial within-subjects experimental design with the following factors and levels:

1. **Types of text:** *Wikipedia and PubMed.* Identical to Study 1.

2. **Parallelism of Parentheses:** *All Inside, Mismatched, and All Outside.* We expect parallelism to provide more cues about the structure and organization of the information in the passage, which should help with simplification. Table 4 provides an example for each level.

<table>
<thead>
<tr>
<th>Parallelism of Parentheses</th>
<th>Sentence</th>
</tr>
</thead>
<tbody>
<tr>
<td>All inside</td>
<td>Heart murmurs are most frequently categorized into systolic (when the heart is contracting) and diastolic (when the heart is expanding) heart murmurs, differing in the part of the heartbeat on which they can be heard.</td>
</tr>
<tr>
<td>Mismatched</td>
<td>Heart murmurs are most frequently categorized into systolic (when the heart is contracting) and diastolic (when the heart is expanding) heart murmurs produced when the heart is expanding (diastolic), differing in the part of the heartbeat on which they can be heard.</td>
</tr>
<tr>
<td>All outside</td>
<td>Heart murmurs are most frequently categorized into heart murmurs produced when the heart is contracting (systolic) and heart murmurs produced when the heart is expanding (diastolic), differing in the part of the heartbeat on which they can be heard.</td>
</tr>
</tbody>
</table>

As in Study 1, we evaluate simplification using actual difficulty, perceived difficulty, and reading time using the same scales.

In this study, each subject was assigned 4 passages (since we have fewer conditions).

**Results**

We recruited 48 workers for our study for $2 each. Similar to Study 1, we removed 6 workers for spending an unreasonably long or short amount of time reading or answering the questions and those with high background knowledge.
The majority of our respondents are under 40 years old (see Table 5). Just over half hold a bachelor’s or associate’s degree. Over three-quarters are white and most speak only English at home. Females make up just above half of our respondents.

Table 6 summarizes the mean values of our major metrics for each experiment condition. The reduction in actual difficulty of Wikipedia text is significant when we insert all explanations in parentheses ($t_{34} = 3.647$, $p < .001$) or insert some explanations in a mismatched manner ($t_{31} = 3.647$, $p < .010$). In general, the baseline condition is most difficult. Mismatched parentheses are an improvement over the baseline, but are still more difficult than any parallel formulation. Curiously, for PubMed passages, inserting explanatory content increased perceived and actual difficulty (decreased content question accuracy). However, results for Wikipedia passages appear consistent with our expectation, though not statistically significant.

We performed 2-way ANOVA for actual difficulty, perceived difficulty, and reading time ($N = 116$ without baseline condition).

**Actual Difficulty.** Readers scored much higher on Wikipedia (81.6%) than on PubMed passages (66.4%). The difference in difficulty is significant ($f_{1.90} = 4.222$, $p < 0.043$). No significant effects were observed for term-specific questions.

Contrary to our expectations, actual difficulty is not significantly affected by the misalignment of parentheses. However, the interaction effect between different source material and placement of parentheses is still evident, though not statistically significant. Figure 2 illustrates this. For passages from PubMed, integrating all explanatory content into the text yields higher accuracy scores, but for passages from Wikipedia, keeping explanatory content in parentheses yielded higher accuracy scores.

**Perceived Difficulty.** PubMed passages are perceived to be more difficult than Wikipedia passages ($f_{1.92} = 7.333$, $p < 0.008$). PubMed passages had an average perceived difficulty of 3.572, while Wikipedia passages’ was 3.106.

**Reading Time.** None of our experiment variables were significantly related to reading time. As in Study 1, reading time did not impact our results and was not correlated with actual difficulty ($r = 0.107$, $p < 0.254$), term comprehension ($r = 0.017$, $p < 0.858$), or perceived difficulty ($r = 0.098$, $p < 0.294$).

</table>
Although we were able to significantly reduce the actual difficulty of the text using optimal strategies identified in Study 1, Study 2 did not provide conclusive results about the effect of parallel parentheses for simplifying a list of difficult terms. Therefore, in a post hoc analysis, we examined the properties of the lists in our study. Six of the eight Wikipedia passages included lists of similar terms (terms are semantically related, such as “systolic” and “diastolic”), while five of the PubMed passages were lists with dissimilar terms. Parallel parentheses may highlight the similarity between related terms and make reading easier. The significant main effects we observed in Study 2, in which Wikipedia passages are actually and perceived to be easier than PubMed material, may be partially attributed to the similarity between the terms in the lists. However, in this study, similarity is also confounded with the difficulty of the source material.

Limitations

The small scale of the study, with only 16 passages in each experiment, is a limitation. We selected and edited the passages to restrict the number of difficult words and the position in the sentence. This allowed us to precisely control different parameters in the experiment. To draw more generalizable conclusions, future research should use passages that were originally published with difficult terms in positions of interest in the sentence. Additionally, we used Wikipedia articles and PubMed abstracts to represent simple and difficult texts, respectively. However, in addition to lexical difficulty, these texts also differ in writing style, which is a nuanced concept we can’t address in the scope of this study.

Conclusion and Lessons Learned

Through our studies, we found that parenthetical expressions can simplify text, but only under the correct conditions. Augmenting the text with simple explanations for difficult terms can reduce the difficulty of the text. However, there exists a significant interaction between difficulty of the text overall and whether to enclose the difficult term or its explanation in the text. Modifying the text without taking these factors into account will be ineffective or even counter-productive to text simplification.

The following text simplification lessons result from our two studies:

1. Difficult content benefited from putting the target term (i.e., difficult term) inside parentheses and incorporating the explanatory content into the text. In Study 1, PubMed passages with the term inside the parentheses had lower actual difficulty, while Wikipedia passages with an explanation in the parentheses had lower actual difficulty. The same pattern is observed in Study 2, though it is not statistically significant. Also in Study 1, in difficult texts, the texts were easier when a definition (i.e., difficult text) was incorporated in the text rather than in parentheses. A possible explanation is that parentheses provide a clear boundary for snippets of text. When the text is more difficult, the reader becomes unwilling to read the difficult material and will simply skip to the end of the parentheses. By incorporating explanatory content into difficult text, or difficult definitions into any text, readers are encouraged to read the difficult content and benefited from absorbing the information.

2. If we want to add explanatory content to a text, adding a simple explanation helps more than a detailed, technical explanation. Practically, we need to generate more resources with consumer-friendly explanations of medical terminology, which is part of our ongoing research.

3. The position of the target term does not significantly affect actual or perceived difficulty of the text. Even though parenthetical expressions interrupt the flow of a sentence, the location of the interruption is not significant. Its impact on the reader’s processing of the sentence is overshadowed by the difficulty of the content.

4. We have preliminary but non-significant evidence suggesting that parallelism in a list may play a role in simplification. We can consider parallelism as the similarity between difficult concepts in a list, which indicates a consistency in the theme or semantic types. Another aspect of parallelism is using parentheses and other cohesion markers in a consistent manner. This is a topic for future research.
5. In general, simplification strategies are inconsistent across different types of text. For example, PubMed passages in Study 2 became more difficult after employing parenthetical insertion in non-optimal configurations. From patients to caregivers to health professionals, the medical domain produces many types of text, ranging from electronic health records to scientific research to general guidebooks. Simplification strategies need to be tailored to the task at hand to be effective.

Abstract

Social media are important platforms for risk communication during public health crises. Effective dissemination of accurate, relevant, and up-to-date health information is important for the public to raise awareness and develop risk management strategies. This study investigates Zika virus-related information circulated on Twitter, identifying the patterns of dissemination of popular tweets and tweets from public health authorities such as the CDC. We leveraged a large corpus of Twitter data covering the entire year of 2016. We analyzed the data using quantitative and qualitative content analyses, followed by machine learning to scale the manual content analyses to the corpus. The results revealed possible discrepancies between what the general public was most interested in, or concerned about, and what public health authorities provided during the Zika outbreak. We provide implications for public health authorities to improve risk communication through better alignment with the general public’s information needs during public health crises.

Introduction

Social media have become important information hubs, where individuals and organizations create and disseminate real-time content beyond their personal social networks and physical location. As a result, social media have become a powerful channel for information seeking and sharing, especially in times when timely information is critical, e.g., during crisis breakout⁴. An increasing number of public health authorities are seizing this opportunity to improve risk communication during public health emergencies (e.g., disease outbreaks, natural disasters)⁵,⁶. For instance, during the H1N1 influenza pandemic, governmental institutions such as the U.S. Centers for Disease Control and Prevention (CDC) and Department of Health & Human Services (HHS) disseminated information to the general public through social media and other websites⁵,⁶. Similarly, during the 2011 South East Queensland floods crisis, state and local authorities shared information and updates through this avenue⁴. The existing research assessing using social media for risk communication in practice, suggests that social media can be a powerful channel for communication during crises. For example, several studies have shown that using social media is highly beneficial for effective and fast risk communication during disease outbreaks and disasters⁷,⁸.

Although many public health organizations use social media in risk communication, it is unclear whether the general public actually receive such information properly⁹. More evaluations of the effectiveness of crisis-specific risk communication efforts are needed for developing best practices in social media use⁹. In this sense, research that investigates the distribution and determinants of public health messages on social media has important implications. First, public health organizations can monitor and evaluate the general public’s attitudinal and behavioral reactions during emergency situations. Second, public health organizations and practitioners can learn to adopt more effective communication strategies to improve the dissemination of health-related knowledge, announcements, and recommendations⁹. For example, by identifying a surge of misinformation, public health professionals can adapt their communication efforts to counterbalance the misinformation on social media⁹. Similarly, investigating surges in information demand can provide insights on common information gaps that exist and, thus, inform what kinds of information to disseminate⁹.

In this study, we analyzed risk communications during a 2016 public health emergency, the Zika virus outbreak, on one social media platform, Twitter. Our goal was to understand how public health authorities, and the general public, communicated on Twitter during the Zika virus outbreak, and to provide implications for effective risk communication efforts. Most people, at least outside of infectious disease physicians and researchers, had not heard of the Zika virus prior to the recent, highly publicized outbreak. On February 1, 2016, the World Health Organization (WHO) declared a cluster of infants born with microcephaly and other neurologic disorders in Brazil to be a public health emergency of international concern (PHEIC)⁹. WHO noted that, while Zika virus infection was strongly suspected to be the cause, it had not yet been scientifically proven⁹; thus, declaring the cluster to be a PHEIC signaled the need for an urgent international effort to fill this research gap⁹,¹⁰. By November 18, 2016, WHO
reported that there was now sufficient evidence that Zika virus infection was the cause, and ended this PHEIC12. While this likely resulted in reduced media and public attention, it does not mean that the Zika virus is no longer a public health threat or priority. On the contrary, WHO described the consequences of Zika virus infection as “a highly significant long-term problem” that requires a “robust longer-term response mechanism,” and stated that WHO was shifting focus and resources accordingly12. Therefore, public health organizations will most likely continue to communicate risk information related to the Zika virus.

Based on existing research, Twitter is the best social media platform for our research goal. Among the various platforms, Twitter has frequently been used by public health authorities, such as WHO, the U.S. National Institutes of Health (NIH), and local health departments, to publish information about disease outbreaks14–16. Therefore, it is very likely that many public health organizations also disseminated risk information during the Zika virus outbreak. Recent research also shows the great potential of mining and analyzing Twitter data that can be used as “a proxy measure of the effectiveness of public health messaging or public health campaigns”17.

We collected a 10% sample of all tweets that contain “Zika” and were circulated on Twitter throughout 2016 (from January 1st to December 31st), as this was the time period when Zika obtained the most international attention (due to WHO’s announcement). We analyzed the typology of these tweets and their relation to tweets that were the most retweeted. Using the same strategy, we also analyzed tweets that came from authoritative accounts. Authoritative accounts are those that are affiliated to public health organizations. Unlike in noncontagious diseases, epidemics and pandemics necessitate effective and timely communications from public health organizations, as they need the general public’s cooperation to mitigate the situation. Our case study of risk communication during the Zika virus outbreak can shed light on how public health organizations could (1) improve their ongoing Zika-related communications, and (2) better leverage Twitter to target the general public’s information needs, communicate more effectively and reach more people in shorter amount of time during public health crises.

Methods

We used a mixed-methods approach that combines quantitative and qualitative content analysis methods to analyze a sample of tweets. To scale up the mixed approach to a large collection of tweets, we leveraged machine learning to assist in qualitative coding. Our general analysis flow contains seven steps (see Figure 1 for a flow chart):

**Figure 1.** Flow of our methodology. Each block is described in detail in text.

(a) Through Twitter’s gardenhose API, we can access 10% of the entire Twitter data stream. We prepared our dataset by selecting tweets that contained the keyword “Zika” in the year 2016. By doing this, we yielded a dataset consisting of 1,495,480 tweets. Only English tweets were used in the manual content analysis. English tweets account for 54% of all Zika-related tweets.

(b.1) We defined “popular tweets” to be those that had been retweeted at least 100 times. We identified popular tweets based on Twitter’s “retweet” data field. This gave us 3,581 unique tweets, which we refer to as the “popular set.”

(b.2) We sorted all the accounts ranked by “# of mentions” (using @ token), and manually selected 17 authoritative accounts that are dedicated to public health issues, and represent public health agencies, medical experts, and institutions from top 300 accounts. Though these accounts themselves do not publish many tweets, they are frequently mentioned (using @ token). Table 1 shows the top mentioned authoritative accounts. During the accounts selecting process, we excluded some indirect accounts such as POTUS (the U.S. president’s Twitter account) and JuanOrlandoH (Official account of the President of the Republic of Honduras). These 17 authoritative accounts gave us 1,227 unique Zika-related tweets, which we refer to as the “authoritative set.”
(c) We sampled 200 tweets from the popular set. From the authoritative set, we sampled five tweets from each of the 17 authoritative accounts. In total, we had 285 tweets. Employing a grounded-theory approach\(^\text{18}\), each of the two authors coded the content of these 285 tweets. They first read the tweets to get a general sense of the content. After that, each author followed the open coding process to code the 285 tweets and generate a set of initial codes independently. Through several rounds of reading, coding, and comparing emerging data to existing themes, the two authors generated a set of codes that emerged naturally to describe the tweet content. The two authors discussed and consolidate the codes through the axial coding process. The final codebook contains a set of 8 codes for the sample of 285 tweets.

</tr>
</tbody>
</table>

(d) We used a machine learning approach to generalize from the manually coded tweets and assign codes to the remaining tweets. Using coded tweets as the training set, we developed a text classification model. The model was a one-versus-rest multiclass logistic regression classifier, taking in the content of a tweet, and predicting the most likely category. The preprocessing steps included lowercasing, removing common punctuations (".", "," and ",") and normalizing URLs (replacing by the token "URL"). Each tweet was represented as bag-of-unigram feature vectors with binary values. The classifier was trained using LibLinear package, with default regularization weight \(C = 1\)^19.

Table 2 shows each code’s definition, example, frequency in the sample, frequency in the whole dataset, and top informative content keywords with highest information gain in each category.

(e) We manually checked randomly sampled tweets with those applied codes to ensure the accuracy of the prediction. To ensure that the text classification model generates accurate predictions, we also conducted 10-fold cross-validation on the 285 coded tweets to evaluate the quality of the text classification model. Cross-validation is a commonly used statistical procedure for estimating the quality of machine learning models on uncoded data instances. For multi-class classification, the accuracy, macro-averaged precision, and macro-averaged recall are defined as

$$\text{accuracy} = \frac{\sum_{y \in Y} TP_y}{N}$$
$$\text{macro-averaged precision} = \frac{1}{|Y|} \sum_{y \in Y} \frac{TP_y}{P_y}$$
$$\text{macro-averaged recall} = \frac{1}{|Y|} \sum_{y \in Y} \frac{TP_y}{N_y}$$

Where $Y$ is the set of 8 categories; $TP_y$ is the number of tweets correctly predicted to belong to category $y$; $N$ is the total number of tweets; $P_y$ is the number of tweets predicted to belong to category $y$; $N_y$ is the number of tweets actually belong to category $y$. Our text classifier achieved 79.6% accuracy, 75.2% macro-averaged precision, and 74.0% macro-averaged recall on the multi-class classification task, which is reasonably good. These predicted codes were used as a basis for further content analysis.

(f) We generated and compared typological difference between popular tweets and authoritative tweets.

**Results**

**Temporal and Geographical Characteristics of Zika-related Tweets**

We first describe general characteristics of the whole zika related tweets. As the word “Zika” is shared across languages, these tweets are sent from regions speaking diverse languages, where English (54%), Spanish (27%), and Portuguese (12%) are among the top three. Figure 2 shows the timeline of these tweets, annotated with important events. To cross-validate our data collection, we also show the Google Trend of “Zika” for the entire year. The two timelines are consistent. We found that tweets peaked often right after a major event. The tweet amount peaked around late January, during which locally transmitted infection had been reported from more than 20 countries. The severity of the outbreak triggered a massive amount of discussions on Twitter. In July and August, Twitter users paid more attention to Zika again, as the 2016 Olympic Games took place in August in Brazil, the place where the Zika outbreak originated from. Interestingly, the trajectory of Tweet amount rose and dropped sharply during the first peak, possibly because the initial shocking news lasted very briefly. By contrast, the trajectory of Tweet amount during the Olympic Games covers a much longer period of time with gradual increase and decrease, possibly because the general public’s attention to the Olympics spanned over longer time and discussion continued prior, during and after it, since the Olympic Games was a major event that lasted for weeks.

Using 1% of these tweets that have GPS information, we visualize the worldwide discussion of Zika in an evolving heatmap. Due to the scope and space of this paper, we only show two screenshots from mid-January and mid-February (see Figure 3).
The discussion was heated in the first three months of 2016. It originates from countries nearby the tropical region, especially South American countries. At the end of January, it has attracted attention in many countries, and swept the world in February. We notice that the spots on heatmap correlates with monthly infection update worldwide. By mid-February, Zika cases had been reported in Latin and Central America, the United States, Africa, Southeast Asia, among other countries and regions \(^{20}\).

Typology of Zika-related Tweet Content

We classified all the English tweets into eight categories. Within the typology, joke and sports events are the least relevant to the Zika virus itself, compared to other categories that directly point to scientific discovery and effective countermeasures. A closer read of tweets in these two categories suggested that joke was prevalent possibly because of the characteristics of Twitter as a source of entertainment; and sports events was also popular mostly because the 2016 Olympic Games were held in Brazil, where the Zika started to spread. We posit that during a health crisis, critical information such as infection update, knowledge, and progress should be disseminated as broadly as possible. Knowing the basic types of tweet content, it is crucial to understand whether critical information about health crisis is related to the tweet’s popularity, in terms of retweet number and like number. Based on the typology, we explore descriptive statistics of these categories to understand each category’s distinct characteristics. Table 4 shows each type’s length, retweet number, and like number.

Table 4 shows that jokes were the most popular type of content on Twitter, in terms of retweet (avg=1362) and like numbers (avg=1425). We suggest that it is possibly because Twitter’s one primary function is to entertain. This finding correlates with other work reporting humor as a major type of content on social media\(^ {21}\). Such information might have negative consequences to Zika-related public communication, as the amusement caused by these
widespread jokes might dilute the general public’s awareness and caution of the severity of Zika infection. For example, the top retweeted tweet was an English translation of a Portuguese tweet:

BrazilStats2: USA goalkeeper joked about Brazil being dangerous due to Zika. Every time she hit the ball, Brazil fans scream ZIKA. https://t.co/2dZnY1qY4R

Table 4. Descriptive Statistics of Top Retweeted Tweets (# of retweets >= 100).

</tbody>
</table>

The Twitter account then only had 15771 followers, but the tweet was retweeted 21982 times. Noticeably, among these top retweeted tweets, factual information related to policy, infection update, and scientific knowledge had the least popularity. Each of these three received averagely less than 400 retweets and less than 570 likes. For example, an authoritative “infection update” tweet from CDCMMWR that was aimed to disseminate latest report but only retweeted twice, possibly because the reports are lengthy and require sufficient health literacy to understand:

CDCMMWR: Read @CDCgov's latest #Zika reports on the @CDCMMWR website: https://t.co/lwLgL1RQKol
https://t.co/ysP6vhlur

Such huge discrepancy in popularity between different types of content signifies Twitter’s ineffectiveness in disseminating critical health information during a public health crisis.

After discussing popular tweets’ characteristics, now we examine authoritative tweets. In Table 5 we discuss the tweets from 17 authoritative accounts. Among the 1,277 authoritative tweets, only 27 are retweeted more than 100 times (“popular”). We found that authoritative tweets do not contain content related to joke and sports events. This phenomenon correlates with our previous interpretation that joke and sports are the least relevant to Zika itself. Public health authorities might consider it inappropriate and does not match their authoritative identity.

</tbody>
</table>
Comparing Table 4 and Table 5, we noticed categorical differences between popular tweets and authoritative tweets. People retweet jokes and sports events, which can be problematic in conveying the critical information about health crisis, especially when those jokes and events include unverified information. Other than jokes and sports events, the general public was interested in research progress, consequence, and pharmaceutical progress, in terms of numbers of retweet and like numbers. However, most of the authoritative tweets fall into the categories of policy, infection update, and scientific knowledge. This difference suggests that in terms of public communication on Twitter, it seems that the general public’s attention and the information that authoritative accounts attempt to disseminate diverge significantly: the general public is seeking and broadcasting information that tells them the results of Zika infection and what can be done against it. However, public health authorities seem to tend to publish objective, verified information in a scientific, rational tone. This discrepancy and its influence are worthy of future research.

Temporal Development between Popular and Authoritative Tweets

We compare the difference between popular and authoritative tweets in terms of their typological distribution. Figure 4 shows each type of tweets’ development across time, where popular tweets are highlighted in blue and authoritative tweets in red.

As shown in Figure 4, popular tweets mostly correlate with the overall trajectory in Figure 2, peaking from January to early February and in early August. This is understandable because social media oftentimes mirror the general public’s attitude, concern, and interest in real time. However, authoritative tweets do not correlate with the temporal trajectory of major Zika events (See Figure 2.). Public health authorities broadcasted information at a regular pace that did not match the general public’s interest and concern. This can be easily observed in the diagrams of policy, research progress, infection update, scientific knowledge, and pharmaceutical progress. Public health authorities also tweeted more about consequence at the beginning of 2016, possibly because such information was still new to the general public at that time. However, they stopped broadcasting such information later. This suggests that when public health authorities used Twitter, it seems that they showed little timely sensitivity to major news and events. It is also possibly because public health authorities possess limited capacity in generating popular, or “viral,” content.

Discussion

Our results indicate that Twitter does support widely and real-time communication during public health emergencies. It was widely used by the general public to discuss the Zika virus outbreak on a timely manner, suggesting that it is an important channel during public health emergencies.

By analyzing Zika-related tweets, we found that both the general public and public health authorities actively used Twitter as a platform to circulate Zika-related information. However, authoritative accounts constantly published factual information such as infection update and established scientific knowledge, and their tweets rarely gained as

<td>0.2</td>
</tr>
</tbody>
</table>
much popularity as tweets published by the general public, suggesting there may be discrepancies between what the general public is most interested in, or concerned about, and what public health authorities are providing during the risk communication processes. Indeed, the two had vastly different interests in terms of content, with the former being more interested in joke, sports, research and pharmaceutical progress, and consequence, while the latter focused on infection update, policy, and scientific knowledge. One possible reason for these differences is that, contrary to the general public, public health authorities have a responsibility to provide the most accurate information possible, are accountable for the content of their tweets and, often, must obtain approval (from multiple people) before content is released to the general public. Any error could cause unexpected harm, and erode public confidence in the institution. While these concerns are very real, our results suggest that Twitter messages from public health authorities are not reaching as broad of an audience as Twitter affords. Public agencies such as CDC use multiple ways (e.g., dedicated websites and press releases) to broadcast authoritative information, the traffic of which our collection of Twitter data cannot capture. However, the limited social media interaction and communication between the general public and public health agencies in our data might have negative consequences considering the popularity of Twitter, such as general Twitter users spreading rumors about public health situations, or even referencing pseudoscience. Previous studies of social media communication found that authorities often do not correct rumors quickly enough—at that point, they have already been widely transmitted\textsuperscript{22–25}. During our manual coding process, we indeed identified a set of unverified information from the popular tweets published by the general public. This suggests that while social media is often imagined as a singular space where information flows freely, divisions exists, and some types of information (e.g., infection updates) only circulates in specific populations (e.g., authoritative accounts’ followers), which can be a barrier to effective risk communication during health crises.

As people increasingly seek health information on social media, previous research has demonstrated the benefits and the necessity of directing people to trustworthy information sources\textsuperscript{26–28}. Therefore, it is important to promote the accounts of public health authorities on social media, so that accurate information triumphs over unreliable information, i.e., unverified and speculative. By analyzing the dissemination of Zika-related health information, we identified implications that may improve the reach and effectiveness of public health authorities’ future Zika-related communications, and public health emergencies more broadly.

First, our results show that popular tweets are often not directly relevant to Zika itself and contains noise such as jokes. This finding indicates that social media users may prefer entertaining and engaging content. Thus, rather than mainly doing one-way information dissemination, public health authorities may conduct more interactive communication strategies, such as building conversations with the general public, answering questions from ordinary citizens, and produce more engaging messages. For example, even with consideration of previously identified challenges, it is possible for public health authorities to produce more engaging content, as evidence by CDC’s viral Zombie Apocalypse campaign which teaches about emergency preparedness\textsuperscript{29}. Also, another possible reason that public health authority messages did not gain popularity is that the messages (e.g., scientific reports) may be lengthy and requires sufficient health literacy to understand. When publishing messages on social media, authoritative accounts may consider restating scientific messages in plain language. Furthermore, our study shows that, the general public cared more about Zika’s research progress, consequence, and pharmaceutical progress, probably because these are pragmatically related to their everyday lives, countermeasures, and future plans. Similarly, a study of travel decision making during the Zika crisis shows that people actively sought information from both authorities, local residents, and previous travelers in order to make informed travel decisions\textsuperscript{30}. To better attend to the general public’s information needs, authoritative accounts can engage in such conversations to both interact with the general public and correct rumors, providing more details about the research and pharmaceutical progress.

Second, based on our analysis of temporal patterns of zika-related tweets, people’s interests in Zika correlated with the latest news and major events. This suggests that public health authorities may consider publishing more timely content related to influential news in order to ease the panic, and to proactively provide information regarding the general public’s foreseeable concerns, such as major international sports events. Additionally, noting that Zika attracted the largest number of tweets from January to February, 2016, possibly because of its newness, we suggest that public health authorities should pay special attention to these moments as opportunities to engage and educate the public. Moreover, we found that public health authorities focused on information that had been verified or clinically proven, such as policy, infection update, and scientific knowledge. However, such information often takes time to be developed after an event. Thus, we suggest that public health authorities publish previous verified or just
other related information right after influential news was published or the major event happened, which may draw more public interests and also likely to get them more engaged with the information.

Third, our analysis suggests that monitoring information dissemination trends on social media can be an effective way of understanding the general public’s interests and concerns. Public health authorities might consider improving capacity in social media monitoring, gaining familiarity with major conversations and debates that take place among the general public. In this way, public health authorities may have better chances in getting involved in these public discussions and broadcasting necessary knowledge.

Fourth, our study also indicates a disconnection between the public’s understanding of a public health situation and available, scientific information sources provided by public health agencies in various ways. The dissemination of rumors highlights the disconnection. It is an urgent question as to how public health authorities can raise the public’s health literacy and eHealth literacy in taking full advantage of authoritative, scientific information to understand public health issues and make informed health-related decisions.

Limitation

We based our analysis and drew conclusions on a portion of data from one social media platform. Therefore, our findings and suggestions may not generalize to other social media, websites, or traditional media, or other crisis situations. Our study is formative rather than definitive. Further hypothesis tests are necessary to examine our findings.

Conclusion

This research concerns risk communication during a public health crisis induced by the Zika virus. We employed mixed-method approach and machine learning to understand the content of both popular tweets and authoritative tweets. We discussed the information gap between the general public and public health authorities and practitioners. We suggested implications that may help improve public health authorities’ risk communication strategies, including providing more engaging and straightforward health message contents that attend to people’s information needs, adopting more interactive communication strategies, delivering messages timely after related news and major events, conducting social media surveillance and raising the public’s health literacy and eHealth literacy.

Abstract

In modern life, the nonstop and pervasive stress tends to keep us on long-lasting high alert, which over time, could lead to a broad range of health problems from depression, metabolic disorders to heart diseases. However, there is a stunning lack of practical tools for effective stress management that can help people navigate through their daily stress. This paper presents the feasibility evaluation of StressHacker, a smartwatch-based system designed to continuously and passively monitor one’s stress level using bio-signals obtained from the on-board sensors. With the proliferation of smartwatches, StressHacker is highly accessible and suited for daily use. Our preliminary evaluation is based on 300 hours of data collected in a real-life setting (12 subjects, 29 days). The result suggests that StressHacker is capable of reliably capturing daily stress dynamics (precision = 86.1%, recall = 91.2%), thus with great potential to enable seamless and personalized stress management.

Introduction

There is mounting evidence that psychological stress from work-related pressures, financial concerns, and family responsibilities is an important public health issue in the United States1. A majority of Americans report frequently feeling stressed and that stress negatively impacts their physical and mental well-being2. Further, psychological stress is associated with adverse health outcomes such as cardiovascular disease, diabetes, depression, and substance use disorders3–4. Despite the evidence that stress negatively affects health, there are few effective and practical stress management solutions that can be seamlessly integrated into an individual’s daily life. In order to develop truly personalized, targeted stress management solutions, we need to be able to accurately and reliably identify occasions of stress in real-world settings.

Daily stress processes are typically assessed via self-report measures and/or biomarkers of stress system functioning, which are limited in their ability to capture the dynamic nature of daily stress. Self-reported stress cannot be assessed continuously and consequently may not capture all stressful events5. Further, it is subject to recall issues and self-report bias. Biomarkers of stress commonly used in real-world settings include cortisol, ambulatory blood pressure, and heart rate variability (HRV). Neither cortisol nor blood pressure can be measured continuously and they are also fairly invasive6, 7. Although HRV can be assessed passively and continuously using commercially available wrist and chest sensors, these wearable sensors do not provide automated information about stress system functioning in real-time. Recently, numerous research efforts8–10 have been made to advance the technologies for assessing stress in real-world scenarios using a variety of sensors including ECG (electrocardiography), RIP (respiratory inductance plethysmography), camera, microphone, etc. However, these technologies have limited practicality as they either require custom devices8 or are cumbersome and therefore not suited for daily use9, 10.

The present study aims to address these limitations by evaluating the feasibility of using a novel HRV-based stress monitoring system to passively, continuously, and accurately capture occasions of stress in a person’s daily life. HRV is a commonly used measure of autonomic nervous system (ANS) functioning, which is one of the two primary stress systems – the other being the hypothalamic-pituitary-adrenal axis11. The ANS consists of the sympathetic nervous system (SNS; “fight or flight”) and the parasympathetic nervous system (PNS; “rest and digest”), which work in opposition of each other to control stress reactivity and recovery12. HRV measures the variation in time between two consecutive heart beats13 and numerous studies have demonstrated that HRV is a valid measure of reactivity to acute psychological stressors14–16. Our HRV-based stress monitoring system, called StressHacker, uses photoplethysmography (PPG) sensor data that is available in commercially available wearable devices. StressHacker does not require the use of a custom biosensor devices. Rather, it can be easily integrated into commercially available smartwatches allowing for seamless integration into individuals’ daily lives. Thus, StressHacker has the potential to make automated and
personalized stress management a reality by detecting stress and offering real-time stress reduction recommendations in real-world settings.

In this paper we present preliminary data from an in-field study evaluating StressHacker’s ability to monitor stress in people’s daily lives. In summary, StressHacker is a system empowered by mobile sensing technologies that can translate continuous PPG signal or RR intervals into stress index – an indicator that is reflective of the change of stress level. At the current stage, we evaluate StressHacker using PPG data collected from wrist-worn wearables. However, the underlining algorithms of StressHacker can be tailored to take similar signals from other devices as input (e.g., electrocardiogram from chest band sensor). Ultimately, our hope is that through a set of data-driven analytical tools, StressHacker will be able to uncover powerful insights about daily stress processes by identifying sources of stress, recognizing patterns, and making personalized stress reduction recommendations. Possible real-world applications of StressHacker include corporate wellness programs, telemedicine in populations highly vulnerable to stress (e.g., chronic health conditions, substance use disorders, depression, anxiety), and automobiles to increase safety and enhance the driver’s experience.

In-field Experiment

The primary goal of the in-field study is to assess the feasibility of continuously monitoring daily stress using smartwatches. To this end, we have recruited 12 subjects who are IBM employees, among which 8 are female and 4 are male. Most of the subjects are young adults. All the subjects voluntarily agreed to contribute to the data collection, and signed a consent form.

In order to simulate real-life scenarios, all of the experiments were un-controlled with the following procedure. Prior to data collection, the researchers briefly informed the subject of the purpose of the experiment, types of data to be collected, and their responsibilities. Then a wrist-worn wearable device (Empatica E4 wristband) was provided to the subject. The device is designed to record bio-signals for research and development purposes, and equipped with the same sensors we intend to use in smartwatches. The device’s extended battery life allows a continuous data collection for up to 2 days. The recorded data was stored locally in the flash memory of the device, and was later downloaded for further analysis. We demonstrated to each subject how to start and stop the recording. The subjects were allowed to start and stop the recording anytime, however, they were informed that a data collection that covers most of their daily activities is preferred (e.g., a recording starting in the morning before work and ending in the evening after work or before sleep).

After the recording was started, data including pulse wave and acceleration was continuously sampled from the PPG heart rate sensor and accelerometer, respectively, and stored locally for off-line examination. In the current stage of our evaluation, the subjects did not get any feedback from or have any interaction with the system during data collection. To simulate real-life scenarios, the subject was informed to conduct their daily activities as they normally do during data collection. After the data collection was completed, the subject was asked to provide a log containing a list of their daily activities covered by the recording. Each entry should include a time period and a brief description of the

Table 1: An example of the logs provided by the subjects reporting their daily activities and the associated stress information (optional). The stress information can be given in the form of a short descriptive sentence and/or perceived stress level (PSL) on a scale from 1 to 10. In the log shown in this table, both descriptions and PSLs are provided.
activity, for example, “1:00-2:30 group meeting.” In addition, to help us better evaluate StressHacker, we also asked the subjects to report stress information associated with each reported activity in the form of a short description and/or perceived stress level (PSL) on a scale from 1 to 10. In the evaluation, such stress information was considered as references of their daily stress dynamics, and compared with StressHacker’s result. Table 1 shows a log provided by one of the subjects as an example. Note that the stress information is optional, meaning the subjects can choose not to include stress information for certain or all of the activities in the log.

Figure 1: An example of StressHacker’s stress level output based on a 10-hour recording with annotated activities and stress information from the log shown in Table 1.

Dataset

We have conducted in-field experiments across 29 days, collecting recordings from 12 subjects. The durations of the recordings range from 3.78 hours to 46.6 hours (see Table 2 for details). The total duration of all recordings is 306.2 hours, containing a total of 237 reported activities, 130 of which were reported with associated stress information. Among the 130 activities with stress information, 102 of them were labeled as stressful.

After the recording device was started, it continuously recorded pulse wave signal (i.e., blood volume pulse) from PPG heart rate sensor (sampling rate = 64 Hz), and acceleration from accelerometer (sampling rate = 32 Hz), along with their timestamps. The pulse wave collected from the PPG sensor was used to calculate HRV-based features, which in turn were used to derive stress levels. The collected motion data was used to estimate the motion level, which was primarily used to gauge the quality of the PPG signal. Specifically, we first extracted RR intervals from pulse wave. Then the RR intervals contained within a 5-min window were used to calculate short-term HRV features that have been studied and suggested to be a good indicator of stress level\(^{18,19}\). We adopted the time-domain methods\(^{20}\) to calculate two HRV features that reflect the total power and the high frequency power of HRV. Finally, we fed the resulted features into a model that maps the features to a stress level ranging from -1 to 1, where -1 indicates very relaxed, and 1 represents very stressed.

Figure 1 demonstrates StressHacker’s continuous stress level output using data from a typical in-field experiment as an example. The final output is a time series of stress levels ([-1, 1]) with a 5-minute interval. The stress level is categorized into four states: Relaxed [-1, -0.2], Less Relaxed (-0.2, 0], Slightly Stressed (0, 0.2] and Stressed (0.2, 1]. Note that in the current stage of evaluation, we use a fixed mapping from HRV features to stress level, and a pre-defined categorization of stress states. However, in practice, the system will be able to adjust the related parameters over time according to the user’s feedback.
Table 2: A list of detailed information for each individual experiment. N(Activity) is the number of activities reported by the subjects. N(StressInfo) indicates the number of reported activities with stress information. N(Stress) is the number of activities that have stress information and are labeled as stressful activity. The evaluation results are represented in TP (true positive), FN (false negative), TN (true negative) and FP (false positive). They are obtained by comparing StressHacker’s stress level output against the stress information reported by the subject (precision=86.1%, recall=91.2%, F-measure=88.6%).

Result

In this section, we evaluate the feasibility of continuously monitoring daily stress using smartwatches using quantitative metrics that reflect the correlation between StressHacker’s output and subject-reported stress information. Therefore, the evaluation is based on the 20 in-field experiments in which the subject provided stress information (i.e., experiments in Table 2 with N(StressInfo)>0).

First, we identify “stressful” activities based on the reported stress information. Specifically, we classify an activity as “stressful” when its associated stress information satisfies one of the following two conditions: (1) it contains word(s) such as “stressful”, “stressed”, “nervous” or “anxious”; (2) its associated perceived stress level (PSL) is larger than the baseline 1 (in a few cases, subjects reported PSL=2 as relaxed, thus we used 2 as baseline in such cases).

Next, for the purpose of calculating the correlation, we determine a similar binary label (“stressful” or “not stressful”) for each activity using StressHacker’s output within the activity’s associated time period. Specifically, an activity will be labeled as “stressful” if the stress levels within its time period satisfy one of the following two conditions: (1) at least one of the stress levels are categorized as “Stressed” (0.2, 1]; (2) at least 10% of the stress levels are categorized...
Lastly, we compare the binary labels determined by the self-report stress information and StressHacker’s output. The detailed result of the comparison is shown in Table 2. We can see StressHacker labels 108 activities (93TP+15FP) as “stressful,” with 93 classifications being true positives, leading to a precision of 86.1%. Out of 102 “stressful” activities reported in the subjects’ logs, 93 activities are correctly labeled by StressHacker, resulting in a recall (sensitivity) of 91.2%. Overall, StressHacker achieves an accuracy of 81.8% in the binary classification of “stressful” activity. We believe that such evaluation results are sufficient to suggest that the stress level information provided by StressHacker can be used to reliably monitor the dynamics of one’s daily stress.

Discussion

In this section, we look beyond the scope of quantitative evaluation and discuss StressHacker’s potential for offering valuable and timely insights that could fuel a broad range of decision makings in not only stress management at an individual level but also mental wellness at an organization or community level.

![Figure 2: Comparing StressHacker’s stress level output across three typical work scenarios.](image)

We first look at StressHacker’s stress level output in three typical work scenarios reported in the in-field experiment, which are working individually (83 hours), passively attending a meeting (20 hours) and actively engaging in a meeting (52 hours). As all of the in-field experiments were conducted during week days, the combination of these three scenarios accounts for more than half of the overall data collection. Figure 2 shows the comparison of stress levels. A key observation is that, overall, the subjects were most stressed while actively engaging in a meeting (40% of the time), compared with while working individually (26% of the time) and during a passive meeting (15%). Such insight can also be supported by the percentages of the “relaxed” state detected by StressHacker in each scenario, which suggests that the subjects were less relaxed during active meetings (only 6% of the time), compared with 15% of the time when working individually and 20% of the time during passive meetings. As all of the 12 subjects are employees at IBM Research, we speculate that the result above could be reflective, to some extent, of the overall “stress profile” of the organization under different working scenarios.

In addition to the work scenarios, we have also captured a typical non-work scenario that was labeled as “getting ready in the morning” (reported by 4 subjects in 6 days). Figure 3 shows the percentages of different stress levels. We can see that, although it has higher percentage of time being relaxed, the overall percentage of time being stressed (41%) is similar to that in the scenario of actively engaging in a meeting. Such insights offered by StressHacker could potentially
be used to identify major stressors and provide personalized recommendations to help users navigate through daily stress. For instance, when significant stress has been detected on every Monday morning, the system could recommend trying to get up half an hour earlier.

**Figure 3:** Percentages of stress levels detected by StressHacker in a typical non-work scenario labeled as “getting ready in the morning.”

**Figure 4:** Demonstrating StressHacker’s ability to reveal fine-grained and insightful stress dynamics using two daily events captured in the in-field experiments as examples. The continuous stress level detected by StressHacker and the self-report activity/stress information are plotted over time.

Next, we zoom in on StressHacker’s continuous stress level output, and use two examples captured in the in-field study to showcase that StressHacker’s result allows us to take a closer look at the dynamics of stress associated with an event of interest, which in turn could potentially help us make more informed decision to minimize the negative impacts of stress. Figure 4 (a) shows that StressHacker captures the subject’s stress level changes before, during and after
her presentation. During the time when she was preparing for the meeting, we can observe the transition from being relaxed to slightly stressed, which could be the effect of working under a close deadline and/or the anticipation of the coming presentation. Interestingly, around the 200th minute, StressHacker’s result shows that she recovers from being slightly stressed to less relaxed, which could be because that she had finished the preparation resulting in a reduction in her stress from working under deadline. Unsurprisingly, StressHacker’s result shows a substantial increase in her stress level especially in the first half of her presentation, which is confirmed by the self-reported stress information where the subject reported as being “nervous”. In the course of the following group discussion, we can see the subject stayed at being slightly stressed for about 10 minutes before she started recovering and became relaxed at around the 260th minute.

The second case shown in Figure 4 (b) captures the subject’s stress dynamics while watching a close basketball game. From StressHacker’s result, we can see that overall, the subject was stressed throughout the game, with a brief recovery during the half-time break. Interestingly, StressHacker’s result reveals the subject’s transition from being slightly stressed to stressed in both the first and the second half of the game, which might reflect the effect of stress accumulation. Another interesting observation is that, in the second half of the game, the subject only stayed being slightly stressed for about 15 minutes (from around the 425th to the 440th minute) until his stress elevated to a higher level (shown in dark bars), whereas the duration of which in the first half of the game was about twice as longer (from around the 350th to the 380th minute).

We believe that StressHacker’s ability to offer such fine-grained and real-time stress monitoring can significantly advance the automation of personalized stress management. To put it into perspective, we compare StressHacker with cStress, a stress monitoring system proposed in a recent research study. Compared with StressHacker, cStress relies on data collected from a larger set of sensors including inductive plethysmography (RIP), a two-lead electrocardiograph (ECG) and 3-axis accelerometers, which are integrated into a chest band that users need to wear all the time. An in-field study had been conducted to evaluate cStress in real-life scenarios based on a similar task to the one used in our study (identifying “stressful” and “not stressful” activities and comparing with subjects’ self-report data). The evaluation result suggests that cStress achieves a median accuracy of 72%, whereas StressHacker’s overall accuracy is 81.8%. Therefore, although only relying on data from PPG sensor, a less reliable heart rate sensor compared with ECG, StressHacker is still able to provide reliable results that are sufficient for daily stress monitoring.

Limitations and Future Work

In the paper, we focus on evaluating the feasibility of using bio-signals obtained from off-the-shelf wearables to infer daily stress. A major cause of the limited 81% accuracy is that data collected from PPG sensor is susceptible to various interferences. We have examined the collected data in attempts to identify factors that might affect the robustness of the system. Such factors include daily activities that involve relatively high level of motion (e.g., walking up/down stairs). As PPG sensor is susceptible to motion artifacts, such activities can lead to unreliable or even corrupted sensor data, which in turn, result in inaccurate stress detection results. As part of our future work, we aim to resolve this limitation by developing algorithms that can identify and mitigate the impacts of motion artifacts. To further improve the robustness, we plan to leverage the user’s historical data to better understand the user’s response to a certain context. For instance, the system might be able to learn over time that the user rarely gets stressed when s/he is driving home, and therefore classifies an isolated stress state with a short duration incorrectly detected in that scenario as false alarm.

As a next step of this study, we will investigate how users can address their stress experiences in real time and how not to distract users during high concentration activities. We are in the process of conducting a study aimed at providing users with real time data on their stress levels via a smartwatch. We intend to make these devices adaptive and personalized to deliver context aware notifications and stress management recommendations. This means that the notification and recommendations should not be delivered when users are performing high concentration tasks or activities. The printout of stress level output shown in Figure 1 is the first step toward such a real-time stress feedback and management system. In future studies we will investigate if the notifications help individuals become more mindful of stress from common daily activities and if increased mindfulness is associated with improved well-being. Further, we will evaluate if completion of real-time stress management recommendations (e.g., meditation, deep breathing) is associated with improved well-being.
Conclusion

In this paper, we present the result of our uncontrolled in-field study that aims to evaluate the feasibility of continuous daily stress monitoring using smartwatches. Based on more than 300 hours of data collected in real-life setting, the quantitative results of the evaluation suggest that the proposed system, StressHacker, can be used as a practical tool for effective and personalized stress management. Moreover, we have also presented analyses at both individual and community levels to showcase StressHacker’s potential to offer valuable data and insights that can be used to advance the automation and personalization of stress management and promote mental wellness in general.

A mobile system for the improvement of heart failure management: Evaluation of a prototype

Sarah C. Haynes, MPH1, Katherine K. Kim, PhD, MPH, MBA1
1University of California Davis, Sacramento, California

Abstract

Management of heart failure is complex, often involving interaction with multiple providers, monitoring of symptoms, and numerous medications. Employing principles of user-centered design, we developed a high-fidelity prototype of a mobile system for heart failure self-management and care coordination. Participants, including both heart failure patients and health care providers, tested the mobile system during a one-hour one-on-one session with a facilitator. The facilitator interviewed participants about the strengths and weaknesses of the prototype, necessary features, and willingness to use the technology. We performed a qualitative content analysis using the transcripts of these interviews. Fourteen distinct themes were identified in the analysis. Of these themes, integration, technology literacy, memory, and organization were the most common. Privacy was the least common theme. Our study suggests that this integration is essential for adoption of a mobile system for chronic disease management and care coordination.

Introduction

Heart failure is a major public health concern, affecting more than 5.7 million Americans1 and projected to increase 46% by 2030.2 Heart failure is the most common cause of hospitalization among adults over age 653 and accounts for more than 30 billion dollars in health care spending each year.1 Management of heart failure is complex, often involving interaction with multiple providers, continuous monitoring of symptoms and measurements, and numerous medications. Newly diagnosed heart failure patients are faced with the challenge of adapting to these major lifestyle changes and often struggle to successfully self-manage.4 As a result, heart failure readmissions are common. More than 50% of patients are readmitted within six months of initial discharge.1 Additionally, heart failure patients often suffer from one or more comorbidities; a large national study of Medicare patients found that 40% of heart failure patients also had diabetes, and around one-third had chronic obstructive pulmonary disease.5 A recent systematic review of depression in heart failure patients found an average prevalence of depression of 29%.6 Thus, patients with heart failure often have the task of managing multiple chronic conditions, adding further complexity to self-management.

Several heart failure management interventions have been associated with decreased readmissions and mortality.7-10 Characteristics of these interventions associated with improved outcomes include face-to-face contact,8 use of multidisciplinary teams,8,9 and longer intervention duration.10 However, because these interventions are extremely resource-intensive scalability is limited. A 2016 systematic review found 34 existing mobile systems for heart failure self-management.11 While data collected from these types of systems have the potential to inform healthcare decisions, existing applications are largely limited to the collection of physical measurements and symptom tracking and lack integration with the health system.11 Furthermore, most existing mobile systems for care management do not facilitate two-way communication, which has been found to be preferred by patients using heart failure monitoring systems.12 Finally, most self-management applications are focused on a single disease, rather than allowing patients to manage multiple conditions. These limitations reflect a lack of attention to patient-centeredness in the design of current mobile systems. Patient-centered applications are defined as “systems that enable a partnership among practitioners, patients, and their families (when appropriate) to ensure that procedures and decisions respect patients’ needs and preferences.”13 Such systems can facilitate care coordination, in which all members of the care team work collaboratively with the patient to make decisions about care and facilitate delivery of services.14 This type of shared decision-making requires that patients have a comprehensive understanding of their health condition, treatment options, and the roles and responsibilities of each care team member.15,17 User-centered design can help to create patient-centered applications for care coordination by understanding how patients would use the system in their daily lives and building features and functionalities around patient preferences and use cases.13,18,19 User-centered design may also increase the likelihood of adoption and satisfaction with the system.20,21 The OnPoint study was initiated to improve understanding of how patient-centered mobile
systems may improve care coordination with for people with multiple chronic conditions, such as those with heart failure and other comorbidities.

**Objectives**

The objectives of this study were to 1) assess the major strengths and weaknesses of a high-fidelity prototype of the OnPoint application, a mobile system for the management of complex chronic disease, with patients with heart failure and key members of the care team and 2) identify additional functions and features that would support adoption of the application by patients and members of the care team.

**Materials and methods**

We used principles of user-centered design to design and evaluate a high-fidelity prototype of OnPoint, a patient-centered mobile application for collaborative chronic disease management. A high-fidelity prototype is an application that is similar to the intended final product, allowing the user to experience realistic interactions; this is in contrast to a low-fidelity prototype, which may be rendered on paper or screenshots. In a previous paper we reported on interviews with key informants, including patients, clinicians, caregivers, and health coaches that resulted in a list of key user functions and user scenarios, around which we created the prototype. The prototype focused on the medication reconciliation and medication taking, priorities identified by both patients and providers: constructing a comprehensive medication list, creating a medication schedule, filling a pillbox, and tracking medications. Other features included care team contacts, tracking weight/blood pressure, managing appointments, and screening for symptoms. When possible, we created digital representations that complemented the tools that patients use in daily life for care coordination (the user-interface metaphor). For instance, because patients often use pillboxes to manage medications, we created an interface that evokes a pillbox metaphor to connect the digital representation on the tablet to the patient’s physical pillbox. The novel medication management features allow a user to take a picture of the medication bottle label which scans the data into the application, inserts a picture of the pill itself, sorts medications into appropriate day/time compartment in the rendered physical pillbox, which all serve to help the patient organize medications accurately and efficiently. The high-fidelity prototype was developed using Ionic, an open-source software development kit that allows creation of hybrid mobile applications. Adobe PhoneGap was deployed to allow development of a cross-platform application that would run on both iOS and Android. Figure 1 shows several screens from the high-fidelity prototype.

We recruited participants from the UC Davis Health System to test the high-fidelity prototype. We selected patient participants who had experience living with or managing heart failure along with another health condition as well as clinicians or health coaches who provide care for heart failure patients. Participants tested the mobile system on a 7.9-inch internet-connected iPad mini tablet during a one-hour one-on-one session with a facilitator. Following a structured patient scenario, the facilitator instructed the participant to attempt each feature of the prototype. For 1) the medication management feature, participants were asked to a) add several medications, b) create a schedule of medications, c) fill a pillbox using the application, d) record the taking and skipping of medications, and e) view medication history. For 2) the measurements feature, participants were asked to a) set up new measurements (weight, blood pressure, and heart rate), b) add measurements to the schedule, c) record measurements, and d) view measurement history. For 3) the appointments feature, participants were asked to enter new appointments and view appointments in the timeline. Finally, participants were asked to use 4) the comments feature of the timeline to record notes and questions to use share with other members of the care team. The symptom management feature was not ready to be tested at the time of the interviews, and was therefore not included in this evaluation. We applied a think-aloud methodology to elicit participants’ thoughts and perceptions of use of the application. The facilitator took notes capturing both verbalized feedback and visually observed challenges with using the application. The facilitator then interviewed participants about the strengths and weaknesses of the prototype, additional necessary features and functionalities, and willingness to use the technology, following a semi-structured interview guide.

Field notes and interview notes were analyzed using a three-phase qualitative content analysis process: 1) immersion, consisting of numerous close readings of the transcripts, 2) reduction, in which themes were identified, defined, and coded, and 3) interpretation, in which themes were organized and conclusions were drawn and verified. Initial codes were inductively developed by one investigator (SH) on analysis of the
first three interview transcripts. The codes and their associated themes were discussed in detail with a second investigator (KK) and revised. The revised coding scheme was applied to the remaining transcripts. A final review of transcripts and codes was completed by the two investigators with discussion of any discrepancies with the goal of consensus on issues identified. A basic quantitative content analysis consisting of counting the number of times a theme was mentioned by any participant was calculated to provide a high level indication of the themes that are “top of mind” among the participant group. The UC Davis Institutional Review Board concluded that this study was not human subjects research (IRB# 782917-1).

Figure 1. Selected medication features of OnPoint high-fidelity prototype, including A. Medication setup, B. Medication scheduling, C. Pillbox filling feature, and D. Timeline view showing list of today’s tasks
Results

Eight individuals participated in the testing of the prototype. These included five patients with heart failure who also manage multiple health conditions, including cancer, diabetes, hypertension, and depression. Three care team members participated including a cardiologist, a cardiac care nurse, and a primary care health coach. Themes fell into three main categories: strengths and potential benefits, potential barriers to use, and features and functions for future development. Fourteen distinct themes were identified during the content analysis. These themes are shown in Table 1 along with a count of the number of times the theme was mentioned, and the proportion (%) of patient and care team members who mentioned the theme at least once.

Potential Barriers to Use of OnPoint Prototype | | | | |
| Technology literacy | Affordances for users with different levels of familiarity with technology to use technology effectively | 16 | 80.0 | 100.0 |
| Burden | Challenges facing users that may inhibit effective use of the system | 10 | 40.0 | 66.7 |
| User types | Differences between user personalities and profiles that may affect how the system is used | 4 | 40.0 | 33.3 |
| Connectivity | Reliance of a technology system on wireless Internet | 3 | 0.0 | 66.7 |
| Privacy | Protection of personal information | 1 | 0.0 | 33.3 |

Features and Functions for Future Development | | | | |
| Integration | Linkage with other data sources, applications, or devices | 20 | 80.0 | 100.0 |
| Personalization | Tailoring of the system to meet an individual’s specific needs | 9 | 60.0 | 66.7 |
| Communication | Exchange of information between patients and providers | 6 | 40.0 | 66.7 |
| Tracking | Recording information (patient-generated) | 5 | 60.0 | 0.0 |

Integration was the most common theme overall, mentioned by 80% of patient participants and all of the clinician participants. Participants stressed that the usefulness of a mobile system depends upon its ability to integrate with other important sources of information. These sources include other applications such as calendars and applications that allow users to track salt, fluids, and other nutrition information; they also include devices such as physical activity trackers and Wi-Fi-enabled scales and heart rate monitors. The ability to link the application to clinical data, including lab results and prescription information, was
especially important to patient participants, particularly for those taking medications like warfarin that require continuous monitoring. Integration may also help to decrease the burden on patients that may be associated with setup and management of a mobile application:

“The application would need to be smart about how to pull data from multiple places; I wouldn’t want to enter the same information in two different places.” – Patient participant

Technology literacy, the second most common theme, was mentioned by both patient and clinician participants as a potential challenge to implementation. They expressed concern that those with low technology literacy, particularly many elderly patients, would need substantial support from others to set up and use the system. For this reason, participants thought that this group of people might be reluctant to adopt the technology:

“Setting up the application by yourself would be really difficult, particularly if you’re not familiar with technology.” – Health coach

Memory was the next most common theme. Several participants described memory as a common problem for heart failure patients. Participants believed that the system would improve the ability to remember both routine and infrequent tasks:

“A lot of people have brain fog from heart failure- mental reminders are helpful so you know which pills have been taken and which haven’t.” – Cardiac nurse

Participants felt that the system would improve the ability to organize data in one place so that information was available when it was needed. Patient participants reported that they currently used a variety of methods and systems to manage information; patients felt that this was a burden for daily self-management as well as for sharing information:

“Right now, I have tracking on lots of different devices, papers, calendars… it would be much easier if it was all in one place.” – Patient participant

“If you go to the ER, you could just show all of the information. It would be so much easier to provide your information when someone needed it because it’s all in one place.” – Patient participant

Importantly, participants also saw the benefit of the mobile system as something that could help them better understand their condition and their care plan, an important component of shared decision-making.

“This would be useful for familiarizing yourself with your medications… I realize I need a closer look at what’s going on with my meds.” – Patient participant

“I like that you can see the purpose of all the [medications] – you can really know what you’re taking and why.” – Patient participant

Several themes were more important to either patient participants or care team participants. Tracking, or the recording of patient-generated information, was mentioned by 60% of patient participants but mentioned by none of the care team participants. Conversely, several care team participants spoke about connectivity issues, while none of the patient participants mentioned connectivity as a potential barrier to use.

Privacy was the least common theme, mentioned by only one of the care team participants:

“Personal information protection is a concern - not everyone wants to have their wife or husband or adult children know what they’re taking.” – Cardiologist
Discussion

In their review of 34 mobile applications for heart failure, Masterson Creber et al. found that most applications are focused on building healthy habits, rather than on shared disease management. One reason for this may be the difficulty of integration with existing health care systems. Currently, incompatibility between systems and data sharing policies inhibit integration with mobile applications. In our study, the voice of patients themselves brings attention to a key challenge for chronic disease management: the challenge of unifying multiple data streams to create a single personalized system tailored to each individual patient’s needs. This type of system requires not only the ability to gather and organize patient data but also the capacity to learn and respond to information. Integration with the electronic health record (EHR) is one example of this. Clinicians commonly rely on EHR systems and patient portals for managing patient data and communicating with patients. Health system regulations, in addition to feasibility and workflow considerations, prevent adoption of a system that is separate from the EHR. Because shared information and communication are crucial components of successful disease management and effective care coordination, integration with the EHR should be a priority for any chronic disease management system. Our study suggests that integration is also crucial to patients’ adoption of a mobile system for chronic disease management. Because chronic disease patients often manage multiple comorbidities and have varying nutrition and activity requirements, fluid restrictions, or other specific measurements, integration with other devices and applications is necessary to ensure completeness of a shared care plan. A useful application will also have the ability to integrate with the patient’s existing management strategies, such as calendar or pharmacy applications. This is in line with previous findings on user preferences for self-management applications.

Our study suggests that integration of an application with existing external data sources and systems is more important than developing additional features; this is an important implication for prioritizing future work in this area. In addition, our findings indicate that there is a need for organized summary data for all types of users: patients, caregivers, and care team. Each type of user requires different types of information to make informed decisions. Development of data visualizations for these various users will require in-depth exploration into how users make decisions about care, and how data collected by a mobile system can assist in the decision-making process.

To create a usable application for chronic disease management, concerns about technology literacy must be addressed. Many previous studies have used mobile systems to deliver chronic disease management interventions. However, these studies often suffer from low usage of the technology, which may be in part a function of low technology literacy. To date, there have been few studies examining technology literacy in the context of mobile applications for disease management. Principles of user-centered design can help to create a system that can be used effectively even by those with little previous experience with mobile applications.

Although privacy was not mentioned by patient participants in this study, concerns about privacy are often mentioned with respect to use of technology. Some studies that have found low levels of concern about privacy threats with regard to mobile technologies. In a national public opinion survey of radio frequency identification (RFID) technology for healthcare, Katz and Rice found only a minority of participants who were concerned about threats to privacy. In a qualitative study by Pinnock et al., neither patients nor healthcare professionals considered privacy to be a major issue with regard to adoption of a healthcare management technology. Nevertheless, a recent statewide survey found high levels of concern regarding privacy in sharing of electronic health data for provision of healthcare and willingness to agree to share these data. Hence, assurance of privacy should continue to be considered in development and implementation of mobile care coordination solutions.

Findings of our study suggest several implications for building systems for care coordination. First, while reminders and tracking can be useful management tools, they are not sufficient for facilitating shared care. The patient participants in our study desired a thorough understanding of the health condition and care plan. Improved understanding of medications was seen as especially useful for patients. This suggests that patient-centered mobile systems should have the capacity to enrich a patient’s understanding of the disease and the treatment plans, instead of simply recording it. These findings align with existing literature on shared care and shared decision-making, which emphasize the informed participation of the patient in the creation of a care plan. Second, our findings indicate that the ability to share information quickly and easily is an
important part of a mobile system for chronic disease management. Access to the same information by everyone involved in the patient’s care will likely allow for improved coordination and collaboration among the care team, characteristics of care found to be associated with improved health outcomes.\textsuperscript{45}

There are several limitations to our study. First, we interviewed a small convenience sample of potential users, recruited from a single academic medical center in California. Although appropriate for a user-centered design study,\textsuperscript{46} the sample was not large enough to quantify differences between types of users or to discuss how preferences differed by age, disease severity, familiarity with technology, or other characteristics. Second, four of the participants (three patients participants and the cardiologist) were also involved in previous design phases, where they provided details on how they manage care and what aspects of care management and coordination are most important to them. For this reason, they may have been more inclined to provide positive feedback on the high-fidelity prototype, biasing the study results. As is common for qualitative studies such as the one present in this paper, the findings are not intended to be generalizable.

Next steps

We are currently using the feedback provided by patient and care team participants to develop the OnPoint prototype into a fully functional application for chronic disease management. The working version of the system will include additional features and integration with other systems, including specifications for EHR integration. We plan to use a participatory design process to test the application with patient and clinician participants in simulated home and clinical environments; we expect that this will provide insight into how a system can be optimized for different types of users. Our next steps will also include the creation and testing of data visualizations, to explore how patient-generated data collected by the application can be used for care coordination and shared decision-making. Understanding how these types of data will be shared and used is essential for building a system that can support coordination and management of multiple complex chronic diseases.

Conclusion

Although many mobile applications have been developed for the management of chronic disease, none has achieved widespread adoption. Our study provides insight into potential reasons for this by highlighting key barriers and facilitators of adoption of a mobile system for heart failure care coordination. The findings of this project emphasize the need for an integrated solution. Such a system will have the potential to improve self-management for patients managing multiple chronic conditions. It will also facilitate collaboration between patients and their care team, by allowing for the development and management of a shared care plan. Integration of the resulting care plan with the electronic health record is crucial for meaningful sharing of patient-generated information between patients and healthcare providers. The unique requirements, restrictions, and circumstances facing each patient require a flexible system that has the ability to capture and summarize information from multiple sources.

Abstract

Clinical trials are indispensable tools for evidence-based medicine. However, they are often criticized for poor generalizability. Traditional trial generalizability assessment can only be done after the trial results are published, which compares the enrolled patients with a convenience sample of real-world patients. However, the proliferation of electronic data in clinical trial registries and clinical data warehouses offer a great opportunity to assess the priori generalizability during the design phase of a new trial. In this work, we compared and contrasted a priori (based on eligibility criteria) and a posteriori (based on enrolled patients) generalizability of Type 2 diabetes clinical trials. Further, we showed that comparing the study population selected by the clinical trial eligibility criteria to the real-world patient population is a good indicator of the generalizability of trials. Our findings demonstrate that the a priori generalizability of a trial is comparable to its a posteriori generalizability in identifying restrictive quantitative eligibility criteria.

Introduction

Clinical trials, which test the efficacy and safety of an intervention (e.g., medication, device, procedure, and behavioral change), are indispensable tools for evidence-based medicine [1]. However, the generalizability of clinical research studies has long been a concern [2]. For example, elderly patients are reported to be underrepresented in clinical trials across major medical conditions, including cardiovascular diseases [3], cancers [4], dementia [5], and diabetes [6]. Most research on the generalizability of clinical studies has focused on the a posteriori generalizability (i.e., the representativeness of enrolled participants), which compares the characteristics of enrolled patients of a study with a convenience sample of a real-world patient population [7] or those in other studies [8]. For example, van der Water et al. evaluated the external validity of a cancer clinical trial by comparing the socioeconomic status, number of comorbidities, treatments, and various stage information between the enrolled patients and the patients in the Netherlands Cancer Registry [7]. Cahan and colleagues proposed an a posteriori generalizability score that incorporates demographic information, clinical attributes, and clinical settings to compare a trial to multiple target clinical scenarios in other trials [8]. However, with such an a posteriori approach, the generalizability issue is not detected before the conclusion of the studies. Typical clinical trials cost over hundreds of millions dollars or more and take 10 - 17 years to complete [9]. Thus, it is crucial to assess a clinical trial’s generalizability before conducting the trial. Nevertheless, existing methods for assessing the a priori generalizability (i.e., the representativeness of eligible participants) have historically been scarce and laborious [10].

The rapidly growing amount of electronic patient data such as electronic health records (EHR) data, presents an unprecedented opportunity for optimizing eligibility criteria in the design phase of a new trial towards balanced internal and external validity (i.e., generalizability) [11]. In recent years, a suite of informatics methods has been introduced to quantify the population representativeness of clinical studies and characterize underrepresented population subgroups [12-14]. Notably, the Generalizability Index on Study Traits (GIST) metric quantifies the a priori generalizability of clinical trials with respect to selected quantitative eligibility criteria that specify a permissible value range (e.g., HbA1c > 7%), one at a time [12]. The extension of GIST, mGIST [15], can quantify the population representativeness of clinical trials with joint use of multiple criteria of interest. Both GIST and mGIST focus on the generalizability assessment at the disease domain level (i.e., assessing the generalizability of trials targeting the same disease). Recently, Sen and colleagues introduced GIST 2.0 as a scalable multivariate metric for quantifying the population representativeness of individual clinical studies by explicitly modeling the dependencies among all eligibility criteria [16]. However, to the best of our knowledge, no work has compared the a priori and the a posteriori generalizability assessment of trials.

Diabetes, recognized as an important public health problem by the World Health Organization [17], has caused 1.5 million deaths in 2012 alone and may, over time, lead to serious damage to the heart, blood vessels, eyes, kidneys,
and nerves. More than 400 million people live with diabetes [18]. Type 2 diabetes mellitus (T2DM), which can be developed at any age, accounts for 90% - 95% of people who have diabetes [19]. Many countries, including United States (US) and United Kingdom (UK), have invested heavily in research on treating and controlling diabetes [20, 21]. In this study, we compared and contrasted \textit{a priori} (i.e., using GIST, Weng et al. [12]) and \textit{a posteriori} (i.e., using van de Water et al. [7]) generalizability of T2DM clinical trials. We hypothesize that the \textit{a priori} generalizability of a trial is comparable to its \textit{a posteriori} generalizability in identifying certain restrictive quantitative eligibility criteria. To enable such a comparison, we will use univariate GIST metric to assess \textit{a priori} generalizability of T2DM trials with respect to three most frequently used quantitative eligibility criteria, age, HbA1c, and BMI. We chose GIST rather than its multivariable extensions, mGIST, as we want to compare individual variables' \textit{a priori} generalizability with their \textit{a posteriori} generalizability independently. We used the eligibility criteria of T2DM trials registered on ClinicalTrials.gov to profile the study populations, and extracted the published summary-level statistics of the enrolled patients. We compared the \textit{a priori} (based on the study populations) and the \textit{a posteriori} (based on the enrolled patients) generalizability of US-based T2DM trials using the target population profiled by the T2DM patients in the OneFlorida Data Trust [22], and further validated the results using UK-based T2DM trials with the target population profiled by the patients from the CALIBER research platform [23]. The OneFlorida Clinical Research Consortium (CRC) is one of the 13 Clinical Data Research Networks (CDRN) in the United States funded by the Patient-Centered Outcome Research Institute (PCORI) as part of the National Patient-Centered Clinical Research Network (PCORnet). The CALIBER resource generates and investigates deep, longitudinal phenotypic data from linked electronic health records for people registered in participating clinical practices in UK. The four main data sources include primary care EHR, hospital billing data, and death certificate records. Our work will inform the research community of the difference of \textit{a priori} and \textit{a posteriori} generalizability of T2DM trials with respect to quantitative eligibility features.

\section*{Background}

\textbf{ClinicalTrials.gov and the COMPACT Database}

ClinicalTrials.gov, created and maintained by the National Library of Medicine, is a clinical study registry in the United States. Since September 2007, all the United States-based clinical trials of FDA-regulated drugs, devices, and biologic products must be registered in ClinicalTrials.gov prior to participant recruitment. In September 2016, the United States Department of Health and Human Services issued the final rule of that expands the regulatory procedure for trial registration and summary results reporting [24]. Mandated by the final rule, trial sponsors are required to report summary statistics on race, ethnicity, and other measures assessed at baseline that are used in study descriptors such as study phase (i.e., Phase I, II, III, and IV), intervention type (e.g., drug, device, biologic product), locations, are stored in structured fields, whereas eligibility criteria are largely free-text.

To facilitate \textit{a priori} generalizability analysis, we leveraged the numeric expression extraction tool “Valx” [26, 27] and the frequent tag mining tool [28] to transform study summaries in ClinicalTrials.gov into a relational database, and we named it “COMPACT” [29]. COMPACT contains various study descriptors (e.g., study phase, intervention), and numeric eligibility features. With Valx, different names for the same variable in the eligibility criteria, such as “hemoglobin A1c”, “HbA1c”, “Glycohemoglobin”, are unified. Different measurement units are also unified. COMPACT indexes trials by medical conditions.

\textbf{OneFlorida Clinical Research Consortium and Data Trust}

The OneFlorida CRC is a collaborative statewide network that seeks to improve health research capacity and opportunities in the State of Florida through the facilitation of clinical and translational research in communities and health care settings. OneFlorida includes nine unique health systems that provides care for \textasciitilde{}9.7M or 48% of all Floridians through 4,100 physician providers, 1,240 clinic/practice settings and 22 hospitals with a catchment area covering all 67 Florida counties. In 2015, OneFlorida became one of 13 PCORI-funded clinical data research networks in the US.

The OneFlorida Data Trust is the centerpiece of the OneFlorida CRC and is the informatics infrastructure that supports pragmatic trials; comparative effectiveness research, implementation science, and other research in OneFlorida. The OneFlorida Data Trust currently contains collated EHR, health care claims, and other data on a
broad-based, unselected population of ~10 million people in Florida. The data are limited to a Health Insurance Portability and Accountability Act (HIPAA) Limited Data Set (LDS), which restricts the types of protected health information (PHI) to only dates (e.g., birthdates and dates of service) and location (to the zip code level).

**CALIBER (Clinical research using Linked Bespoke studies and Electronic health Records)**

CALIBER is a unique research platform consisting of ‘research ready’ variables extracted from linked EHR from primary and secondary care, social deprivation information and cause-specific mortality data in UK. Led from the University College London Institute of Health Informatics and the Farr Institute of Health Informatics Research, London, CALIBER enables researchers to recreate the longitudinal journey of patients through care pathways to study disease onset and progression. This research platform accesses linked electronic health records and recreates the healthcare pathways of approximately 10 million patients with 400 million person years of follow up. The aim of CALIBER is to foster an open community developing methods and tools to accelerate replicable science across all clinical and scientific disciplines spanning the translational cycle (from drug discovery through to public health). The resource consists of disease and risk factor phenotyping algorithms, methods [30], tools and scripts, specialized infrastructure and training and support. All finalized EHR phenotyping algorithms are provided in an open-access Portal (https://www.caliberresearch.org/portal) for researchers to extent and re-use.

**Methods**

We first define the three patient populations for a clinical trial:

- **Target population**: patients to whom the results of the clinical study are intended to apply. The target population can only be approximated with available patient data.
- **Study population**: patients who are eligible for the study based on the study inclusion and exclusion criteria.
- **Enrolled patients**: patients who are enrolled in the clinical study. It is a subset of the study population.

Figure 1 illustrates the analytical workflow of this study. We first retrieved interventional clinical studies on T2DM in the US and UK from the COMPACT database. In this work, we chose to focus on three major quantitative eligibility criteria in T2DM studies: age, HbA1, and BMI, which are used in the free-text eligibility criteria of 49.1%, 48.5%, and 43.98% T2DM trials, respectively [13]. Age is also a required field in the eligibility criteria section of a trial summary in ClinicalTrials.gov. We therefore used the structured age field. To profile the target population of T2DM, we identified all the T2DM patients in the OneFlorida Data Trust using both ICD-9-CM and ICD-10-CM codes. To validate the findings of US-based T2DM trials on UK-based trials, we identified T2DM patients from the CALIBER data with the ICD-10 codes in the hospital data and the Readcodes in the primary care data. We applied the GIST metric to assess the a priori generalizability of T2DM trials in the US and UK using the target populations derived from OneFlorida Data Trust and CALIBER, respectively. We also stratified the analysis by trial phase. We assessed the a posteriori generalizability by comparing the characteristics of the enrolled patients reported in ClinicalTrials.gov with the T2DM patients in OneFlorida Data Trust and CALIBER, respectively.

Figure 1. Analytical workflow of this study

**Dataset Preparation**

1) **Processing clinical trial summaries.** From the COMPACT database, we identified interventional clinical trials on T2DM with a study start date between January 2005 and September 2016. There are 1,671 such studies in the United States and 209 such studies in the United Kingdom.
2) Identifying T2DM Patients in OneFlorida Data Trust. Following existing literature [12], we identified patients with T2DM in OneFlorida Data Trust using the following criteria, where the patient (1) needs to have at least two diagnoses of Type 2 diabetes; (2) needs NOT have any Type 1 diabetes diagnoses; and (3) should have at least one HbA1c measurement regardless of their temporal relationships to diagnosis times. Diagnoses of Type 1 and 2 diabetes were identified with ICD-9-CM and ICD-10-CM diagnosis codes.

3) Identifying T2DM Patients in CALIBER. We utilized descriptive data from a previous study [31] using a deterministic to identify patients with Type 2 diabetes in CALIBER using diagnostic codes (Read codes in primary care, ICD-10 in secondary care).

Assessing a Priori Generalizability

To quantify the population representativeness of studies based on a single quantitative criterion (i.e., age, HbA1c, and BMI in this study), we calculated the univariate GIST scores for trial sets of different study phases [12]. The GIST score is the sum across all consecutive non-overlapping value intervals of the percentage of studies that recruit patients in that interval, multiplied by the percentage of patients observed in that interval:

\[
GIST = \frac{\sum_{j=1}^{N} \frac{I([i_{low}, i_{high}] \subseteq w_j)}{T} \times \frac{\sum_{i=1}^{P} I(y_i \leq i_{low} < i_{high})}{P}}{T}
\]

where \(N\) is the number of distinct value intervals of the quantitative feature, \(T\) is the number of trials, \(P\) is the number of patients, \(w_j\) is the inclusion value interval of the quantitative feature for the \(j^{th}\) study, such that indicator \(I\) can be defined as \(j^{th}\) study interval subsumes the \(j^{th}\) interval low and high boundary values, and \(y_i\) is the observed value of the quantitative feature for the \(k^{th}\) patient such that an indicator \(I\) can be defined when \(k^{th}\) patient has a value of the quantitative feature falls within the \(j^{th}\) interval. The GIST score ranges from 0 to 1, with 0 being not generalizable and 1 being perfectly generalizable. It characterizes the proportion of patients potentially eligible across trials. For more detailed explanation of GIST, see [12, 14]. We have previously evaluated the validity of the GIST metric in quantifying the population representativeness of trials using simulated patient populations [32]. Compared with mGIST which gives an overall score for multiple variables, GIST gives variable-specific scores, allowing us to compare them with the results of a posteriori generalizability assessment which are also variable-specific.

Assessing a Posteriori Generalizability

To compare enrolled patients with the target population, we identified all the US and UK T2DM trials that have reported results in ClinicalTrials.gov and extracted the baseline measures including the number of participants, their gender and race, and the mean and standard deviation (SD) values of the three major measures: age, BMI, and HbA1c. We aggregated the mean and SD for age, HbA1C, and BMI separately for all the trials that report both mean and race distributions with the real world population of T2DM patients in OneFlorida and CALIBER. We used the two-sample t-test to assess differences in quantitative variables (i.e., age, HbA1c, and BMI) and chi-square test to assess difference in categorical variables (i.e., race and gender) between the target population and enrolled patients.

Results

Basic Characteristics of T2DM Trials

Basic characteristics of the clinical trials on T2DM included in our analysis are shown in Table 1. Even though the number of trials differed significantly between the US and the UK, they exhibit similar characteristics. The rates of missing data for study phase are 23.6% and 27.3% in trials in the US and the UK respectively. A majority of trials are sponsored by industry (63.4% and 64.1%). Drugs were the most common interventions (72.1% and 72.7%).
followed by behavioral interventions (11.6% and 8.1%). Treatment was the primary purpose for the majority of the trials (75.9% and 77.0%). Most of the trials were randomized (86.9% and 90.1%).

A Posteriori Generalizability of T2DM Trials

Among all the T2DM trials in our analysis, 428 (25.6%, out of 1,671) US trials and 86 (41.1%, out of 209) UK trials report summary-level results (e.g., baseline characteristics and outcome measures) in ClinicalTrials.gov. Table 2 illustrates the number of T2DM trials that report mean values and standard deviation values for age, HbA1c, BMI, as well as race and gender. Within the trials that provided these statistics, most of them provided the mean and standard deviation of age for all the enrolled patients. A higher percentage of UK-based trials reported mean and standard deviation values of HbA1c and BMI than the US-based trials. The primary reasons that the remaining trials did not report any results in ClinicalTrials.gov include (1) still under recruitment, (2) completed before December 6, 2007 and thus not required to submit results, and (3) pending results (results of applicable trials of FDA-regulated drugs, biologic, and device must be submitted within 12 months of trial completion [34]).

We extracted the baseline characteristics of the patient's enrolled in T2DM trials in the trial summaries on ClinicalTrials.gov. Table 3 reports the number of trials that provide the results of each baseline characteristic. We used formula (2) and (3) to calculate the weighted mean and standard deviation values for quantitative variables (i.e., age, BMI, and HbA1c) separately.

Table 4 compares the characteristics of the patients enrolled in T2DM trials and the T2DM patients in the OneFlorida Data Trust and CALIBER. The differences of mean values of age between the patients in OneFlorida and the patients enrolled in US-based T2DM trials of Phase I, II, II and are 21.9, 13.0, and 11.0, respectively, showing an increasing a posteriori generalizability of US-based trials regarding age. The patients enrolled in both US and UK-based T2DM trials were younger than the T2DM patients in the clinical data warehouses (two-tailed P < 0.0001). Regarding race, Caucasian/White and Asian were overrepresented, whereas women, black, and other races were underrepresented. The differences between the target populations and the enrolled patients in US and UK-based trials are both statistically significant with respect to race (two-tailed P < 0.0001). Regarding gender, female patients were underrepresented in both US-and UK-based trials (two-tailed p < 0.0001). The patients enrolled in both US and UK-based trials have higher HbA1c values than the target populations (two-tailed p < 0.0001). The patients enrolled in US-based trials have a slightly lower BMI (two-tailed p < 0.0001), whereas the patients enrolled in UK-based trials have a slightly higher BMI (two-tailed p < 0.0001).

Population Representativeness of T2DM Trials

Figure 2 visualizes the target population, study population, and the enrolled patients in the US and UK-based T2DM trials for each of the three major quantitative eligibility criteria: age, BMI, and HbA1c. The green curves represent the study populations of the eligible patients, i.e., the percentage of trials that allow a certain value of the variable. The red curves represent the distribution of patients enrolled in the T2DM trials over the value spectrum of the variable. The blue curves represent the target population. In general, the visualization of these populations for US and UK trials exhibited similar characteristics. For example, there is a noticeable gap between the patients enrolled in the T2DM trials and the target population with respect to all the three quantitative criteria. The patients enrolled in T2DM trials were younger and had lower HbA1c and BMI values than those in the target populations (red curves vs. blue curves). The T2DM trials usually permit patients of a wide range of age values. The gap between the study population and the target population is obvious for HbA1c (green curves vs. blue curves). The trends of the study populations and enrolled patients are similar (green curves vs. red curves).

Figure 2. Visualization of (a) age, (b) BMI, and (c) HbA1c in the target populations and study populations of US and UK-based T2DM trials, respectively.

We used the GIST metric to assess the population representativeness of US and UK-based T2DM trials with respect to the three major quantitative eligibility criteria: age, BMI, and HbA1c (Table 5). The GIST scores for the US and UK-based trials were calculated using the target populations derived from the OneFlorida Data Trust data and CALIBER, respectively. We stratified the analysis by study phase. As shown in Table 5, US and UK trials have
similar overall GIST scores for all three variables. The GIST scores of age in both the US and UK trials increased from Phase I to Phase III, which is consistent with the results from two previous studies using the T2DM patients data in the Columbia University [12] and a national survey [14] as the target populations. It is also consistent with our finding of the \textit{a posteriori} generalizability assessment conducted in this work. Phase I studies in the UK had lower GIST scores of age than Phase I studies in the US. The GIST scores of 0.27-0.36 indicate a serious population representativeness issue of UK T2DM Phase I trials. However, Phase II trials in the UK had higher GIST scores of age than Phase II trials in the US. With respect to BMI, the UK trials had slightly higher GIST scores than the US trials of all phases. With respect to HbA1c, the GIST scores of the US trials decreased from Phase I to Phase III, which is also consistent with the two previously mentioned studies [12, 14]. The HbA1c’s GIST scores of the UK trials decreased from Phase I to Phase II, while the UK trials had similar GIST scores of HbA1c as US trials. The fact that \textit{a priori} generalizability of HbA1c is the lowest among the three criteria is consistent with the visualization shown in Figure 2, as well as the \textit{a posteriori} generalizability assessment.

Discussion and Conclusions

In this study, we used real-world patient data in the target population to assess the generalizability of T2DM clinical trials in the US and UK. As shown in Table 5, US and UK-based T2DM trials have similar \textit{a priori} generalizability of age, HbA1c, and BMI. However, the GIST scores for age in trials of different phases differ between US and UK-based trials. While GIST provides a quantitative metric for comparing the population representativeness of different sets of trials, visualization of different populations can reveal the systematically omitted or overly included population subgroups. The results of \textit{a priori} generalizability showed that the US and UK-based trials exhibit similar issues with respect to the three most frequently used quantitative criteria. The results of the \textit{a posteriori} generalizability assessment showed that males, whites, and Asians are overrepresented in both US and UK-based T2DM trials while females, blacks, and other races are underrepresented.

Compared to the \textit{a posteriori} generalizability assessment, the use of the GIST metric to assess the \textit{a priori} generalizability assessment has a few advantages. First, it can be performed during the trial design phase, which would help reveal issues of eligibility criteria that are biased towards certain population subgroups, and help trial designers optimize the balance between internal and external validity. Trial designers can fine-tune the criteria without diminishing the internal validity. For example, UK T2DM Phase I trials have a very low GIST score of age. Trial designers should thus adjust the restrictive age criterion in Phase I trials in the future to improve their population representativeness. Second, GIST quantifies the difference of the distributions of the eligible patients and the target population over a variable, whereas the \textit{a posteriori} generalizability compares the mean difference of a variable. It can be done using cost-effective informatics tools. Meanwhile, the \textit{a priori} generalizability assessment has a few disadvantages. First, it does not take into account the practical issues in the trial recruitment phase, such as
geographic locations, accessibility of trial information, and consideration of comorbidities. For example, due to real-world complications, most studies failed to recruit representative samples of their study population as specified in trial eligibility criteria [10]. On the other hand, the \textit{a posteriori} generalizability assessment, which compares the enrolled patients with the target population, can provide a more accurate assessment of the population representativeness. The issues of gender disparity and race disparity, as well as other disease-specific outcome measures can be accurately detected. Both \textit{a priori} and \textit{a posteriori} generalizability results showed increasing generalizability of US-based T2DM trials from Phase I to Phase II with respect to age, which confirmed our hypothesis that \textit{a priori} generalizability is comparable to \textit{a posteriori} generalizability in identifying certain restrictive quantitative eligibility criteria. It should be a common practice to assess both \textit{a priori} generalizability based on trial design factors such as eligibility criteria before patient recruitment as well as \textit{a posteriori} generalizability \textit{post hoc} based on enrolled patients. The trial design issues that are found in \textit{a priori} generalizability can be addressed before patient recruitment, thereby improving the \textit{a posteriori} generalizability and the cost-benefit ratio of the trials. Nevertheless, clinical trial investigators should also consider practical issues in the trial recruitment phase. For example, most trials still use a traditional hospital-based recruitment strategy. Thus, the trial designers of these studies should carefully choose recruitment sites, and take into account the population characteristics of these sites’ catchment areas.

A number of limitations should be noted in our study. First, less than 40% of T2DM trials reported results in ClinicalTrials.gov. Therefore, the aggregate results of the enrolled patients represent merely a convenient sample. Second, the OneFlorida Data Trust contains data of patients who have visited healthcare organizations in the state of Florida, and thus might not be representative. Even though we only used patient data from the state of Florida in the US, Florida is the third most populous state (~19.9 million) in the US. Third, it is possible that not all clinical trials conducted in the UK are registered on ClinicalTrials.gov. We identified trials based on the study site. Some trials are conducted in multiple countries. Therefore, some UK-based trials may also have study sites in other countries.

Abstract

Bar charts are crucial to summarize and present multi-faceted data sets in biomedical publications. Quantitative information carried by bar charts is of great interest to scientists and practitioners, which make it valuable to parse bar charts. This fact together with the abundance of bar chart images and their shared common patterns gives us a good candidates for automated image mining and parsing. We demonstrate a workflow to analyze bar charts and give a few feasible solutions to apply it. We are able to detect bar segments and panels with a promising performance in terms of both accuracy and recall, and we also perform extensive experiments to identify the entities of bar charts in the images of biomedical literature collected from PubMed Central. While we cannot provide a complete instance of the application using our method, we present evidence that this kind of image mining is feasible.

Introduction

Bar charts are necessary resources for scientists and practitioners to describe experimental results such as comparisons among categories or grouped data in published biomedical literature. Recently, there has an enormous increase in the amount of open-access heterogeneous biomedical image production and publication, and a trend in the area of literature mining is allowing users to query the figures of biomedical articles which are otherwise not readily accessible.¹, ², ³ These researches focus mostly on image retrieval, image classification and making text within image available. However, biomedical images contain much structured information and quantitative information, which is not yet accessible through search. Below, we present our approach to detect and access bar charts in biomedical publication. For the purpose of further study, we also illustrate some possible situations which take advantage of our bar charts mining method.

Image types are of great importance for image mining. Kuhn et al. manually annotate the segment sub-graphs in the constructed corpus of 3000 images and classify them into five basic categories: Experimental/Microscopy, Graph, Diagram, Clinical, and Picture. The results show that bar chart is the most common types of subfigure accounting for 12.4% of entire set of images,⁴ which reinforces our determination to study bar charts. Furthermore, the bar charts share the common patterns that have at least two straight and visible axes that one represents specific categories being compared, and the other represents a discrete value, and uses rectangular bars with lengths proportional to the values that they represent.

A closer look at bar chart reveals that they follow regular patterns to encode their semantic relations. Since the priority target of our approach is to automatically extract the relation of the corresponding quantitative proportion to the categorical data, we focus on the text information (the axes labels and the legends) as well as the length proportion of

Figure 1. Four typical examples of bar charts.
the bars. Figure 1 shows four typical bar chart images. The slight differences about the text and the bars should be noticed. Panel (a) shows the most common bar chart, which has a horizontal x-label, y-label and legends. Panel (b) shows a figure with a horizontal grid and a slanted x-label. Panel (c) shows bars on both sides of the x-axis, and the x-label is vertical. Panel (d) shows the condition in which the bars are filled with slash. These kinds of bar charts represent the most typical bar chart images.

Figure 2 shows two common bar charts together with a table representation of the extracted information. The first one shows the expression patterns of the GmIFR genes in various tissues. The x-label represent the category of the tissues while the y-label represent the expression level of the gene. A bar chart can be considered a kind of matrix with pictures of experimental artifacts as content. The tables to the right illustrate the semantic relations encoded in the bar charts. Each relation instance consists of a condition, a measurement and a result. Gene is the entity being measured under the conditions of the different tissues. The result is a certain level of expression indicated by the lengths proportion to the bars. Second example is a slightly more complex one. The mRNA transcript level of the GmPAD4, GmEDS1 and GmPR1 gene on AtPAD4-overexpressing and control roots. More than one gene are tested against each other in a way that involves more than two dimensions. In this case, legend is the major technique to denote the different possible combinations of a number of conditions.

Background and related work

Image classification and retrieval are two of the most active areas in biological image mining research. Rafkind et al.\textsuperscript{5} proposed a classification system using coherence and frequency features to divide figures into five sets. Then, a retrieval method,\textsuperscript{6} which had better flexibility than the system of Rafkind et al.\textsuperscript{3}, was proposed to retrieve figure types defined conceptually by taking advantage of principles in image understanding, text mining, and optical character recognition (OCR). For searching information in text embedded in figures, YIF (Yale Image Finder)\textsuperscript{7} has been proposed to retrieve biological figures and associated papers in which the retrieved images allow users to find related papers by linking to their source papers. Hearst et al.\textsuperscript{8} developed the BioText Search Engine, which is a freely available web-based application for searching and browsing figures in articles as well as their captions. The study of image processing also includes image segmentation, optical character recognition (OCR) and interpretation of figure captions. Li et al.\textsuperscript{9} proposed an algorithm to segment images that consisted of multiple subfigure into single images and then

![Figure 2](image)

**Figure 2.** Two examples of bar charts from biomedical publications (PMC4655237 and PMC3648381) with tables showing the relations that could be extracted from them.
extract the title and tag information from the graph. Lopez et al. developed a robust image segmentation algorithm in order to perform text retrieval based on images. Kim et al. developed an image and text extraction tool (figtext) through the combination of image preprocessing, character recognition, and text correction to improve the performance of OCR tools.

Research involving biological images is currently subject to some specific limitations. Only a small amount of research has been conducted into the mining of information from image data in biological research or into the construction of a structured biological knowledge base. SLIF (Structured Literature Image Finder) has been developed for automated information extraction from fluorescence microscopy image information, and a series of follow-up studies have been reported for promotion. Their project included image classification, figure title understanding, figure segmentation, and the relationships between sub-images and sub-captions. Also, there is a large amount of existing work on how to process bar charts. Zhou et al. proposed a modified probabilistic Hough transform algorithm to detect and recognize bar charts, which is, however, just the first step in locating them and analyzing their labels and their structure. Al-Zaidy et al. attempts to extract information from bar charts automatically. However, the method takes plain bar chart as input, which are not readily accessible from biomedical papers, because they make up just parts of the figures. Furthermore, the method mentioned above is designed for researchers who want to analyze their bar charts and not to read bar charts that have already been analyzed and annotated by a researcher. Therefore, these approaches do not tackle the problem of recognizing and analyzing bar charts. Some attempt to classify and redesign biomedical images include bar chart, but they are only tested on small data sets that do not satisfy the diversity of images in biological documents. To the best of our knowledge, there is little research into the mining of bar charts, which is a frequently used means of demonstrating the differences among data.

Method

Our approach to image mining from bar charts consists of 6 components: figure extraction, image preprocessing, bar segment detection, in-image text recognition, panel segmentation, and quantitative information extraction (Figure 3). Figure extraction module that extract images accessed in PubMed. Image preprocessing module that removes non-informative figures to reduce computing cost. For bar segment detection, we use a detection procedure based on hand-coded rules and convolutional neural network (CNN) method to detect bar segments. In-Image Text Processing module identifies the corresponding text region in the image by performing a text location method. Additionally, the Panel Segmentation module combines the results obtained from the previous two modules to first estimate. Finally, we extract the quantitative information among the entities.

Figure 3. The procedure of our bar charts mining method. (from PMC4482714)
**Figure extraction.** The data interface (OA web service) are manually accessed in PubMed, which makes it convenient to download article folds consist of documents with different formats (PDF/NXML format articles, GIF/JPEG format images, etc.). We obtain a subset for our future use case by searching the keyword combination of “soybean,” “gene” and “expression.” We only use this subset so far, which makes it easy for us to extract figure. Although it would be definitely feasible, it would also be more trivial for automatic extraction of figures from biomedical articles in PDF format.

**Image preprocessing.** The download figures from PubMed Central typically incorporate a significant number of non-informative figures (e.g., conference and journal logos, formula), which lead to additional computational processing cost. We separate the objects from the background image by using pixel level features. When converting an image into binary image, we give a fixed threshold value of 0.9 instead of automatic threshold value because we want to get a more complete bar segment. Three factors are considered here to filter out figures that are definitely not bar charts: (1) The number of connected domains is less than 5; (2) the absolute width or height is more than 100 pixels, and (3) the 0 value rate is more than 95% of binary image.

**Bar Segment Detection.** We first extract connected components from the filtered image by grouping adjacent pixels of similar color, (for binary image, the adjacent pixels of 1 belong to the same component), and then represent the objects in the figure as a bounding box. The small components (e.g., characters) are filtered according to the area ratio of the connected domains firstly.

As a baseline, we first propose a relatively simple hand-coded bar segment detection method. Such bar segments typically have several bars with the same width distributed uniformly on the x-axis, which is the most distinct feature of the bar chart. For this reason, a projection method is used to detect such bar segments. All the columns are subsequently vertically projected to the x-axis when the area value of the connected domain reached the threshold. The bar charts are detected through defining rules for the ratio of columns that are completely blank and the ratio of the sum of equal columns.

There is an alternative method on using machine learning approaches for image classification. In this paper, we choose a simple CNN model to be the training model for bar charts detecting. With the analysis of the intermediate results (bar segments) generated by the hand-coded method, we can easy get the dataset of CNN. The training set consists of 12000 positive samples and 4000 negative samples, while the test set consists of 3000 positive samples and 1500 negative samples. Experiment of different parameters is conducted and the best model is chosen with the learning rate 1 and iteration times 800.

**In-image text recognition.** Because the text in figures is of great significance, a text extraction method is used to extract the important text in the figure. Not only should we extract the text from the image, but also the position of the text. Text localization detects different text regions in images. In this part, we focus on x-label, y-label, and legends. All above information are obtained respectively for the necessity of constructing complete corresponding relation. To do this, we use a detection procedure with simple rules. The coordinate axes are used to partition the region. Then the direction of the character is distinguished through combination of the character spacing and character size, and the character region, which is vertical and slanted, is rotated. For optical character recognition (OCR), the open-source tool OCROPY (https://github.com/MissCristal/ocropy) is used. Sometimes the deletions, insertions, and substitutions of letter or number tokens appeared in the extracted text information from bar chart can be found from the related figure caption text. Spell correction of the extracted in-image text is realized by computing Levenshtein Distance between the extracted in-image text and the corresponding figure caption text.

**Panel Segmentation.** The last step consists of segmenting the figure into panels using the information extracted from the previous two modules. The sub bar charts detected in the bar segment detection step are found in most case that it is a part of a whole figure in which some parts are not bar charts. Although in our study we just extract information from the image, the information from the article text can be potential additional information to the image. Hence, the order of the sub charts is an important information for further study.

A rectangle segmentation algorithm is used to extract the potential sub bar graphs contained within the figures. After bar segment detection and in-image text recognition processes, the detected bar segments are extended to produce a larger rectangle containing important information such as x-label, y-label, and legends of a sub bar chart. If the area cover the whole figure, the segmentation process is not able to continue because it have only one sub chart. Otherwise, the multiple sub bar charts are generated by reducing the enlarged rectangle based on the in-image text detected. The sub charts that are not sub bar graph were filtered out. On the basis of our observation, sub charts are usually arranged from left to right and from top to bottom. Therefore, we name the sub charts according to the panel position.
Quantitative Information Extraction. The quantitative information in bar charts is obtained through recognition of the x-axis and the height of each bar. Twenty uniformly distributed rows per graph are traversed. If the row crossed the bar, it is traversed up and down to find the critical point and the row index is recorded. The x-axis is here defined as the row at which the row index is recorded the greatest number of times. If the x-axis is in the bottom of the figure, then all of the bars are on top of the x-axis. All the graduated lines including the x-axis are removed to separate all the bars. Then the bars are filled in to make them all solid. Then all of the columns are traversed up to down. The first row index for which the pixel is 0; otherwise, 1 was set as the value, and it is denoted as vector U. Then vector U is traversed the height of a bar is defined if there are no fewer than 5 consecutive identical values. If the x-axis is in the center of the figure, and the bars are located on both sides of the x-axis. All the columns are traversed from both sides, and steps similar to those outlined above are used.

Results
To test our approach, we created a gold standard corpus of images. We randomly selected a sample of 300 open-access articles folds from PubMed Central that consist of jpg image. Altogether, these 300 articles contain 1769 figures, an average of about 6 figures per article. For these figures, we manually annotated the number of image containing bar charts and the number of bar charts, resulting in 534 (32.2%) images containing at least one bar chart and in total 1659 sub bar chart. The analysis demonstrated that bar charts are indeed a very important image type in the biomedical literature. Among the figures contain at least one bar chart, 87 (16.4%) thereof contain more than 5 bar charts. This corpus was selected and annotated after we finished implementing the algorithm presented here. While we develop the method, another corpus is downloaded from PubMed Central. This two corpus have no overlap.

As shown in the top part of Table 1, the hand-coded algorithm is able to detect the bar charts with a high precision of 95.47% and a recall 59.08%. The CNN classifiers based on image features alone have lower precision than the hand-coded algorithm, but higher recall. Overall, the CNN classifier combined with hand-coded algorithm performs better than the hand-coded classifier and CNN classifier alone with F-measures of 88.66%. To clarify the cause of the result, we analyze the result of the combined method. Most of the false positive cases are axis diagram (e.g., line chart), and most of the true negative cases are bar chart with no distinct bars (e.g., very low bars).

The results of the bar panel segmentation algorithm are shown in the middle part of Table 1. We define the complete panel segmentation as to segment the panel with the x-label, y-label and the legends (if the bar chart has legends). Our method correctly produce 98.11% of the panel segmentation at a recall of 52.73%, which leads to an F-measure of 68.59%. In order to determine the different reasons of the low recall, we analyze the figure which is detected as the bar segments but not obtained the complete bar chart panel. (10.31%) Figures identified by our system share at least one data (e.g., x-label), which leads to incomplete panel. Other factors such as the sub charts are very close in a big image, the legends of the bar chart are not below the x-axis or is described in the caption could also make the panel incomplete.

Results of the extracted information are shown in the bottom part of Table 1. If information extracted from the bar charts can fill all the columns of the corresponding table, it is defined as a correct extraction. Almost 39.81% of the bar panels are extracted. 82.40% thereof are correct. Low quality of images is the most important reason of incorrect information extraction. The incorrect cases could be split into two classes of roughly the same size: the wrong number of categories in the group data, the wrong number of bars. The primary cause for the first class of incorrect cases was the fact that different forms of x-label (such as slanted x-label) make it hard to segment the labels. The causes for the second class are the facts that some images contain large numbers of very thin bars that are difficult to detect and the interferences such as the graduated lines, the slash bars of some bar chart lead to more bar numbers than exactly being contained. Usually, the number of detected bars was greater than the number of real bars, owing to the margin of error occurring in lines.

Table 2 shows the results of running the pipeline on the subset of PubMed Central. We start with about 14596 articles folds, which is accessed from the data interface (OA web service) in PubMed and searched by the keyword combination of “soybean,” “gene” and “expression.” About 18% article folds are discarded by the reason of containing no article with XML format or no JPG image. Remaining articles contain around 80378 figures. In order to reduce additional computational cost, no-information figures are filtered in the image preprocessing steps. We ended up with more than 61238 figures, in which about 44537 bar charts are detected.

Discussion

In this paper, we have developed a comprehensive system for automatically extracting information from bar charts. Our result confirm that our bar chart detection method can achieve a high accuracy, allowing us to segment the bar panel with a high precision. While the bar charts are so frequent, the low recall of the panel segmentation is not a severe problem at this point. To extract the relation of the categorical data in perspective, the conditions (x-labels and legends) should match to the bars exactly. Although the recall is low, about 40% is still in a reasonable range.

Since we invested effort in extracting information from bar charts, we give our opinion on the use of such information. Our method can help to construct dataset provided direct reference and evidence for the researchers. For example, the statistical analysis of PCR and phenotypic data are often expressed by means of bar chart. PCR is the gold standard, used to validate the results of RNA-seq.20 PCR data are more accurate and repeatable than high-throughput RNA-seq data. However, PCR data are always reported in academic papers, which have seldom been collected from the specialized databases. A combination of text mining method and our bar chart mining method is able to construct the database not only containing information from articles, but also the quantitative information of the experimental results. Illustration of phenotypic data also account for a large proportion in the bar charts, which is currently a bottleneck of genome-wide association study (GWAS) and molecular breeding. Currently, most public genotype-phenotype databases did not include the corresponding data regarding soybean organisms.21 For this reason, one of the practical values of the current dataset is that it contain correlation information for genotype and phenotype, which could be extracted from bar charts in publications.

It seems reasonable to assume that these results can provide necessary information to biomedical application. We plan to investigate this in future work. The results obtained from bar chart processing pipeline indicate that it is feasible to extract relations from bar charts, but it is clear that this procedure is far from perfect. Aiming to the problem of low image resolution, the automatic analysis of vector diagram seems to be an efficient way to extract such relations from existing publications in the future.

Conclusion

In this article, we present the most common image — bar charts — to be automatically assessed in a reliable way. Our results show that the hand-coded algorithm and the CNN method we proposed can detect the bar segment at a high accuracy. We also depict that relation and quantitative information can be extracted from the bar charts with satisfactory precision. In order to demonstrate and exemplify the algorithm’s ability and advantage, the literatures related to soybean gene expression are selected and tested. Based on these results, we believe that our proposed bar chart mining method is a viable and promising approach to provide more power to gather relations such as gene regulation. All in all, we have demonstrated a novel methodology that detects bar charts for our use case. Further research will be to apply the methodology to a larger set of citations with more diverse content.

Evaluating the Effectiveness of Auditing Rules for Electronic Health Record Systems

Monica Hedda, BE1, Bradley A. Malin, PhD1, Chao Yan, MS1, Daniel Fabbri, PhD1

1Vanderbilt University, Nashville, TN

Abstract

Healthcare organizations (HCOs) often deploy rule-based auditing systems to detect insider threats to sensitive patient health information in electronic health record (EHR) systems. These rule-based systems define behavior deemed to be high-risk a priori (e.g., family member, co-worker access). While such rules seem logical, there has been little scientific investigation into the effectiveness of these auditing rules in identifying inappropriate behavior. Thus, in this paper, we introduce an approach to evaluate the effectiveness of individual high-risk rules and rank them according to their potential risk. We investigate the rate of high-risk access patterns and minimum rate of high-risk accesses that can be explained with appropriate clinical reasons in a large EHR system. An analysis of 8M accesses from one-week of data shows that specific high-risk flags occur more frequently than theoretically expected and the rate at which accesses can be explained away with five simple reasons is 16 - 43%.

Introduction

Electronic health record (EHR) systems can improve the quality of patient care, safety and education, while reducing costs and enabling research. To encourage the adoption and use of EHR systems by healthcare providers, the US government passed the Health Information Technology for Economic and Clinical Health (HITECH) Act of 2009 and established incentives for healthcare providers that demonstrate meaningful use of EHR system to provide better patient care. As a result, integration of EHR systems into healthcare organizations (HCOs) has continually increased. However, the increased accessibility of protected health information (PHI) in EHR systems leads to a greater potential for misuse and abuse by the authorized users. Such events can result in penalties levied by federal and state regulators.

An EHR is fundamentally a collaborative information system, which, traditionally, is protected through proactive strategies, such as fine-grained access control technologies. Such technology is often integrated into EHR systems; however, the dynamics of patient care, in combination with the difficulty in predicting who needs access to a patient's medical record when, make it challenging to deploy such fine-grained control schemas without triggering a substantial quantity of false alerts and slowing care workflows. Despite acknowledging the potential for insider threats, HCOs typically do not instantiate fine-grained controls. This implicitly suggests that HCOs deem the losses associated with impacts on workflow and care to be greater than those brought about by employees who misuse or abuse their privileges.

Still, HCOs do not neglect insider threats entirely. In lieu of fine-grained proactive protections, HCOs tend to rely upon retrospective mechanisms, such as auditing and investigation. In the United States, the Security Rule of the Health Information Portability and Accountability of 1996 (HIPAA) requires that all HCOs maintain audit logs, analyze them for inappropriate use and report misuse. Hospitals maintain audit log of all accesses to PHI and the audit log is often reviewed by administrative officers to detect inappropriate access. However, the sheer volume of accesses documented by large HCOs makes manual review infeasible. The number of access transactions is often over one million per day, while officers have only one or two people at their disposal (often allocating only a portion of their time) to run investigations. As a result, many HCOs prioritize their investigations by monitoring patient records deemed to be very important persons (VIPs) or upon patient complaints. In the latter scenario, compliance officers investigate the accesses to patient records after a complaint has been registered.

More recently, there has been a push to (semi-)automate the auditing process. However, there are many challenges an HCO faces to do so. For instance, the information often required to determine if an access is inappropriate is not stored in the audit log. As a consequence, HCOs have deployed rule-based methods to capture high-risk behavior and promote them to compliance officers for review. Figure 1 shows the process associated with such a traditional rules-based auditing system. Unfortunately, rule-based flagging systems can result in high false positives. For example, a typical rule is to flag when an employee accesses an EHR of a patient with the same last name. Yet, for individuals with a common name, clearly this rule will trigger an excessive amount of alerts.
Given the state of affairs, we set out to assess the validity of rules for auditing accesses made in EHR systems. The goal of this study is to test, through simulation and theoretical analyses, if these flags occur at a higher rate than expected, and therefore serve as a valid means to detect inappropriate behavior. Our contributions in this work are as follows:

1. **Investigate the difference between observed and expected high-risk accesses.** We introduce an approach to investigate the difference between the observed and expected rate of high-risk accesses in EHR systems for typical expert-specified rules. If a rule holds merit, we anticipate that the observed rate of high-risk accesses will be higher than the expected rate of high-risk accesses to the EHR system. Using one week of data from Vanderbilt University Medical Center (VUMC), we show that there are many rules for which this difference is statistically significant.

2. **Select and prioritize rules based on deviation between observed and expected.** We introduce an approach for selection and prioritization of the high-risk rules. This approach is based on the magnitude of the deviation between the observed and expected frequency of high-risk accesses for each rule.

3. **Prioritize flagged high-risk accesses for investigation.** To improve the manageability of a manual review process in resource constrained environments, explanation-based filtering\textsuperscript{10} can be utilized to prioritize the flagged accesses for manual review. Note that rule-based flagging and explanation-based filtering are complementary approaches to detect inappropriate behavior. While rules capture the high-risk behavior, explanations reduce the set of accesses that need to be investigated to a set of un-explained accesses. We find synergy between these two auditing approaches and introduce an explanation-based mechanism to prioritize high-risk accesses flagged by rules for manual investigation. We show that many, though not all, of the high-risk accesses can be explained away with clinically justifiable reasons.

![Figure 1. The process by which an HCO investigates accesses to EHRs deemed to be of high risk.](image)

**Background**

Many HCOs use modern EHR systems equipped with automatic log collection to maintain the audit log. Each time an employee accesses a patient’s record, the automatic log collection process adds a transaction to the audit log with the details of the access including user, patient, action performed (e.g., viewed reports) and time of access.

Various auditing strategies have been proposed to detect inappropriate insider accesses in EHRs. Boxwala et al. introduced an approach to automate the process of detecting suspicious access to EHRs using statistical and supervised machine-learning techniques\textsuperscript{9}. In this technique, audit logs and data from EHRs were applied to construct features to learn predictive models and rank suspicious, as well as non-suspicious, accesses. Training data for such models were provided by HCO privacy officials. Recognizing that not all suspicious accesses are affiliated with a specific pattern, a variety of frameworks have been developed to detect anomalous accesses based on deviations from expected behavior\textsuperscript{14, 15}.

Still, all of these methods assume that all accesses should be considered for predictive purposes, which is potentially problematic because there is substantial class imbalance. Specifically, the rate at which inappropriate accesses actually transpire is likely to be orders of magnitude smaller than the rate at which appropriate accesses are committed. Thus, to mitigate skew in the prior probabilities for such statistical models, as well as manual audits, the notion of an explanation-based auditing system (EBAS) was proposed. EBAS works by filtering out accesses to the
EHR according to explanations generated automatically from the data by a mining algorithm\textsuperscript{16,18}. While all of these auditing strategies offer certain benefits over the simple rule-based auditing system, currently approaches based on the latter are in common use by HCOs.

**Methodology**

We hypothesize that a high-risk audit rule holds merit when the observed frequency at which it fires is higher than what would occur due to routine daily behavior. To test this hypothesis, we compare the observed frequency of high-risk accesses in a large EHR audit log with what one might expect to observe at random. We apply a goodness of fit test to determine if there is a significant difference between the observed and expected frequencies. We further examine the observed high-risk accesses flagged by each rule to determine the minimum rate in that these accesses can be explained with clinical reasons.

**Data overview**

The data investigated in this study is drawn from the VUMC EHR system. Table 1 depicts the data investigated in this study. These data are an integration of EHR audit log, employee personal information, patient personal information (e.g., names, dates of birth, and residential addresses) with information about the department for which the employee is affiliated (e.g., the Anesthesiology department).

<table>
<thead>

</tbody>
</table>

We designate an access as a **Self-access** when the employee has accessed his/her own record. We assume this occurs when the first name, last name and date of birth of the employee and patient in the access are the same. We designate an access as a **Repeat access** when the employee accesses the record of the same patient earlier in the week. All of the accesses except the first access are considered as **Repeat accesses**.

**Types of high-risk behavior**

While there are many types of high-risk behavior, we selected the following types for our experiments through background analysis. Specifically, we investigate five high-risk rules in this study:

1. **HCO Co-Worker**: The EHR user and patient are both employees of the VUMC.
2. **Department Co-Worker**: The EHR user and patient work in the same VUMC department.
3. **Last Name**: The EHR user and patient have the same last name.
4. **Geographic Proximity**: The EHR user lives within 0.25 miles of the patient.
5. **Residential Street**: The EHR user lives on the same street as the patient.

In addition, we added one rule to ascertain if the results of our experiments are merely an artifact of the data or if they are indicative of suspicious behavior:

6. **First Name**: The EHR user and patient have the same first name.

**Method overview**

In this section we provide an overview of the method to test our hypothesis and to determine the minimum rate of high-risk accesses explained with a clinical reason, as depicted in Figure 2.

The steps in this method are defined broadly as follows:

1. Determine the observed frequency of the high-risk accesses.
2. Determine the expected frequency of high-risk accesses by:
   2.1. Using simulations with random samples of users and patients.
   2.2. Using simulations with permutations of users and patients.
2.3. Using a theoretical formulation.

3. Compare the observed frequency of high-risk accesses to the expected frequency of high-risk accesses, and determine the significance of the deviation between the observed and expected frequency.

4. Use the explanation-based method to identify the observed high-risk accesses that can be explained with clinical reasons, and determine the minimum rate that observed high-risk accesses can be explained.

Figure 2. The steps to compute the observed and expected frequencies of high-risk accesses, and the minimum rates that high-risk accesses can be explained.

Figure 3 depicts the method to obtain the observed accesses by sampling the audit log and simulation of the expected accesses using permutation and random sampling methods. We explain these methods in detail in the following sections.
**Observed.** We obtain the observed frequency of high-risk accesses empirically from the set of unique employee-patient pairs \( L_{EP} \), where \( E \) is the list of employees (or users) and \( P \) is the list of patients in the employee-patient access pairs \( L_{EP} \). These pairs are obtained from the 710,000 unique accesses in the audit log and are devoid of any self-access. We select a random sample \( S \) of 100,000 pairs from \( L_{EP} \), each of which is assessed for the high-risk criteria. We count the occurrence of the high-risk accesses across the sample and calculate the frequency of the high-risk accesses in the sample as \(|\text{high-risk accesses}| / |S|\).

**Expected.** To simulate accesses and obtain an expected frequency distribution of high-risk behaviors we apply both permutation and random sampling methods. We use two distinct methods to confirm these simulation methods do not result in selection bias and that the sample selected by our methods are representative of the population. We compare the results of the simulations to verify if the results lead to the same conclusion.

**Expected: Permutation.** In this approach, we construct simulated accesses by shuffling the data points in \( S \). We use two types of permutation methods to simulate accesses and verify that results of both the methods lead to the same conclusion. 1) **Permute Patients:** This method shuffles the list of patients while holding the list of employees in sample \( S \) constant. 2) **Permute Employees:** This method shuffles the list of employees while fixing the list of patients in sample \( S \).

**Expected: Random Sampling.** We obtain the employee list \( E \) and the patient list \( P \) from the set of employee-patient pairs \( L_{EP} \). Next, we select a random sample of 100,000 employees \( S_E \) and 100,000 patients \( S_P \) (without replacement) from \( E \) and \( P \), respectively. We then construct simulated accesses by randomly matching the records in \( S_E \) and \( S_P \).

For each simulation, we calculate the frequency of high-risk accesses in sample \( S \).

**Expected: Theoretical Formulation.** The expected frequency of high-risk accesses is computed empirically, using the probabilities of high-risk accesses occurring among the employees and patients in sample \( S \). We determine the expected frequency for five of the six rules presented above.

The expected frequency of the high-risk accesses using probabilities is computed as \( \sum_{i=1}^{n} P_{E_i}P_{P_{t_i}} \), where, \( P_{E_i} = |\text{Employee with attribute value } x| / |S_E| \), \( P_{P_{t_i}} = |\text{Patient with attribute value } x| / |S_P| \), attributes: [last name, first name, residential street name, work department name] and \( S_E \) and \( S_P \) are the lists of employees and patients in \( S \), respectively.

---

**Figure 3.** An overview of the process for sampling the observed accesses and simulation of the expected accesses.
Experimental Evaluation. We run 10 experiments each for the randomization and permutation methods to compute the observed and expected frequencies of high-risk accesses. We compute the ratio of the mean observed frequency to mean expected frequency for each of the high-risk rules. We also compute the percentage of observed and expected high-risk accesses for each high-risk type to determine the rate of observed and expected high-risk accesses.

Minimum rate of high-risk accesses explained

While there are many operational and clinical reasons that can explain the reason for accesses in an EHR, we select primary treatment, payment and healthcare operations (TPO)\textsuperscript{17} to ascertain the extent to which high-risk accesses can be explained. We specifically focus on explanations in the form of 1) scheduled appointments, 2) ordered lab results, 3) ordered medications, 4) admission, discharge, and transfer events, and 5) clinical documentation. A high-risk access can have multiple explanations (e.g., patient had a scheduled appointment with the accessing employee, and patient also had a lab order with the accessing employee). We use the explanation-based approach to prioritize the observed high-risk accesses for further investigation by administrative officers, with unexplained accesses considered as high priority for the investigation. The explained accesses can be ranked using the type and number of explanations available for the access.

Since we do not exhaust the list of possible reasons, we compute the minimum rate at which high-risk accesses can be explained for each high-risk rule. Additional plausible explanations for the access exist (e.g., user performed surgery on the patient) and could be invoked to raise the rate.

Goodness of fit chi-square test

We apply a \( \chi^2 \) test to determine the goodness of fit between the observed (empirical) and expected (simulated) number of occurrences of high-risk accesses. This test is designed to ascertain if there is a significant difference, such that these deviations are likely not the result of chance alone. The measure of goodness of fit is \( \chi^2 = \sum_{i=1}^{n}(O_i - E_i)^2 / E_i \), where \( O_i \) and \( E_i \) are the observed and expected high-risk event frequencies of type \( i \), respectively.

We test this value against a \( \chi^2 \) distribution with 1 degree of freedom. This is because there are two categories: 1) High-risk accesses, 2) Non-high-risk accesses. We perform this test at the 0.01 significance level (i.e., we accept the alternative hypothesis when the value result is below this level).

Results

In this section, we summarize the deviation of the observed from the expected high-risk access rates obtained by four methods 1) Permute Patients, 2) Permute Employees, 3) Random Sampling and 4) Theoretical formulation, for each high-risk access rule. We begin by presenting the rate of observed and expected high-risk accesses. Next, we summarize the minimum explanation rate for the high-risk accesses. Finally, we report the statistical significance of the deviation between the observed and expected high-risk access rates.

Observed versus expected frequencies of high-risk access

Table 2 summarizes the observed to expected frequency ratios for the various high-risk access rules. It was found that the ratio of observed to expected frequencies varies from 0.99 to 4.33 for the high-risk behavior rules. The observed frequency of the high-risk accesses is higher than the expected frequency for all the high-risk rules except for the HCO Co-Worker rule, which is approximately 1 (at 0.99).

Table 2. Observed to expected frequency ratio for the high-risk access rules.
As expected, the ratio of observed to expected frequencies for the First Name high-risk class ranges from 1.12 to 1.17 for the four methods, suggesting there is no significant deviation between the observed and expected frequencies for this rule.

While the Geographic Proximity rule identifies if the patient and employee live within a fixed distance (0.25 miles), the Residential Street rule identifies if the patient and user live on the same street. Limiting the high-risk criteria to street name results in the higher ratio of observed to expected for the Residential Street rule than the ratio of observed to expected for Geographic Proximity rule.

Table 3 shows the percentage of observed and expected high-risk accesses for each high-risk type in a sample of 100,000 accesses. The average percentage of observed high-risk accesses ranged from 0.03% to 3.8%. Though the percentage of high-risk accesses for HCO Co-Worker is higher than other types (by more than 3%), the observed frequency of high-risk accesses does not deviate from the expected (see Table 2). This suggests that these accesses can be assigned the lowest priority for investigation. The percentage of observed and expected high-risk accesses for the rest of the high-risk rules is less than 1%, but given that millions of accesses are committed per week, this small percentage yields non-trivial numbers of high-risk accesses.

Table 3. The observed versus expected percentage for the high-risk access rules.

Minimum rate of high-risk access explained away

Table 4 summarizes the average rate (over 10 experiments) at which the observed high-risk accesses can be explained with clinical reasons. Notably, the selected set of explanations accounted for less than 50% of the accesses.

Table 4. The rate at which high-risk alerts would be explained away.

<table>
<thead>
<tr>

<td>16.11%</td>
<td>4.88</td>
</tr>
<tr>
<td>Department Co-Worker</td>
<td>43.90%</td>
<td>9.32</td>
</tr>
</tbody>
</table>

Table 5 summarizes the distribution of the explanations per high-risk rule. The highest number of high-risk accesses is explained with the Clinical documentation explanation for all high-risk rules, with the percentage of accesses explained in the range of 15% to 43%. Scheduled Appointment explains 2% to 8% of the high-risk accesses. The other four explanations explain less than 5% of the high-risk accesses for all high-risk rules. The Clinical Documentation explanation shows high standard deviation (9.26) for the high-risk rule Department Co-Worker because of two outlier experiments with the highest and lowest number of explained accesses, respectively.

Hypothesis test

Table 6 shows the $\chi^2$ result for a sample $S$ of 100,000 unique accesses that are devoid of self-accesses. The expected number of accesses for this experiment was simulated through the permutation method (i.e., shuffling the list of patients and keeping list of employee fixed in the observed accesses). It should be noted that we did not include the Co-Worker rule in the $\chi^2$ test because the results showed that there was no difference between the observed and expected accesses for this high-risk class.
The result of the $\chi^2$ for high-risk rules Last Name, Geographic Proximity, Residential Street and Department Co-Worker indicated a probability < 0.0001. This is below the 0.01 significance level, such that we accept the alternative hypothesis for these high-risk rules (i.e., the difference between the observed and expected frequency of high-risk accesses for these rules is statistically significant). The result of the $\chi^2$ for First Name indicated a probability of 0.0113, which is above the 0.01 significance level, such that we reject the alternative hypothesis (i.e., there is no significant difference between observed and expected frequencies of high-risk accesses). This is notable because it suggests that our control rule is functioning correctly.

### Discussion

This study examined the extent to which high-risk EHR access rules are plausible in practice. Our empirical investigation illustrates that the observed rate at which high-risk rules are triggered is higher, at a statistically significant level, than what one would expect at random for several typical classes of high-risk behavior. This significant deviation suggests that there may be systematic EHR user behavior that requires further investigation, implying those rules may hold merit. Still, not all rules deviate to the same degree. In this respect, we further believe that the magnitude of the deviation of the observed frequency of high-risk accesses from their expected frequency obtained from each high-risk class may be a plausible measure to assist in the prioritization of auditing rules in emerging game theoretic frameworks.18
Geographical Proximity and Residential Street rules are designed to capture the same high-risk behavior (i.e. a user accessing records of a patient living in close geographic vicinity of the user). However, these two rules yield different results in terms of number of accesses flagged and the deviation of observed frequency from expected frequency of flagged accesses. Notably, the user and patient in 15% of the accesses flagged by the Residential Street rule do not live within 0.25 miles of each other, and the Geographical Proximity rule missed 37% of the Residential Street rule accesses. Also the length of the streets in the city varies from 0.4 miles to over 10 miles leading to a non-uniform application of the geographic vicinity criteria. This result indicates that rule definitions play an important role in effectively capturing high-risk behavior.

Despite their potential, high-risk access rules often have a high false positive rate. This makes them prohibitively expensive for HCOs to systematically investigate, which is a concern given the limited budgets available to privacy officers. However, we show that high-risk access rules can be complemented through an explanation-based model, such that many accesses can be explained away by valid TPO reasons (16% to 44% depending on the high-risk rule at minimum). We believe this is notable because it suggests that high-risk rules and explanations are not correlated. Nonetheless, we believe that, in this setting, the explanations can be used to prioritize high-risk accesses for manual investigation. The unexplained accesses can be considered high priority for investigation, while the explained accesses can be ranked using the type and number of explanations available for the access.

There are, however, several limitations of this study that we wish to highlight for future investigations. First, it should be recognized that a rule-based auditing system is inherently limited by its reliance on predefined rules, which themselves are often based on domain expertise. More broadly there are many possible reasons for inappropriate access. As a result, the access coverage (i.e., proportion of accesses effectively monitored by high-risk rules) is low. Second, rule-based flagging of high-risk accesses is dependent on the correctness and completeness of EHR data. Incorrect EHR data (e.g., the wrong patient’s last name is entered into the EHR system) leads to gaps in identifying a potential high-risk access. Similarly, an incomplete address or a P.O. Box would lead to gaps in flagging a potentially high-risk access according to the Residential Proximity or Residential Street rule. Third, an explanation-based system relies solely on the data stored in the database to generate explanation for an access. Missing information (or non-documented relationships) may result in few unexplained appropriate accesses. For example, EHR systems maintain records of patient appointments with doctors, but they do not explicitly record the relationship between the doctor and the nurse working together at the appointment. Thus, the system cannot readily explain the access of patient’s record by the nurse working with the doctor, though the access in this case is appropriate. Other research has posited enhancing explanations with additional data learned from diagnosis information. Fourth, this study does not test if a flagged access is in fact an inappropriate access. A flagged access needs to be investigated manually by a privacy officer to determine if it is a true inappropriate access. However, this manual investigation is beyond the scope of this study. Fifth, in this study we only consider simple high-risk rules. In a future investigation we plan to study more complex and nested high-risk rules. Sixth, this study suggests that different high-risk rules yield different results, but does not investigate the reasons for the differences.

Finally, we note that this investigation focused on data from only a one-week period from a single medical center. As such, it will be necessary to validate these findings with data from a broader time period and other healthcare organizations.

**Conclusions**

This paper examined the rate of high-risk access rules in the electronic health record of a large healthcare organization. Specifically, we compared the observed and expected rates to ascertain the extent to which such rules are potentially useful in practice. The primary finding of this investigation was that such rules appear to detect behaviors that are statistically significantly different than what would transpire under random activities. There are many reasons why such deviation might transpire, but our investigation shows that such rules should not be dismissed.

Mining Electronic Health Records to Extract Patient-Centered Outcomes Following Prostate Cancer Treatment

Tina Hernandez-Boussard, PhD, Panagiotis D. Kourdis, PhD, Tina Seto, MS, Michelle Ferrari, RN, Douglas W. Blayney, MD, Daniel Rubin, MD, James D. Brooks, MD
Stanford University, School of Medicine, Stanford, CA

Abstract

The clinical, granular data in electronic health record (EHR) systems provide opportunities to improve patient care using informatics retrieval methods. However, it is well known that many methodological obstacles exist in accessing data within EHRs. In particular, clinical notes routinely stored in EHR are composed from narrative, highly unstructured and heterogeneous biomedical text. This inherent complexity hinders the ability to perform automated large-scale medical knowledge extraction tasks without the use of computational linguistics methods. The aim of this work was to develop and validate a Natural Language Processing (NLP) pipeline to detect important patient-centered outcomes (PCOs) as interpreted and documented by clinicians in their dictated notes for male patients receiving treatment for localized prostate cancer at an academic medical center.

Introduction

Prostate cancer is the most common malignancy in men with an estimated 21% prevalence among new cancer cases in males for 2016.(1) Given the excellent survival rates, patients undergoing clinical treatment for prostate cancer often focus on patient-centered outcomes of care to guide treatment choices, such as rates of urinary incontinence (UI) or irritative voiding symptoms and erectile/sexual dysfunction (ED).(2, 3) However, the measurement of these outcomes at a population level has been hindered due to the lack of availability of these outcomes in generalizable, large-scale study cohorts.

Under the US healthcare reform, there is increased focus on quality of health care delivery.(4) Increasingly, standardized quality metrics have been developed and proposed to measure key components of care across the full continuum of care delivery, including patient-centered outcomes.(5) Benchmarking and reporting such quality metrics from multiple health care providers offers a unique opportunity to improve clinical practice and ensure that patients are receiving high-quality care and treatment options that correspond to their personal values.

Granular clinical information important for quality assessment is routinely collected within electronic health records (EHRs).(6) Due to their significant recent adoption,(7) healthcare workers have identified remarkable benefits and significant challenges in using these data to approach a learning health-care system.(8) Particularly challenging is the fact that most information in EHRs is stored as unstructured free text.(9) However, many quality measures, including patient-centered outcomes, are captured in EHRs only as free text.(10)

We have designed and developed the infrastructure that can leverage routinely collected information from EHRs to efficiently and accurately assess clinicians’ documentation of important patient-centered outcomes following treatment for prostate cancer. Using urinary incontinence and erectile dysfunction as the example, we developed a Natural Language Processing (NLP) pipeline using the Java-based open source software GATE (General Architecture for Text Engineering) to parse strings containing clinical notes stored in the EHRs. This work incorporated electronic phenotypes for each PCOs that can improve its generalizability across systems.

Methods

Data Source

Our pipeline identified patients within a large academic EHR-system using ICD-9/10 and CPT codes. The healthcare system provides inpatient, outpatient and primary care services and has a fully functional Epic system installed since 2008. (Epic Systems Corporation, Verona Wisconsin) To improve cohort identification and validation, the EHR records were linked to the state California Cancer Registry, which includes detailed information on patients’ histology, pathology, disease progression and survival, as well as treatments received outside of our academic health care system. An Oracle relational database was internally deployed to organize the internal and external structured and unstructured data elements. The patient cohort includes demographics, healthcare encounters, diagnoses/problem lists, clinical reports (narratives & impressions), encounter notes/documents, lab &
diagnostics results, medications (down to the ingredient level), treatment plans, procedures, billing summaries, patient history, patient surveys, and follow-up/survival information. To develop vocabularies related to urinary incontinence, irritative voiding symptoms and erectile dysfunction, a minimum of 100 charts selected at random were reviewed and terminology extracted. We performed manual chart review to estimate the positive and negative predicted values of the workflow. We will randomly select 200 records. A urology research nurse manually validated these reports to create a gold standard.

**Patient-Centered Outcome Phenotypes**

Phenotypic algorithms were developed for identifying and extracting both cases and controls of UI and ED assessment from EHRs. Input categories include ICD-9/ICD-10 codes, billing codes, medications and vocabularies matched with existing ontologies from the National Center for Biomedical Ontology (NCBO) and Unified Medical Language System (UMLS) concepts.(11) To improve accuracy, vocabularies were also manually curated with EHR terms found during manual chart review. The phenotypes of each of the three PCOs are available through the publicly accessible repository PheKB (https://phekb.org) a knowledgebase for EHR-based phenotypes.(12)

**NLP Extraction of PCOs**

Our NLP pipeline analyzes the clinical narrative text of EHRs using GATE software.(13) GATE provides several customizable processing resources that perform specific NLP processing tasks, i.e. tokenizers, sentence splitters, gazetteers which annotate documents based on look-up lists of keywords, parsers etc. Below, we describe the building components of our GATE-based NLP application for extracting PCOs from clinical notes, which comprises (1) an ANNIE module to detect PCO mentions in narrative texts, (2) a ConText module to determine the semantic context of the PCO mentions, and (3) A JAPE module to annotate the PCO mentions in the text.

We first used the English tokeniser from GATE's ANNIE plugin component that splits the text into simple constituent tokens such as numbers, punctuation and words of different types. Next, sentence splitting was performed using the RegEx sentence splitter, which is suitable when faced with irregular inputs, such as those regularly encountered in the contents of EHR clinical notes.

Following tokenization and sentence splitting, a Hash Gazetteer (part of the ANNI E) was run on the clinical note to find occurrences of PCO mentions. We developed three types of Gazetteer list files containing the various PCO-related keywords in text that indicate PCO mentions. In addition to detecting the PCO mentions, our pipeline detects the context of the PCO mention using the ConText algorithm.(14) The ConText algorithm determined whether the PCO mentioned in the clinical report was negated, hypothetical, historical, or experienced by someone other than the patient. PCO mentions were Type I if the ConText algorithm did not negate the term but the text indicated a negated PCO. PCO mentions were Type II if the ConText algorithm did not negate the term, but the text indicated an “affirmed” PCO. Finally, PCO mentions were Type III if the ConText algorithm negated them and the text indicated a negated PCO. (Table 1)

PCOs were classified as follows: “Affirmed”, meaning the patient had the symptom; “Negated”, the patient did not have the symptom; or “Discussed Risk”, the clinician documented the discussion regarding risks of PCOs by treatment with the patient.

<table>
<thead>
<tr>

<td>Affirmed</td>
<td>No</td>
</tr>
<tr>
<td>III</td>
<td>No urinary incontinence</td>
<td>No urinary complaints.</td>
<td>Negative</td>
<td>Yes</td>
</tr>
</tbody>
</table>

A gazetteer list file was also used to include keywords related to discussion of post-operative risk. When PCO terms appear with these terms in a sentence, the corresponding sentence is considered as a discussion of post-operative risk with the patient, rather than a PCO per se. Additionally, a Gazetteer list is used to exclude terms that are used in an alternative context (e.g. the term leakage related to urinary incontinence vs. leakage around the foley catheter). Finally, the regular expression pattern-matching engine called Java Annotation Patterns Engine (JAPE) was used to
create annotations in the text of the clinical notes based on the patterns in the text detected by the Gazetteer files and ConText algorithm.

**Evaluation**

The gold standard was used to evaluate our pipeline. The 200 records in the gold standard were processed and recorded all mentions of PCOs and classified each according to the annotation value. These data were compared with the annotations in the gold standard and precision and recall metrics were calculated. The university’s Internal Review Board approved the study.

**Results**

We identified 7,109 male individuals who received treatment for prostate cancer from 2008 to 2016 from a single, large, academic medical center. Patients’ demographics are displayed in Table 2. Patients had a mean age at time of diagnosis of 65.1 (SD 8.9). The majority of patients had localized disease, with 65% Stage II and 83% with a Gleason \(\leq 7\).

Table 3 demonstrates the number of PCOs extracted from the different types of clinical notes, either history & physical or progress. The majority of PCO information extracted from the NLP pipeline came from the progress notes for both urinary incontinence and erectile dysfunction as compared to the information found in the history & physical note set.

The patient-level assessments for the two PCOs in the EHR notes for urinary incontinence and erectile dysfunction within our study cohort are displayed in Table 4. The results indicate that ED was assessed in 77.5% of the patients while UI in 59.4% prior to the primary treatment and 29% and 33% immediately following treatment.

**Table 4. Rates Of PCO Assessment Pre- And Post-Treatment, Stratified By Affirmed And Negated Mentions**

We estimated that patients had a pre-treatment rate of UI to be 16%, with varying severity and pre-treatment rate of 30% for ED (Figure 1). The rates for UI remained at approximately 40-50% 1-2 years after surgery and the rates for ED were between 45-70% following treatment.
The F-measure accuracy scores for the UI annotations against an unseen gold standard manually annotated by our board-certified Urology nurse was 87% affirmed, 96% negated, and 91% discuss risk. For the ED annotations the F-measure was 85%, 92%, and 90%, respectively. (Table 5)

Discussion

Under healthcare reform, stakeholders emphasize the importance of quality and patient-centered healthcare. Accordingly, government officials seek quality metrics that include meaningful outcomes, including those that go beyond mortality and recurrence. However, efforts to establish guidelines for prostate cancer treatment have been difficult to formulate due to insufficient evidence regarding relative benefits and risks of the different treatment options, particularly important patient-centered outcomes such as urinary and erectile dysfunction.(2, 15) Here we found clinicians regularly recorded this information in the unstructured text of EHRs. The current work expands on existing models by focusing on ontology-based dictionaries to annotate free text associated with patient-centered outcomes. We have demonstrated our ability to efficiently and accurately use our methods on EHRs for quality assessment of patient-centered outcomes.

The rates of urinary incontinence and erectile dysfunction identified through our pipeline were highly concordant with rates from surveys that are reported in the literature.(16-18) This highlights the ability of NLP algorithms to leverage routinely collected information from EHRs and efficiently and accurately assess clinicians’ documentation.
of patient-centered outcomes. Our study suggests that patient-centered outcomes, particularly for prostate cancer patients, are important and monitored not only for the patient but also for the clinician. Given the lack of population-based information on these important outcomes, NLP tools can clearly advance research and evidence in this area.

Our NLP pipeline shows promising results for the task of advancing patient-centered outcomes research (PCOR). To date, most quality metric analyses have used administrative datasets. While these datasets are easy to use and readily available, they are generated for billing purposes and lack important clinical details. Paper records may have more detail, but cannot be algorithmically assessed. Prospective studies are not readily available and often contain ascertainment bias. These issues have limited the efficiency and effectiveness of efforts for quality improvement, organizational learning, and comparative effectiveness research, particularly in the area of PCOR. Using our NLP pipeline, we can obtain population rates on PCOs efficiently and with high certainty. Such work can significantly advance the field and depth of PCOR.

There are limitations to our study. First, our algorithms have been developed and tested in a single academic center. However, the clinical terms used in our algorithms are disseminated with a national repository (pheKB.org) and multiple clinicians across different healthcare settings have vetted the clinical terms. We will be testing our algorithms in another healthcare system to ensure their generalizability. A second limitation is that our system only reports what the clinician documents and does not capture patient-reported outcomes. Many studies have highlighted that clinicians’ documentation can be sparse and incomplete. However, our previous work indicated that these patient-centered outcomes are more prevalent in the clinical text than elsewhere in the EHRs. Finally, our algorithms have been developed using American English and vocabularies and language rules would need to be developed for usage where another language is used in the EHR.

A significant benefit of our NLP pipeline is that it leverages multiple sources of data to identify patients and outcomes, including registry data, quality of life surveys, and other information from clinical trials within our institute. Our dataset is updated regularly and it will likely continue to perform well, including the assessment of these outcomes immediately after the introduction of new treatments and technologies.

Conclusions

We developed an NLP pipeline for detecting clinical mentions of patient-centered outcomes in prostate cancer patients. The current performance of the system appears sufficient to be used for population-based health management and to enhance evidence needed to help patients identify treatment pathways that reflect their healthcare values. Given the importance of these events under the healthcare reform, wide deployment of fully computerized algorithms that can reliably capture PCOs will have numerous applications for the healthcare industry. These approaches are the basis of a learning healthcare system and target in fostering healthcare quality through information technology and data resource utilization.

Abstract

There is growing interest in applying machine learning methods to Electronic Medical Records (EMR). Across different institutions, however, EMR quality can vary widely. This work investigated the impact of this disparity on the performance of three advanced machine learning algorithms: logistic regression, multilayer perceptron, and recurrent neural network. The EMR disparity was emulated using different permutations of the EMR collected at Children's Hospital Los Angeles (CHLA) Pediatric Intensive Care Unit (PICU) and Cardiothoracic Intensive Care Unit (CTICU). The algorithms were trained using patients from the PICU to predict in-ICU mortality for patients on a held out set of PICU and CTICU patients. The disparate patient populations between the PICU and CTICU provide an estimate of generalization errors across different ICUs. We quantified and evaluated the generalization of these algorithms on varying EMR size, input types, and fidelity of data.

Introduction

Electronic Medical Records (EMR) are currently adopted by approximately 84% of hospitals in the United States\(^1\). With the recent success of machine learning, there are numerous research efforts to extract medically relevant and actionable information from troves of EMR using machine learning algorithms\(^2\). However, due to varying data entry protocols and bespoke implementations of EMR systems, data quality can vary widely across institutions\(^3\). This work investigated the dependence of advanced machine learning algorithms on the varying EMR quality.

EMR data discrepancies were emulated using permutations of EMR collected from Children’s Hospital Los Angeles (CHLA) Pediatric Intensive Care Unit (PICU) and Cardiothoracic Intensive Care Unit (CTICU). Permutations studied included varying the number of patient encounters available for training; which variables were included and excluded as model inputs; and varying the fidelity of drug information. The effects of the permutations were analyzed on established machine learning algorithms: logistic regression, multilayer perceptron, and recurrent neural network. The analysis of these algorithms illustrate the impact of data quality on varying levels of model complexity.

The task used to evaluate these algorithms was prediction of in-ICU mortality: whether the patient survived their ICU encounter. Mortality was chosen because it provides an objective measure of a model’s ability to extract information from EMR\(^4\). Predictions were generated for each algorithm after 12 hours of observation and used to create Area Under the Receiver Operating Curves (AUROC).

EMR Source

This study used anonymized EMR collected in the Pediatric Intensive Care Unit (PICU) and Cardiothoracic Intensive Care Unit (CTICU) at Children’s Hospital Los Angeles (CHLA) between 2002 and 2016. The database contained 21,881 ICU encounters (defined as the time between a patient’s admission to and discharge from the ICU). Of these ICU encounters, 16,706 were from the PICU (12,093 patients with 4.85% mortality) and 5,175 were from the CTICU (3,088 patients with 3.32% mortality). Each encounter contained irregularly charted measurements of the patient’s physiology (e.g. heart rate, respiratory rate), laboratory test results (e.g. glucose, creatinine), and treatments (e.g. intubation, epinephrine) administered throughout their ICU stay. Additionally, each encounter was accompanied by static information describing demographics (e.g. age, sex, and race), diagnosis, and disposition at the end of the ICU encounter (whether they survived).

Pre-Processing EMR for Machine Learning

The collected EMR was a list of observations and treatments (in long format) charted by the clinical team, time-stamped and uniquely identified to each patient. The following sub-sections describe pre-processing techniques that restructured the EMR for machine learning purposes.
Data Curation: In collaboration with physicians, the dataset was curated to remove erroneous observations and aggregate variables of similar groups. For example, minimum and maximum values were defined for each observation such that measurements which were incompatible with life (e.g. heart rate of 1200 beats per minute) were corrected. Additionally, different observations of similar variables such as invasive and non-invasive blood pressures were combined into a single variable when medically appropriate.

Data Pivot: To accommodate the structure required for machine learning algorithms, the long format EMR was pivoted to wide format. In other words, the EMR was reshaped such that the timestamps were the rows, observations were the columns, and values populated the cells. The result was a sparse, irregularly sampled matrix for each patient, henceforth referred to as a patient-matrix. Figure 1 illustrates an example of this process.

Data Standardization: Data standardization was applied to facilitate training of the machine learning models while maintaining medical interpretability of the variables. Physiologic observations (labs and vitals) were converted to z-scores using the means and standard deviations computed from the training set (described later). This process was done to provide numerical stability when training the models (via stochastic gradient descent). Treatments administered to the patients such as drugs and interventions were normalized to values between [0, 1] using upper limits defined in collaboration with clinicians. Values of 0 indicated the presence of no drugs while values between (0, 1) indicated percentage of dosage from the maximum dose in the training data.

Data Imputation: To control the scope of this study, the imputation method was kept simple to align with the data standardization methods and maintain medical interpretability. Physiologic observations were forward-filled following an initial measurement until the next available measurement. This choice was based on the clinical insight that measurements are more frequently taken during times of hemodynamic instability and less frequently when the patient appears stable. If a physiologic variable had no recorded measurements for an entire encounter, that variable was set to zero. Because of the prior standardization of physiologic variables, this imputation was equivalent to imputing the population mean derived from the training set. For drugs and interventions, missing values were imputed with zero. Since these variables were normalized to [0, 1], a zero entry indicated the absence of treatment. Figure 2 depicts the imputation process.

Figure 1: Illustration of pivot operation (and curation) applied to long format EMR to create a patient-matrix. Note that for a particular patient, a column of the pivoted data may have a blank entry in each row as in PEEP above.

Figure 2: Illustration of imputing a patient-matrix. Data standardization is not applied here to show realistic values.
Table 1: Percentage of demographic groups across the datasets. The numbers in parenthesis are the number of encounters of each dataset.

Train, Validation, Test Partitioning: The data were partitioned into train, validation, and test sets with the demographics summarized in Table 1. The training set consisted of 50% percent of the PICU patients (8,404 encounters, 4.66% mortality), selected at random. Half of the remaining PICU patients (4,122 encounters, 4.97% mortality) constituted the validation set used to tune the algorithm’s hyper-parameters. Model performance was evaluated on two test sets: the last 25% of the patients from the PICU (4,176 encounters, 5.12% mortality); and all of the patients in the CTICU (5,175 encounters, 3.32% mortality). These test sets were not used during any model training and development. Since the CTICU specializes in congenital heart defects and generally treat younger populations than the PICU (see age group distributions in Table 1), the CTICU was used as a surrogate to represent an institution with disparate patient population and treatments. Scores on the PICU test set show the algorithms’ generalization to similar ICUs while scores on the CTICU test set estimate performance across different ICUs.

Data Permutations

Permutations of CHLA EMR were generated to emulate the data disparity found across different EMR systems. The following subsections describe three types of permutations: training set fraction (varying data size), input types (varying input variables), and drug encoding (varying data fidelity).

Training Set Fraction: A common concern with applying machine learning techniques such as neural networks is the amount of data required for training the models to perform well.6,7 This question is particularly relevant because the number of patient records can vary widely across hospitals. Two primary factors contribute to the disparity: 1) the size of the institution (number of critical care beds available) and; 2) the institution’s date of EMR adoption. To assess the dependence of algorithm performance on training data size, the algorithms were trained on successively decreasing sizes – 100, 90, 75, 50, 25, 10% – of the full training dataset described earlier. The resulting model from each of these trainings was then evaluated on the same complete PICU and CTICU test sets. The validation set remained fixed.

Input Types: The medical community has had many discussions on the validity of incorporating treatments and interventions into patient acuity scores.8,9 Since treatments typically are not applied randomly, their application is informative of patient state. However, the ‘insight’ or value of such information is complicated by non-standard practices across clinicians when administering treatments.10 Conversely, the same physiologic measurement can have different interpretations that depend on the treatments being received. For instance a heart rate may appear normal in isolation, but the same heart rate in the presence of vasopressors may indicate a higher risk of mortality. This permutation study parses the dependence of the algorithms on internal and external inputs. Internal refers to the observations describing
the patient’s status (labs and vitals) and external refers to the inputs that describe the treatments given to the patient (drugs and interventions). Figure 3a illustrates the splitting of the inputs from baseline (combined) to internal and external inputs.

**Drug Encoding:** The fidelity of the captured information may vary from institution to institution. For instance, data may be limited and contain only an indication of whether or not a particular drug was administered, but not its exact quantity. Moreover, treatment protocols vary from institution to institution. For example, one institution may preferentially provide albumin infusions while another may favor saline for fluid therapy. This permutation experiment emulates the variance in data fidelity using two drug encoding schemes: 1) decimating drug values to binary indicators; and 2) indexing the drugs based on biomedical ontologies by encoding them to the National Library of Medicine’s Medical Subject Headings (MeSH). Figure 3b illustrates the baseline input’s encoding to these two schemes.

**Figure 3:** The complete patient-matrix contains information about the patient’s internals (vitals, labs) and externals (drug administrations and interventions). a) Illustrates parsing of internals and externals from the complete patient-matrix. b) Shows the encoding of the drug subset in patient-matrix to the two permutation schemes: binary drug indicator and MeSH.

**Methods**

Three representation learning algorithms were assessed: logistic regression (LR), multilayer perceptron (MLP), and recurrent neural network (RNN). These algorithms were chosen because they illustrate the effects of data quality as a function of model complexity and have shown success in a variety of medical applications. The LR and MLP have been used in detection of prostate cancer, detection of Acute Respiratory Distress Syndrome (ARDS), and estimation of childhood asthma risk. The RNN has recently shown success in medical tasks such as predicting critical decompensation of patients on the floor, early detection of heart failure, and predicting ICU mortality. The following sub-sections describe more specifically the variant of each algorithm used. Figure 4 shows the architecture of the three models.

**Logistic Regression:** The logistic regression is one of the simplest machine learning models. It assumes that the input \((x)\) and output data \((y)\) are related by the mapping \(y = \sigma(W \cdot x)\), where \(\sigma(x) = 1 / (1 + e^{-x})\). The matrix of weights, \(W\), is learned from the data. For our task, the input to the LR is the pre-processed EMR derived patient-matrix, and the output is the patient’s mortality response, i.e. disposition (alive or not) at the end of ICU encounter. Although the input is a patient-matrix, the LR operates on individual time-slices (a vector) of the patient matrices.

**Multilayer Perceptron:** The MLP, also called a feed forward neural network, is a classic deep learning method which models the mapping from inputs to output with \(y = f^* (x)\), where \(f^*\) is a series of different functions called layers. The construction is loosely inspired by biological neural networks. Each node (hidden unit) in a layer is associated with a weight, \(w_{i,j}\), that connects to every node in the subsequent layer, analogous to the communication between neurons. The MLP architecture used here consisted of a 2-layer MLP, each with hidden units of 256 (chosen through grid search of validation performance). Note that the MLP also operates on time-slices of the patient matrix, and that the LR described above is equivalent to a 0-layer MLP when trained similarly using stochastic gradient descent.
Figure 4: Model architectures for a) logistic regression, b) multilayer perceptron, and c) recurrent neural network. Each model is composed of layers that operate on the patient’s input sequences (multi-colored vectors) to predict the patient’s in-ICU mortality. The numbers in each layer (purple dense layer and blue LSTM layer) are the number of hidden units of that layer.

Recurrent Neural Network: The RNN refers to the family of neural networks specialized for processing sequential data\textsuperscript{18,19}. The RNN can be regarded as an extension of the MLP that contains connections which feed each layer’s outputs back into itself. This recurrent structure makes RNNs ideal for processing EMR because the hidden states and feedback loop can elegantly integrate and incorporate past information about the patient with newly acquired measurements\textsuperscript{17}. This characteristic also makes it a fitting choice for modeling the dynamic disease progression encountered in a critical care setting. The particular RNN variant used is the Long Short Term Memory (LSTM)\textsuperscript{20}. The model is composed of a 2-layer LSTM, each with 397 hidden units (equal to the number of variables in the input patient-matrices). The output layer is a dense layer applied to every time-step of the output from the previous LSTM layer. Although the RNN ingests only a single time-slice (vector) from the patient matrix at each time step, its feedback loop effectively gives the RNN a look into the previous time-slices also. This is a contrast to the LR and MLP.

The above three models were trained using mini-batch sizes of 128 and optimized using RMSprop\textsuperscript{21}, a gradient descent optimizer that utilizes an adaptive learning rate, to minimize the binary cross-entropy between the model’s predicted in-ICU probability and the patient’s true mortality response. Each model’s layers were initialized using Glorot uniform, a method that samples weights from a uniform distribution with the variance scaled based on the number of parameters of the preceding and subsequent layers. After every epoch of training (an epoch is defined as one cycle through the training set), the models predicted the in-ICU mortality for patients in the validation set and the binary cross-entropy was computed. If the binary cross-entropy did not decrease after 15 epochs, the model’s learning rates were decimated by 5. After 2 reductions, training is stopped and the weights associated with the best validation performance are used to predict the mortality of the patients in the two test sets. During training, dropout of 20\% was applied to the input sequences (across time) as a data augmentation parameter.
Results

Model training for each data permutation study was iterated five times, with each iteration corresponding to a different initialization point (for the model weights) and different validation stopping point. The resulting model from each iteration was then applied to the PICU and CTICU test sets, and the Area Under the Receiver Operating Curve (AUROC) was generated from the model's in-ICU mortality prediction after 12 hours of observation. The numbers reported in Tables 2–4 are the mean and standard deviations of the AUROCs from these iterations. Baseline (BL) refers to the processed-EMR containing all available training encounters and input variables. Baseline is the same across the different EMR permutation studies and occupies the first row of Tables 2–4 while being named accordingly (100%, Combined, NoEncoding).

Table 2 shows the performance of each algorithm as a function of the number of patients in the training set. Table 3 shows the performance when limiting the model inputs to either only internal (physiologic observations) or only external (treatments) variables. Table 4 shows the performance as a function of drug encoding strategy. Figure 5 offers a visual summary of Tables 2–4. As a point of reference, AUROCs were also computed from the predictions of two standard pediatric severity of illness scoring systems, PIM2 and PRISM3. PIM2’s AUROCs on the PICU and CTICU test sets were 0.868 and 0.774, while those of PRISM3-12 were 0.856 and 0.723, respectively.

Discussion

A large performance disparity was observed between the PICU and CTICU test sets across all data permutations and algorithms. The performance on CTICU data was approximately 10% lower than on the PICU data. This is not surprising since the models were trained on PICU encounters only, and the CTICU patient population and treatments can be very different from those in the PICU. On the PICU test set, the RNN models substantially and consistently outperformed their LR and MLP counterparts across the different permutation experiments, with the lone exception coming from the experiment using only 10% (840 encounters) of the training data for model development. On the CTICU test set, the MLP models consistently outperformed their RNN and LR counterparts; the lone exception was again observed in the 10% of training data experiment, where RNN outperformed MLP. The results indicate that...
the MLP learned more generalizable patterns than the RNN, despite the latter’s more advanced sequence-processing capabilities. The MLP proved more robust, relative to the RNN, in transferring across disparate ICUs. The RNN’s large number of parameters (∼15 times more trainable parameters) may have led to overfitting to the PICU data.

Table 2 and Figure 5a illustrate reduction in each model’s performance on both PICU and CTICU as the amount of training data was reduced. When trained using only 840 encounters (training fraction of 10%), the models perform reasonably well on the ∼4000 encounters in the PICU and CTICU test sets, with the weakest performing model (LR) scoring 0.867 and 0.773 on the PICU and CTICU, respectively.

Table 3 and Figure 5b show little performance degradation when external information was removed from the baseline inputs. This indicates that internal information contributed almost entirely to the each model’s prediction of the patient’s severity of illness. Although externals alone performed significantly lower than internals and baseline, the performance increase from internals to baseline indicates that the models extracted additional information from the external variables.

The results in Table 4 and Figure 5c show that model performance, regardless of algorithm, remained about the same when changing drug information from real-valued to binary indicators (absent or present). This similar performance may be due to standard quantities and protocols frequently being followed during drug administration. Consequently, knowledge of a clinical decision to apply a particular drug, regardless of its numerical value, may be sufficient to understanding the patient’s severity of illness.

Table 4 and Figure 5c further show that on the PICU set, the models using baseline drug encoding performed similarly to models using MeSH-encoded drug information. On the CTICU set, however, the degradation of RNN performance from its baseline model to the one using MeSH was 5%. The RNN’s significantly worse degradation on the CTICU (compared to slight degradation on the PICU test set) was also observed in the baseline-to-externals experiment (Table 2 and Figure 5b). This pattern may be due to the RNN overfitting the information gleaned from external variables. The LR and MLP models process a time-slice in isolation of the other time-slices in a patient-matrix, but the RNN builds a history of the applied treatments. This sequential processing of data likely made the RNN learn to weigh external information more. Since the CTICU contained a more disparate distribution in treatments, over-utilizing the
information learned from the PICU may have improved its performance on the PICU but hindered its generalization to the CTICU.

Conclusions

This work measured the effects of varying EMR quality on the performance of three advanced machine learning algorithms: logistic regression, multilayer perceptron, and recurrent neural network. Three sets of permutations of CHLA EMR were generated to emulate the EMR data disparity across institutions. The first measures the performance of the models as a function of training data size. The second measures the dependence of the models on varying input types. The third measures the effects of varying fidelity in drug data. The algorithms were analyzed by measuring their performance in predicting in-ICU mortality in two different ICUs.

Performance of all three models degraded with decreasing size of the training set. Even when trained on 10% of the available encounters (840), all models still performed comparably with two standard pediatric severity of illness scores, PIM2 and PRISM3-12. Additionally, the MLP generalized better than the RNN when they were trained on PICU but tested on CTICU data.

Future work includes measuring the effects of the machine learning models on other varying types of EMR. For example, measuring the difference in performance due to varying temporal fidelity by incorporating waveform measurements from bedside monitors. Moreover, the analysis can be further strengthened by analyzing the performance on other clinically relevant tasks such as predicting ICU readmission.

Abstract

Models have been developed to predict stroke outcomes (e.g., mortality) in attempt to provide better guidance for stroke treatment. However, there is little work in developing classification models for the problem of unknown time-since-stroke (TSS), which determines a patient’s treatment eligibility based on a clinical defined cutoff time point (i.e., <4.5hrs). In this paper, we construct and compare machine learning methods to classify TSS<4.5hrs using magnetic resonance (MR) imaging features. We also propose a deep learning model to extract hidden representations from the MR perfusion-weighted images and demonstrate classification improvement by incorporating these additional imaging features. Finally, we discuss a strategy to visualize the learned features from the proposed deep learning model. The cross-validation results show that our best classifier achieved an area under the curve of 0.68, which improves significantly over current clinical methods (0.58), demonstrating the potential benefit of using advanced machine learning methods in TSS classification.

1 Introduction

Stroke is the primary cause of long-term disability and the fifth leading cause of death in the United States, with approximately 795,000 Americans experiencing a new or recurrent stroke each year [1]. Several treatments exist for stroke, including intravenous and intra-arterial tissue plasminogen activator (IV/IA tPA), and mechanical thrombectomy (clot retrieval). Guidelines support selecting tPA treatment administration only within a maximum of 4.5 hours from stroke symptom onset due to the increased risk of hemorrhage for longer times since stroke (TSS). However, about 30% of the population have unknown time since stroke (TSS), making these patients ineligible for treatment with tPA despite the fact that their strokes may have actually occurred within the treatment window [2].

Predictive models have been made in attempt to predict stroke patient outcomes (e.g., mortality) using clinical variables (e.g., age) and imaging features (e.g., lesion volume) [3–5]. Additional algorithms are under development that attempt to predict patient response to a specific treatment [6]. While much work has been done in predicting stroke patient outcome and treatment response, there is limited work in determining TSS. Studies are underway to investigate the use of a simple imaging feature, a mismatch pattern between magnetic resonance (MR) diffusion weighted imaging (DWI), on which stroke pathophysiology is immediately visible, and fluid attenuated inversion recovery (FLAIR) imaging, on which strokes are not visible for 3-4 hours [7–9], to estimate TSS. The mismatch pattern is known as “DWI-FLAIR mismatch.” While this method is the current state-of-the-art for determining eligibility for thrombolytic therapy in cases of unknown TSS, computing mismatch is a difficult task that requires extensive training and for which clinician agreement has been found to be only moderate, leading to less accurate performance [10–12]. Separately, limited work has been done in TSS classification using MR perfusion-weighted image (PWIs) for TSS classification, which may contain information that encodes TSS [13].

Machine learning models have been applied widely and can achieve good classification performance for problems in the healthcare domain because of their ability to learn and utilize patterns from data to make prediction [14]. Recent developments in deep learning [15] have drawn significant research interest because of the technique’s ability to automatically learn feature detectors specific to the data for classification and prediction tasks, achieving state-of-the-art performance in challenging problems (e.g., ImageNet [16], video classification [17], etc.). In this work, we hypothesize that machine learning models can be used to better classify TSS by learning latent representative features from MR images. We developed a deep learning algorithm based on an autoencoder architecture [18] to extract imaging features (i.e., deep features) from PWIs and evaluate the effectiveness of four machine learning classifiers with and without the deep features to classify TSS. We performed retrospective testing on images from stroke patients by censoring the known TSS and comparing performance to published results using DWI-FLAIR mismatch.

2 Related Work

“DWI-FLAIR mismatch” is defined as the presence of visible acute ischemic lesion on DWI with no traceable hyper-intensity in the corresponding region on FLAIR imaging (Figure 1) [7]. The work of using DWI-FLAIR mismatch
was first introduced by Thomalla et al. [10], in which they used the mismatch pattern to identify stroke patients with less than 3-hour stroke onset. The method achieved a high specificity of 0.93 and a high positive predictive value (PPV) of 0.94, with a low sensitivity of 0.48 and a low negative predictive value (NPV) of 0.43. Aoki et al. [19] and Petkova et al. [20] followed the same method and applied on their datasets. Both achieved a high sensitivity (0.83 and 0.90 respectively) and a high specificity (0.71 and 0.93 respectively), but Aoki et al. reported a moderate PPV of 0.64.

Work has also been done in using DWI-FLAIR mismatch to classify TSS<4.5hrs, which is the current clinical cutoff time for IV tPA treatment. Ebinger et al. [21] developed a mismatch model and it achieved a specificity of 0.79 and a sensitivity of 0.46. Later, a large multicenter study was done by Thomalla et al. [22] to assess the ability of DWI-FLAIR mismatch. The mismatch method achieved a specificity of 0.78 and a PPV of 0.83, with a sensitivity of 0.62 and a NPV of 0.54. The study interobserver agreement of acute ischemic lesion visibility on FLAIR imaging was moderate (kappa = 0.569). Emeriau et al. [23] also investigated the use of mismatch pattern and the model achieved a PPV of 0.88, but a sensitivity of 0.55, a specificity of 0.60, and an NPV of 0.19. The AUC of using mismatch patterns in the identification of TSS was 0.58. There are ongoing large multicenter clinical trials, such as the WAKE-UP trial in the European Union [8] and the MR WITNESS trial in the United States [24], to further investigate the use of DWI-FLAIR mismatch in guiding treatment decisions for patients with unknown TSS.

The above preliminary work using DWI-FLAIR mismatch demonstrates a potential opportunity for using image analysis to classify TSS. However, existing studies all suffer from the use of relatively simplistic features and models [10–12]. Furthermore, it has been proposed that DWI-FLAIR mismatch may be too stringent, and therefore miss individuals who could benefit from thrombolytic therapy [25]. In this work, we develop machine learning models to classify acute ischemic stroke patient TSS using MR imaging features. We proposed a deep learning model, which is based on an autoencoder architecture [18], to extract latent representative imaging features (deep features) from PWIs. We compared the performance of various models (stepwise multilinear regression, support vector machines, random forest, and gradient boosted regression tree) to classify TSS with and without the deep features, and determined the best model for classifying TSS. We also provided a visualization strategy to interpret the deep features, and correlate them to the input images.

3 Methods

3.1 Dataset

In a study approved by the UCLA institutional review board (IRB), clinical stroke data was transferred from our institution’s data repository into a REDCap [26] database. The database holds 1,059 acute stroke patients from 1992 to 2016 who have received at least one or more of the following revascularization treatments: IV tPA, IA tPA, or mechanical thrombectomy. The corresponding patient pre-treatment MR PWIs, apparent diffusion coefficient (ADC) images, DWIs and FLAIR images were obtained from the UCLA Medical Center picture archiving and communication system (PACS).

For this study, we define the following inclusion criteria: 1) patients must experience acute ischemic stroke due to middle cerebral artery (MCA) occlusion; 2) patients must have a recorded time for which the stroke symptoms are first observed; 3) patients must have a recorded time for which the first imaging is obtained before treatment; and 4) patients must have a complete imaging set of PWIs, DWIs, FLAIRs, and ADCs. Patients’ TSS was calculated by
subtracting the time at which the stroke symptoms were first observed from the time at which the first imaging was obtained. We followed the existing DWI-FLAIR TSS classification task [23] to binarize the TSS into two classes: positive (1; <4.5hrs) and negative (0; ≥4.5hrs). After applying the inclusion criteria, 105 patients were obtained (83 positive class; 22 negative class). The patient characteristics are summarized in Table 1. This cohort subset was used to build the models for TSS classification.

### 3.2 Image Preprocessing

Intra-patient registration of pre-treatment PWI, DWI, ADC and FLAIR images was performed with a six degree of freedom rigid transformation using FMRIB’s Linear Image Registration Tool (FLIRT) [27]. Gaussian filters were applied to remove spatial noise and a multi-atlas skull-stripping algorithm [28] was used to remove skulls. Different tissue type masks (e.g., cerebrospinal fluid (CSF), gray/white matter) were identified using Statistical Parametric Mapping 12 (SPM12) [29] and CSF was excluded from this analysis. The sparse perfusion deconvolution toolbox (SPD) [30] and the ASIST-Japan Perfusion mismatch analyzer (PMA) were used to perform perfusion parameter map generation and arterial input function (AIF) identification (see Section 3.3.2.2).

### 3.3 Feature Generation

#### 3.3.1 Baseline MR imaging feature

PWIs are spatio-temporal imaging data (4D) that show the flow of a gadolinium-based contrast bolus into and out of the brain over time. They contain concentration time curves (CTCs) for each brain voxel that describe the flow of the contrast (i.e. signal intensity change) over time. Perfusion parameter maps [31] can be derived from PWIs that describe the tissue perfusion characteristics, including cerebral blood volume (CBV), cerebral blood flow (CBF), mean transit time (MTT), time-to-peak (TTP), and time-to-maximum (Tmax). Briefly, CBV describes the total volume of flowing blood in a given volume of a voxel and CBF describes the rate of blood delivery to the brain tissue within a volume of a voxel. By the Central Volume Theorem, CBV and CBF can be used to derive MTT, which represents the average time it takes the contrast to travel through the tissue volume of a voxel. TTP is the time required for the CTC to reach its maximum, which approximates the time needed for the bolus to arrive at the voxel with delay caused by brain vessel structure. Tmax is the time point where the contrast residue function reaches its maximum, which approximates the true time needed for the bolus to arrive at the voxel.

Intensity features (e.g., DWI voxel intensity, CBF voxel value) are often generated for voxel-wise stroke tissue outcome prediction [32]. Yet, generating intensity features based on entire brain MR images may be less descriptive to the stroke pathophysiology and less predictive of TSS because often stroke occurs in only one cerebral hemisphere. Therefore, we generated the imaging features only within regions that have Tmax>6s [33], which capture both the dead tissue core and the salvageable tissue that can possibly be saved by treatments. Feature generation involves two steps: 1) perfusion parameter maps were calculated using the SPD toolbox [30], and the region of interest was defined by Tmax>6s; and 2) the average intensity value was calculated within the region of interest for each image (DWI, ADC, FLAIR, CBF, CBV, TTP, and MTT), resulting in a set of data with seven intensity features. All the features were then standardized independently to zero mean with a standard deviation of 1. These baseline imaging features were used in building the classifiers for TSS classification.

3.3.2 Deep feature Generation

3.3.2.1 Deep Autoencoder (AE)

We hypothesized that a deep learning approach can automatically learn feature detectors to extract latent features from PWIs that can improve TSS classification. We therefore implemented a deep autoencoder (deep AE) that is based on a stacked autoencoder [18] to learn the hidden features from PWIs (Figure 2). Each PWI voxel CTC, with a size of 1 x t (t = time for perfusion imaging), is transformed by the deep AE into k new feature representations that can represent complex voxel perfusion characteristics. The learning of these features is automatic and it is achieved by the hierarchical feature detectors, which are sets of weights that are learned in training via backpropagation. The deep AE consists of an encoder and a decoder. The encoder consists of two components: 1) an input layer; and 2) fully-connected layers, in which input neurons are fully-connected to each previous layer’s output neuron. The encoder is connected to the decoder, which follows reversely the same layer patterns of the encoder. The encoder output (i.e., the middle layer output of the deep AE) is the k new feature representations that can be used for TSS classification (in this work, k = 4).

The proposed network is trained via an unsupervised learning procedure in which the decoder output is the reconstruction of the encoder input. The network is optimized to obtain weights, Θ, that minimize the binary cross entropy loss between the input, I, and the reconstructed output, I(Θ), across the samples with size n [34]:

\[
\text{arg min}_\theta \text{ loss} = \frac{1}{n} \sum_{i=1}^{n} \left[ (I_i \ast \log(I(\Theta)) + (1 - I_i) \ast \log(1 - I(\Theta)) \right]
\]  
(Eq. 1)

3.3.2.2 Training data generation

As previous work suggests [35], regional information corresponding to a voxel’s surroundings can improve classification in MR images. Therefore, a small region was included in each training voxel, leading to a size of 3 x 3 x t patch (width x height x time; the z-dimension is omitted; t = 64 in our dataset), where the center of the patch is the voxel of interest for the deep AE feature learning. Each training patch was also coupled with its corresponding arterial input function patch [36], which describes the contrast agent input to the tissue in a single voxel, to improve the learning of hidden features. Each training patch was unrolled into a 1D vector, leading to a size of 1152x1. The 1D data were used to train the deep AE. In total, 105,000 training data were generated by sampling randomly and equally from all the patient PWIs.

3.3.2.3 Deep AE Configuration and Implementation

We observed that standard batch gradient descent did not lead to a good convergence of the deep AE during training. We suspect that this may be due to an inappropriate learning rate (default: 0.01), which typically requires careful
tuning. Therefore, we optimized the deep AE using Adam, which computes adaptive learning rates during training and has demonstrated superior performance over other methods [37]. An early-stopping strategy was applied to improve the learning of deep AE weights and prevent overfitting, where the training would be terminated if the performance did not improve over five consecutive epochs (max number of training epochs: 50). The deep AE was implemented in Torch7 [34], and the training was done on two NVIDIA Titan X GPUs and an NVIDIA Tesla K40 GPU. We explored different architectures of the deep AE, including different numbers of encoder hidden layers (from 1-3) and different numbers of hidden units (factor of 2, 4, and 6). Ten-fold patient-based cross-validation was performed to determine the optimal architecture for the deep AE (with an input size of 1152×1 and k = 4 new feature representations). Once the deep AE was trained, we used it to learn four new AE feature maps from each patients’ PWIs by aggregating the deep AE encoder output of all voxels. Then, average intensity values from AE feature maps (denoted as deep features) were generated in the regions of interest following the same procedure as described in Section 3.2.1.

3.4 Machine Learning models for TSS classification

We constructed and compared the performance of four machine learning methods for TSS classification: stepwise multilinear regression (SMR), support vector machine (SVM), random forest (RF), and gradient boosted regression tree (GBRT). Briefly, SMR is a stepwise method for adding and removing features from a multilinear model based on their statistical significance (e.g., F-statistics) to improve model performance [38]. SVM is a supervised learning classification algorithm that constructs a hyperplane (or set of hyperplanes) in a higher dimensional space for classification [39]. RF is an ensemble learning method in which a multitude of decision trees are randomly constructed and the classification is based on the mode of the classes output by individual trees [40]. GBRT is an ensemble learning method similar to RF, in which a multitude of decision trees are randomly generated, yet these trees are added to the model in a stage-wise fashion based on their contribution to the objective function optimization [41].

Different machine learning methods may not perform equally on the same feature set. Also, different model hyperparameter (e.g., a SVM’s hyperparameter, C) contribute differently to the classification. Evaluating model performance without hyperparameter tuning may lead to decreased predictive power due to over-fitting, especially on small and imbalanced datasets. Therefore, we performed leave-one-patient-out validation for evaluation, with a nested cross-validation for tuning model hyperparameters, following the proposed method [42]. A feature selection method, stability selection [43], was also applied to select the optimal feature subset before cross-validation to determine the best features for modeling (except for SMR because it has built-in feature selection method). This feature selection method produces a fairer feature comparison by aggregating different feature selection results from random subsampling of data and feature subsets. An overview of steps is shown in Figure 3. The SVM and RF were developed using the Python Scikit-learn library [44]. The SMR and GBRT were developed using MATLAB and the XGBoost library [45] respectively.

Figure 3. An overview of steps to predict TSS (<4.5 hrs). The SPD toolbox was used to generate perfusion parameter maps (e.g., Tmax) from the PWIs. A region of interest mask was defined on Tmax>6s region. Then, the mask was applied to the perfusion maps and MR images (DWI, ADC, and FLAIR) to generate average intensity values. A total of seven baseline average intensity features were used to train the classifiers to predict TSS<4.5hrs. Classifier performances (with and without the addition of deep features) were compared.
4 Results and Discussion

4.1 Deep AE training

The optimal model architecture for the proposed deep AE is 1152-192-4-4-192-1152, with an average mean square error (MSE) of $0.675 \pm 0.246$ (average deep AEs MSE is $1.29 \pm 0.755$). The small MSE indicates the reconstruction of input signal is efficient with the encoder-decoder structure, and the encoder output is a compact representation for the input. Figure 4 shows the MSE along epoch of each fold for the optimal deep AE. All the models across folds converged within first ~10 epochs, with minimal weight adjustments in the following epochs as indicated by small changes in the MSE. Most of the models were stopped within 25 epochs (except the model in fold 9).

![MSE vs. epoch for each fold of the validation for the optimal deep AE (in logarithmic scale for better visualization). All the models across folds converged within ~10 epochs, with minimal adjustments in the following epochs as indicated by small MSE change.](image)

4.2 TSS classification

Leave-one-patient-out validation (see Section 3.3) was performed to evaluate each classifier. The model performance was measured via AUC and model bias via F1-score (Table 2). Youden’s index [46] was used to determine optimal receiver operating characteristic curve (ROC) cutoff points, which were used to calculate the F1-score, sensitivity, specificity, true predictive value (TPV), and negative predictive value (NPV) (Table 3).

**Table 2.** The AUC and F1-score of different classifiers on predicting TSS with baseline imaging features and with/without deep features. B (baseline features), B+AE (baseline and deep features).

With the additional deep features, all classifiers (SMR, SVM, RF, and GBRT) showed improvement in AUC. The increase (~10%) of AUC after adding the deep features demonstrated the usefulness of these deep features and their association with the TSS. Figure 5 shows the ROCs of the classifiers trained with the baseline features and the deep features, with a reference ROC based on the DWI-FLAIR mismatch method is shown for comparison [23]. All the classifiers generally performed better with the addition of the deep features. These classifiers performed better than AUC=0.60 (as compared to reference AUC of 0.58), demonstrating the ability of using imaging features with machine learning models to classify TSS. Among all the classifiers, the SMR trained with baseline imaging features and the deep features performed the best, with an AUC of 0.683. Comparing to the reference mismatch method, SMR achieved higher sensitivity (0.69 vs 0.55) and NPV (0.33 vs 0.19) while maintaining similar specificity (0.59 vs 0.60) and TPV (0.86 vs 0.88). Therefore, SMR was determined to be the most suitable classifier for TSS classification.

We observed that the models trained with only the baseline imaging features had low performance. The best model was the SMR with an AUC of 0.570, and other models had lower AUCs (<0.55). This may be due to the insufficient baseline features for classifier construction (i.e., only mean intensity features across MR images and perfusion maps were used). In future work, feature generation techniques, such as descriptive statistics, will be investigated to generate more features for TSS classification. Although these models were less predictive, models trained with additional deep features showed significant improvement in TSS classification. This supports our hypothesis that PWIs contain information encoding TSS, and that the proposed deep AE extracted hidden features in PWIs are predictive of TSS.

4.3 Deep Feature Visualization

To understand what the deep AE learned to extract in the encoder output layer, we applied the visualization technique, top-m selection [47], on the encoder output layer and correlated the results to the four deep AE activation maps (denoted as ae1, ae2, ae3, and ae4). Briefly, every input CTC will cause a hidden neuron unit to output a value (i.e., activation). Some input CTCs will give a higher activation while other inputs will give a lower activation. High activation values indicate the presence of relevant features in the input (e.g., wide and high peak) that can “excite” the hidden units [47]. For each hidden unit of the optimal deep AE encode layer, we performed top-m selection to obtain the top m signals ($x^*$) from the training data that cause the most activations:

$$x^* = \{x_j\}, j \in \text{first m of Sort}(h_i(\theta, x)),$$

(Eq. 2)

where $\text{Sort}(\cdot)$ is a descending operation, and $h_i(\theta, x)$ is the activation of the $i$th hidden unit. Figure 6 shows the four deep AE activation maps and their corresponding average curves of the top-50 (i.e., $m=50$) input CTCs. Our results show that different hidden units appear to capture different type of input signals. For example, the ae1 map shows higher activations (brighter) in the acute stroke region (left brain; high Tmax), and the corresponding average top-50 CTC (blue curve) has delayed and low concentration, which matches the visualization (that is, the hidden unit detects...
the stroke-affected CTCs). In contrast, the ae3 map shows low activations (darker) in the acute stroke region and the corresponding average top-50 CTC (red curve) has early sharp and high peak. We also calculated the Pearson correlation coefficient between the deep features generated from these activation maps and TSS. The ae3 deep feature showed statistically significant correlation with TSS (p-value<0.05). These visualization and correlation results demonstrated that the learned features from the optimal deep AE contained information that was predictive of TSS.

Understanding deep learning representations is challenging because it requires making sense of non-linear computations performed over many network weights [48]. Our visualization result is the first step to attempt to understand what the deep AE is learning. This is important for using deep learning model in medical image analysis because deep learning is often a “black-box” approach that yields superior, but hard-to-interpret results. However, the visualization result in this work is not conclusive. Further research is required to understand what the deep network is learning. One next step we plan to pursue is to apply different visualization techniques (e.g., deconvolution [49]) on the learned networks and perform statistical tests to draw correlations between them to an observation (e.g., small TSS).

5 Conclusion and Future work

In this paper, we showed that SMR, SVM, RF, and GBRT models were able to classify TSS, with SMR achieving the highest AUC. We proposed a deep AE architecture to extract representative features from PWIs and showed that adding deep features boosted the classifiers’ performance, showing the potential application of deep learning feature extraction techniques in TSS classification. In addition, we utilized a visualization method to interpret the features learned in the deep AE and discussed the possible research opportunity in understanding deep learning models for medical images.

We now discuss a few limitations and areas of future work. First, there are roughly 1,100 patients available in our dataset, but the majority of them were missing one or more MR images and were therefore not included in this analysis. Our next step will be looking into multimodal and denoising deep learning frameworks that are capable of handling missing data. Second, we will explore different feature generation techniques (e.g., descriptive and histogram statistics) to enlarge the feature set for training the classifiers. Third, we plan to explore several visualization techniques, such as deconvolution [49] and gated backpropagation [50] in order to understand the deep AE’s features and to draw both visual and statistical correlations to TSS classification. Finally, TSS<4.5hrs is the current clinical cutoff time for IV tPA treatment, yet this may not be an absolute time point in which a stroke patient can benefit from treatment because of changing brain pathophysiology [51]. We therefore plan to investigate and extend our models to more classes (e.g., a ±0.5hr boundary), rather than just TSS<4.5hrs/TSS≥4.5hrs.

Abstract

Pregnancy produces important health-related needs, and expectant families have turned to technologies to meet them. The ability to predict needs and technology preferences might aid in connecting families with resources. This study examined the relationships among Multidimensional Health Locus of Control (MHLC) scores, information-seeking behaviors, and health-related needs in 71 pregnant women and 29 caregivers. Internal MHLC scores were positively correlated with information-seeking behaviors, including website and patient portal use. Higher Chance scores were associated with decreased portal or pregnancy website use (p=0.002), with the exception of FitPregnancy.com (p=0.02). MHLC scores were not significantly correlated with number of health-related needs or whether needs were met. Individuals with needs about disease management had higher Powerful Others scores (p=0.01); those with questions about tests had lower Powerful Others scores (p=0.008). MHLC scores might be used to identify individuals less likely to seek information and to predict need types.

Introduction

Improving maternal and infant health are key priorities of many national and international women’s health initiatives1,2,3. There are nearly 6.5 million pregnancies and 4 million births each year in the United States4, and the Agency for Healthcare Research and Quality’s Healthcare Cost and Utilization Project reported up to 94% of births are complicated by maternal or fetal conditions5. Pregnancy is a time in which women not only have many questions pertaining to their own health but also distinct health concerns about their unborn children. In the last two decades, infant and maternal mortality rates have decreased, but increases in maternal age, obesity, opioid abuse, use of assisted reproductive technologies, and chronic health conditions have resulted in a doubling of severe maternal morbidity6. Infant mortality and prematurity, with their associated lifelong health problems, remain important problems in minority populations7. Studies of first time parents have shown the transition to parenthood, including the timeframe from pregnancy to postpartum, to be one of the most stressful periods of adult development. During this time, there are increased social and emotional needs for both mothers and fathers8. All pregnancies, even uncomplicated, healthy pregnancies, may raise significant health-related questions for all individuals involved in the care of the mother or child. The role and concerns of extended family and additional caregivers are becoming increasingly important as 27% of children live with a single parent and 10% live with a grandparent9.

There has been little research about the specific information needs of pregnant women and their caregivers, whether these needs are met, and what populations are at risk for unmet needs. Studies that have been completed are mostly small and restricted usually focused medical questions related to genetic risks and prenatal diagnoses10,11,12,13. The organization and educational content of prenatal visits have not adapted to the increasingly complex population of pregnant women and their family structures. Many women have turned to technologies such as smartphone apps and the Internet to address their unmet needs during pregnancy14,15,16. An easy method connect expectant families with appropriate health information technologies might ultimately lead to improved maternal and fetal outcomes.

Prior research has shown that healthcare consumers have strong technology usage preferences, which are not reliably predicted by demographic characteristics17. Tools to predict health-related needs and technology preferences would be useful in tailoring or recommending resources to specific populations. The Multidimensional Health Locus of Control (MHLC) is a potential target. The MHLC is a survey, based on social learning theory and designed to measure beliefs surrounding sources of health-related behaviors. The survey contains 18-items with 6-items for each of its three subscales: Internal, Chance and Powerful Others. Each item is scored on a 6-point, Likert-type, scale from 1 (Strongly Disagree) to 6 (Strongly Agree). Scores for each subscale reflect the total score for the corresponding 6 items, with subscales having a minimum score of 6 and maximum score of 3618.
The Internal subscale measures the strength of the belief that the respondent’s health is the result of their own behaviors. Higher scores on the Internal subscale indicate a more Internal Health Locus of Control. Lower scores on the Internal subscale indicate a more External Health Locus of Control or stronger belief that the respondent’s health is determined by factors aside from themselves. The Powerful Others subscale measures the degree to which the respondent believes health is controlled by individuals seen as “powerful others”, such as clinicians or a higher power. Higher scores on the Powerful Others subscale indicate a stronger belief in external control of health by such influential forces. The Chance subscale indicates the degree to which the respondent believes that health is out of his or her control. Higher scores on both the Powerful Others and Chance subscales represent a more External Health Locus of Control while lower scores on the Powerful Others and Chance subscales indicate a more Internal Health Locus of Control.

The MHLC has been used in numerous studies, primarily in the nursing and health psychology realm, to predict health behaviors and health status. In particular, the scale has been used to predict categories of patients who are likely to adhere to medication regimens or engage in preventative care. Observational studies examining medication adherence have consistently demonstrated External Health Locus of Control, higher scores on Powerful Others and Chance subscales, is predictive of medication non-adherence. Studies examining the relationship between MHLC and preventative or healthy lifestyle behaviors, in contrast, have produced conflicting results. Studies of pregnant women have shown that MHLC scores do not change significantly following delivery and that development of post-partum depression is significantly correlated with MHLC scores. The MHLC has been suggested as a potential screening tool for post-partum depression.

Additionally, several studies have provided evidence that MHLC can predict health-related needs and information-seeking behaviors. The relationship between Health Locus of Control and information-seeking behaviors was examined initially in 88 undergraduate students using a predecessor to the MHLC. This study showed that individuals with high Internal Health Locus of Control scores sought out more health-related information in the form of pamphlets. A small sociological study published in 2004 examined the relationship between MHLC and the desire for information in 81 mothers of children with disabilities. This study found that mothers with low scores on Chance and Internal subscales (i.e., those individuals with a low External Health Locus of Control) may be motivated to initiate an extended search for a cure to their child’s disability. However, few contemporary studies have examined the relationship between MHLC and information-seeking behaviors with new technologies such social media, the Internet, and smartphone based applications.

This study examined the relationships among MHLC scores, health-related needs, and information-seeking behaviors of pregnant women and their caregivers. We hypothesized that higher Internal Health Locus of Control scores would be predictive of increased information-seeking behaviors and that individuals with higher Internal Health Locus of Control scores would have more numerous and different categories of health-related needs than those with higher External Health Locus of Control scores.

**Methods**

**Overview**

This study employed data from a comprehensive study of health-related needs and information management practices of pregnant women and their caregivers. We describe the study population and data sets available from the larger study, and the specific methods of analyses employed for this project.

**Study Population**

Pregnant women and caregivers were recruited for the study from the Junior League Fetal Center (FCV) and Expect with Me (EWM) group prenatal program at Vanderbilt University Medical Center (VUMC). The FCV is an interdisciplinary advanced maternity care setting, which provides expert care in the diagnosis and treatment of fetal anomalies or pregnancy complications in a single location. EWM is a group prenatal care program, which provides traditional prenatal care, education, and peer support during pregnancy. Groups of 8-12 women of similar gestational ages meet 10 times throughout pregnancy. The group prenatal care model has been demonstrated to reduce preterm births and healthcare costs during and after pregnancy, and it is aligned with the Institute of Medicine’s Six Domains of Quality. These recruitment sites were selected to include participants experiencing both complicated and relatively normal pregnancies.

English- or Spanish-speaking adults, age >=18 years, with pregnancies less than 36 weeks gestational age, and addresses within 100 miles of VUMC were eligible for the study. Pregnant women enrolled in the study were allowed
to invite up to three caregivers to participate in the study. Caregivers were defined as any individual who would have significant involvement in the care of the mother or baby during and after pregnancy. Written informed consent was obtained from all participants. The research protocol was approved by the VUMC Institutional Review Board.

**Measures**

Enrolled participants completed multiple questionnaires, including a socio-demographics survey, technology usage assessment, and the MHLC; a semi-structured interview was completed during a research visit to VUMC. Participants were compensated with a $25 gift card for their time, and travel to VUMC was reimbursed.

The socio-demographics questionnaire included items to assess age, race, ethnicity, home location, and whether the participant had other children. Gestational age of the pregnancy was calculated based on the interview date and expected delivery date. Relationships between pregnant participants and caregivers were recorded. A technology usage questionnaire asked participants if they 1) had access to or had used Vanderbilt’s online patient portal, My Health at Vanderbilt (MHAV) and 2) had used online resources to obtain information about pregnancy, and if so, which resources (i.e., BabyCenter.com, TheBump.com, FitPregnancy.com, WhatToExpect.com, Pregnancy.com, Text4Baby.org, or other). Participants were able to indicate using multiple websites as sources of information.

Participants also completed a semi-structured interview with one to two members of the research team. Participants answered questions related to prior pregnancies, their current pregnancy, information-seeking behaviors, health-related needs, and biggest concerns. All interviews were audio-recorded, transcribed, and de-identified prior to analysis.

---

**Figure 1. Consumer Health-Related Needs Taxonomy**

Health-related needs were manually extracted from interview transcripts and classified by semantic type using a validated Consumer Health-Related Needs Taxonomy. Major categories from this taxonomy are depicted in Figure 1. Previous studies have utilized this taxonomy to categorize consumer health questions from patient journals and patient portal messages and have validated the taxonomy with inter-rater reliability of its application. The taxonomy divides health-related needs into five semantic categories: informational, medical, logistical, social, and other. Informational needs are questions that require clinical knowledge, such as prognosis of a particular diagnosis. Medical needs request medical care, such as the request for a medication change after a side effect. Logistical needs are questions regarding practical information, such as what facilities offer a particular treatment. The social category involves emotional or social needs. Lastly, the other category includes needs not currently included in the taxonomy schema or needs that span multiple categories, such as how to be a good parent. Identified needs were classified independently by at least
two research team members, and consensus was achieved by discussion for discrepancies. The results of this needs analysis and inter-rater reliability of the taxonomy application for this task are reported elsewhere.

In our analysis, we report descriptive statistics as appropriate on all measures, including scores on the MHLC. Regression analyses examined the relationships among MHLC scores, information-seeking behaviors, and health-related needs for all participants. In subsequent regression models, we controlled for whether the current pregnancy represented the participant’s first child, differences between the two models are reported in the results section text below. Significance values and corresponding test statistics (e.g. Pearson coefficients or logistic regression) are reported. All analyses were completed in SPSS version 24 (IBM, 2016).

Results

Study Population and Demographics

One hundred participants were enrolled in the study, and five were excluded from this analysis due to incomplete MHLC data. Thus, 67 pregnant women and 28 caregivers were included in the analysis. Table 1 shows participant characteristics. This population included 21 men and 74 women with a mean age of 29.3 years and average gestational age of the pregnancy of 30.8 weeks. Sixty-eight (71.5%) of pregnant women and their caregivers were white and 90 (94.7%) were English speakers. Seventy-nine (83.2%) pregnant women and their caregivers were recruited from FCV and 49 participants (52.5%) reported having other children.

Multidimensional Health Locus of Control Scores

Figure 2 reports the mean MHLC scores calculated for all participants, pregnant women, and caregivers. Average scores and standard deviation (SD) for participants were Internal - 26.9 (4.2), Chance - 15.9 (5.0), and Powerful Others - 17.9 (4.5). Pregnant women’s scores were: I - 26.4 (4.0), Chance - 17.7 (4.7) and Powerful Others - 15.6 (4.5). Caregivers on average had higher scores on all three subscales: Internal - 27.9 (4.7), Chance - 16.8 (5.8), Powerful Others - 18.2 (4.6). Scores on the Internal subscale were found to be independent of scores on the Chance and Powerful Others subscales. Scores on the Chance and Powerful Others subscales were significantly positively

905
correlated with each other (p=0.004). Internal scores were negatively correlated with Chance scores and positively correlated with Powerful Others scores but these relationships were not significant (p=0.49 and p=0.47, respectively).

Table 2 summarizes the information-seeking behaviors of the participants. Of the 95 participants, fifty-four (54.7%) reported using the MHAV patient portal. Fifty (52.6%) reported using MHAV and websites to obtain information about their pregnancy. Thirty-five participants (39.8%) reported using only one of either websites or MHAV, and 10 individuals (10.5%) reported using neither MHAV nor websites to obtain information about their pregnancy.

In pregnant women and caregivers who reported using the Internet, the average number of websites participants accessed to obtain pregnancy related information was 2.0. BabyCenter.com was the most frequently accessed website by both pregnant women and caregivers. Forty-five participants (47.4%) reported accessing “other” websites to obtain pregnancy information. “Other” websites reported by participants included search engines (e.g., Google.com, WebMD.com, Yahoo.com), hospital specific websites (e.g., MayoClinic.com, ClevelandClinic.com), and pregnancy focused websites (e.g., EverydayFamily.com, JustMommies.com). Pregnant women were more likely than caregivers to access any of the specified resources to obtain information regarding pregnancy.

Table 3 shows the relationships between information-seeking behaviors and MHLC scores. Higher Chance scores were found to be associated with fewer information seeking behaviors (p=0.002). Neither Internal nor Powerful Others
scores were predictive of number of resources sought. These relationships remained constant when controlling for whether the current pregnancy was the participant’s first child. Regression analyses looking at specific websites accessed by pregnant women and their caregivers revealed that lower Chance scores were predictive of MHAV use, regardless of whether this was the participant’s first child (p=0.007, 0.02). Higher Chance scores were significantly associated with accessing FitPregnancy (p=0.02). Access of the other specified websites was not associated with MHLC scores.

Table 3. Relationships between MHLC scores and information-seeking behaviors.

Health-Related Needs

A total of 1014 health-related needs were reported by 95 participants. On average, participants reported 10.7 health-related needs, 11.8 for pregnant women and 7.9 for caregivers. Of these needs, 672 (66.3%) were classified as informational, with 305 being about problems (i.e., diseases or conditions). Informational needs regarding interventions were more often reported by pregnant women compared to caregivers (21.3% vs. 10.4%) while informational needs regarding management of problems were more often reported by caregivers than pregnant women (14.8 vs. 16.7%). Of the remaining health-related needs identified, 87 (8.6%) were classified as medical, 162 (16.0%) logistical, 90 (8.9%) social, and 3 (0.3%) other.

Of the 1014 needs identified, half (50.5%) were partially met while approximately one-fourth (26.8%) were unmet. Caregivers reported fewer met needs than pregnant women (16.2% vs 24.5%). Additional details regarding health-related needs of pregnant women and caregivers can be seen in Table 4.

Relationships between MHLC scores and the total number of health-related needs are shown in Table 5. MHLC scores were not significantly correlated with the total number of health-related needs. Internal score was positively correlated...
with number of logistical needs, and this relationship approached significance (p=0.06). In modeling relationships between MHLC scores and subcategories of health-related needs, the Powerful Others score was associated with management and test categories of informational needs. Informational management needs were positively correlated with Powerful Others score (p=0.01) and informational test needs were negatively correlated with Powerful Others score (p=0.008). When controlling for whether this pregnancy was the first child for the participants, Powerful Others score were not associated with informational management needs. There was no significant relationship between MHLC scores and the whether health-related needs were met.

Discussion

This study explored the distribution of MHLC scores in both pregnant women and their caregivers and the relationships among MHLC scores, health-related needs, and information seeking-behaviors in this population. We found that pregnant women and caregivers had MHLC scores consistent with published norms. Wallston and Wallston reported normative averages for each MHLC subscale following survey administration to college students in multiple studies: Internal - 26.6; Powerful Others - 17.87; Chance - 16.72. These initial norms have been validated by contemporary data sets and in pregnant women. A 2013 survey of 230 pregnant Iranian women showed means and standard deviations for Internal - 25.48 to 27.2, (SD: 3.39-3.42), Powerful Others - 26.73 to 22.83 (SD: 4.42-4.79), and Chance - 19.03 to 19.2 (SD: 5.71-5.90). These studies show that scores on Chance and Powerful Others subscales are similar in magnitude, while Internal scores are consistently higher, which is congruent with our findings. These studies demonstrate that individuals often have a more Internal than External Health Locus of Control.

Relationships among the three subscales were unique to our population. Prior studies have shown Internal and Powerful Others subscales were independent of one another while Internal and Chance subscales were significantly, negatively correlated. In our population, Powerful Others and Chance scores were significantly, positively correlated; however, there was no significant association between Internal scores and Chance or Powerful Others scores. Differences in these relationships could be population specific. Prior studies have performed analyses on healthy, undergraduate students and not adult patients currently experiencing the stress and unpredictable nature of pregnancy. Our study participants might have been more likely to view health as a result of multiple sources.

In examining information-seeking behaviors, the majority of pregnant women and caregivers used both MHAV and websites to obtain information about pregnancy. Most individuals who reported using the Internet as an information source visited multiple websites related to pregnancy. This finding confirms prior research showing that health information technologies have become common resources for pregnant families and further supports initiatives and additional research into what technologies, including mobile phone applications, websites, or interactive technologies, would be most effective during pregnancy. Health information technology design research should focus on preferences for technology usage and the unique health-related needs of pregnant women and their caregivers. In this study of
pregnant women and caregivers, our findings were not consistent with prior work that found Internal Health Locus of Control to be positively correlated with information-seeking behaviors. Previous studies examining these relationships were completed using either healthy volunteers or mothers of children with disabilities. In both studies, the participants were not themselves experiencing a health condition. In contrast, our sample was composed of a majority of pregnant women and caregivers going through complicated pregnancies. The correlation of Internal scores with information seeking behaviors then might be stronger in individuals who are healthy and weaker in those intimately connected to the illness, such as a mother pregnant with a fetal anomaly.

Our study demonstrated that feeling like health is a result of fate or luck (i.e., higher Chance scores) was associated with reduced use of resources to obtain health-related information. In particular, individuals with higher Chance scores were less likely to report using MHAV, Vanderbilt’s patient portal. This was true regardless of whether the current pregnancy was the participant’s first child or not. Utilization of patient portals or Internet resources is an active process that provides patients the opportunity to take ownership of their health and participate actively in their care. It would follow that individuals who feel their actions have no impact on their health status would be not be as likely to engage in such activities. However, active participation in care has been shown improve health outcomes. The MHLC may offer an alternative way to identify individuals not likely to actively seek information to maintain or improve their health. Future research should focus on the best strategies to engage these individuals in health-related activities. Participants with higher Chance scores were likely to access FitPregnancy.com, a website which compiles short articles on various pregnancy topics, more than other websites. This finding may offer design guidance for developers of health information technologies to engage a population that may not be inclined take ownership over their healthcare. The brevity of articles and entertainment-news style of this site may have been less intimidating than the more formal style of sites such as BabyCenter.com or WhatToExpect.com and more approachable than services that require sign up, such as Text4Baby.org.

We found that individuals with health-related needs regarding the clinical management of pregnancy problems were significantly more likely to feel that their health was the result of the actions of others (i.e., had higher Powerful Others scores). This significant relationship remained even after account for whether the participant had other children. The most common clinical management questions included inquiries into the options available to treat a particular diagnosis or to manage conditions of pregnancy in general. Additionally, participants without other children who expressed questions regarding clinical tests were significantly less likely to feel their health was in the hands of others (i.e., had lower Powerful Others scores). This finding suggests that pregnant women or caregivers with low Powerful Others scores may seek a better understanding of their pregnancy-related testing because they feel expert healthcare providers are fully in control of the maternal or fetal outcomes. This difference between participants with children and those expecting their first child could potentially be explained by increased trust in prenatal testing after having a successful pregnancy.

This study has important limitations. This research was completed at a single, large, academic medical center using a patient population where a majority of pregnancies were complicated by either maternal or fetal diagnoses. Further, the nature and structure of care provided at FCV and EWM group prenatal care resulted in participants having more frequent interactions with the healthcare system during pregnancy than traditional prenatal care models. Our findings may not be applicable to uncomplicated pregnancies or individuals receiving traditional prenatal care. Additionally, while larger than most studies examining health-related needs in pregnancy, this study is still relatively small. The study design is also cross-sectional in nature, and MHLC scores, information-seeking behaviors, and health-related needs may change over the course of pregnancy. We are currently enrolling participants in a longitudinal study using a similar research protocol to assess changes in MHLC, information-seeking behaviors, and health-related needs over time during and after pregnancy. This latter study will provide a larger cohort and multiple time points at which to examine these variables and their relationships.

Conclusions

This study is one of the first to measure MHLC scores in pregnant women and caregivers and to determine relationships between the MHLC scores, information-seeking behaviors, and health-related needs in the perinatal setting. MHLC scores in pregnant women and caregivers were consistent with published norms, but their relationships differed from prior studies. Powerful Others and Chance scores were significantly and positively correlated, but there were no significant correlations between Internal scores and Chance or Powerful Others scores. Similar to other studies, Internal MHLC scores were positively correlated with information-seeking behaviors in pregnant women and caregivers. Expectant mothers and caregivers with higher Chance scores were less likely to access pregnancy websites or a patient portal, regardless of whether they had other children. The exception to this
trend was that individuals with higher Chance scores were significantly more likely to access FitPregnancy.com, an entertainment-style site with short articles. Pregnant women and caregivers who feel their health outcomes are due to chance may prefer the less formal and extensive resources. MHLC scores were not significantly correlated with the total number of health-related needs expressed or whether needs were met. Pregnant women and caregivers with informational questions about management had higher Powerful Others scores, and those with informational questions about tests had lower Powerful Others scores. These findings may guide designers of health information technologies in tailoring content for pregnant women and caregivers who are likely to express certain types of informational needs. Our ongoing research is exploring relationships among MHLC scores, information-seeking behaviors, and health-related needs over time.

Abstract

This study describes a simulation of diagnostic coding using an EHR. Twenty-three ambulatory clinicians were asked to enter appropriate codes for six standardized scenarios with two different EHRs. Their interactions with the query interface were analyzed for patterns and variations in search strategies and the resulting sets of entered codes for accuracy and completeness. Just over a half of entered codes were appropriate for a given scenario and about a quarter were omitted. Crohn’s disease and diabetes scenarios had the highest rate of inappropriate coding and code variation. The omission rate was higher for secondary than for primary visit diagnoses. Codes for immunization, dialysis dependence and nicotine dependence were the most often omitted. We also found a high rate of variation in the search terms used to query the EHR for the same diagnoses. Changes to the training of clinicians and improved design of EHR query modules may lower the rate of inappropriate and omitted codes.

Introduction

The almost seventy thousand codes that comprise the 10th revision of the International Statistical Classification of Diseases and Related Health Problems (ICD-10-CM) are far more detailed than those in the preceding version that clinicians in the United States were working with since the late 1970s.1 This new level of complexity is expected to not only facilitate documenting and reporting causes of mortality and morbidity but to also extend the ability to identify and manage clinical processes with information technology by identifying changes in medication management and by monitoring data for health maintenance and preventive care purposes.2 Highly granular and more accurate data are also indispensable for rapidly expanding secondary uses such as detecting healthcare fraud, developing patient safety criteria, setting healthcare policy and developing public health initiatives, improving clinical performance and, crucially, allowing large-scale analyses for medical research. Codes are also essential in clinical care for phenotyping and predictive modeling of patient state.3 The transition also has significant implications on reimbursement from health care insurers. Diagnostic codes may be used to determine the severity of illness of a provider’s patient population and affect payment rates with newly adopted payment models. Codes that previously could not differentiate between several types of diabetes, for example, are now refined to capture important distinctions but require clinicians to add to their documentation causal underlying conditions or whether the disease was induced by drugs.4 A more detailed description of laterality and location in the patient’s body is also a newly added specification. The previous emphasis on organs and disease that prioritized physician-oriented content is expanded to also cover human responses to disease that are necessary for advanced nursing and long-term care.5

Many electronic health record (EHR) systems integrate clinical documentation and billing information and provide cross-mapping between primarily care-oriented and reimbursement- or report-oriented data. Problem lists, for example, need to conform to standardized vocabularies based on ICD-10 or SNOMED codes for the CMS EHR Incentive Program known as Meaningful Use.6 EHRs may employ their own proprietary reference terminologies that allow to search for and display diagnostic and other concepts in forms that clinicians find customary and meaningful while maintaining mapped connections in the background to more or less granular codes intended for reporting, financial or automated decision-support purposes. Typically, a clinician adding a coded term to a problem list or a fully-qualified ICD-10 code to a billing record starts with typing one or more words, an abbreviation or a string of characters into a free-text query field. A record search engine within the EHR then returns results based on their relevance to the search string and ranks them in a list according to differentiating logic for complete word or partial word matching. For example, a search initiated by typing “esrd” may return many diagnostic codes related to end-stage renal disease. Further search through the results may be necessary, either by reading the list or by repeating the search with different terms, to find the exact code appropriate for the intended purpose. More sophisticated systems...
provide automated assistance with this refinement by using “wizards” or other support interventions to help locate the target diagnosis quickly.

The almost four-fold increase in the number of diagnoses in the current coding system presents a formidable challenge to computer engineers and designers to develop algorithms and human interfaces that can, in the same short time available to clinicians and medical coders in routine practice, query, compare and select the best descriptive diagnostic or other code in the vastly expanded field. A recent survey of perspectives that coders and physicians had about the practical usefulness of ICD-10 showed that most agreed on the need for computer-assisted coding. If the query process is not effective, however, clinicians may find themselves facing a choice between accurate and “close enough” coding when time constraints preclude further refinement of the process. This learned behavior would directly contravene the goal of improved and precise documentation of clinical care made possible with the ICD-10 system.

This study was intended to describe search behavior of clinicians using tools available in large EHR systems who were entering ICD10 codes. Our objectives were to observe interactive behavior that may contribute to incomplete or inaccurate coding and to analyze variations in coded diagnoses for standardized clinical scenarios. Findings of systematic errors or difficulties in completing the coding task may help inform or revise training that clinicians currently receive and to provide evidence and insight for improvement to electronic coding and indicate a need to revise the coding system itself.

Methods

The study was designed as a simulation of a clinical documentation task where clinicians used standardized case scenarios to enter diagnostic codes into the EHR. We asked 23 physicians to read short vignettes describing a variety of ambulatory visits and then enter relevant ICD-10 codes into a mock patient record. Seventeen participants completed two sets of three scenarios, using each set for a different EHR; six completed only one set, using EHR 1, due to technical reasons. In total, there were 40 completed sets: 23 on EHR 1 (12 Sets A and 11 Sets B), and 17 on EHR 2 (10 Sets A and 7 Sets B). The order of set completion (A vs. B) alternated to minimize possible learning bias.

EHR 1 was a commercial and EHR 2 an internally-developed clinical information system. Both required an initial entry of a search term into a free-text field that returned a list of ICD-10 codes with descriptions. If the target term was in the results they could simply select it or further refine the list by entering a different search string. Decision support interventions were available on both systems and were either triggered automatically for a subset of diagnoses in EHR 1, with an option to disregard, or were designed as a part of the entry process on EHR 2. Participants choosing to use decision support on EHR 1 could click on modification terms in pre-determined sets and an algorithm would refine the results accordingly to a single ICD10 code. Initial search on EHR 2 returned a list filtered by patient parameters such as age and gender that could be also modified by selecting answers to term-specific questions (e.g., Laterality? Left, Right, etc.) Both systems used algorithms and branching logic during the guided-search phase to refine result lists and suggest fully specified billable codes. For example, if “otitis media” was the initially entered search term, the support intervention would show subsets of optional terms for laterality, chronicity and recurrence. The visual presentation of these terms, their number and content were different for each system.

Practicing ambulatory clinicians (22 physicians, 1 physician assistant) were recruited through internal email advertising as a sample of convenience. Twenty-one (91%) had ten or more years of professional experience, sixteen (65%) as primary care providers and seven as specialists. Ten (44%) used EHR 1 for 6 months or more, twenty-one (91%) daily in practice. All were proficient in using EHR 2 as it served as the primary ambulatory record system prior to an institution-wide transition to the commercial system. The ICD10 requirement went into full effect in the hospital during the transition period and clinicians have therefore been entering codes with both EHRs for approximately the same time. Both systems had proprietary interface terminology and participants did not use any other sources such as ICD10 on the web.

Participants completed the task individually in the presence of an experimenter on a single workstation that was connected to both EHR systems. They were instructed to read each scenario and then find relevant codes according to their own clinical judgment, and to use their preferred strategy in order to best simulate authentic behavior. The number of codes expected for each scenario was not explicitly stated, only that more than one may be necessary. Interactions of clinicians with the two systems were recorded into an audiovisual media file using Morae screen-capture software running in the background. The recordings of full screens and verbal comments were later analyzed.
Scenarios and accuracy-rating criteria for diagnostic codes

Study scenarios were taken verbatim from interactive case studies made available by the Centers for Medicare & Medicaid Services (CMS) on their Road to Ten website. Since the CMS recommendations for the correct ICD-10 codes were only one example of proper coding, we developed rating criteria for the appropriateness of codes in order to accommodate other correct coding options. Two physicians (HZR, EAD) independently reviewed codes entered by the participants and rated whether they were appropriate in the context of each scenario. They reached consensus on disagreements through a series of discussions. Ratings were based on two criteria: clinical accuracy and completeness. Although the rating was binary (appropriate or not), the reviewers acknowledged the potential range of responses due to variations in clinical judgment and in the complexities of the structure and intent of the ICD-10 coding system. A code rated “appropriate” could be clinically accurate but incomplete in a way that did not alter the diagnosis or miss a clinically crucial information. For example, indicating that allergic rhinitis was seasonal but not explicitly including the causative agent of pollen, or documenting tonsillitis or pharyngitis for a patient with an inflamed pharynx with tonsillar exudate, would be still considered “appropriate”. However, codes without clinically significant information would not. This would include omitting streptococcus as the etiology of tonsillitis in a case where the rapid strep test was known to be positive, or not specifying large intestine in a case of Crohn’s disease complicated by colonic abscess.

We identified one diagnosis in each scenario that was primary and reflected the main reason for visit. All others were categorized as secondary but were still required for complete documentation. They are identified in Table 1. Three of the six scenarios included an itemized clinical assessment in the vignette, as in the example below:

The patient is a three-year-old male brought in by his mother. He has had a low-grade fever of 100.5 for 3 days. He is complaining that his ears hurt with difficulty sleeping. He also has a non-productive cough that started yesterday. Examination of both ears reveals significant redness and fluid in both middle ears with no apparent involvement of the eardrum or tympanic membrane. Further examination of the patient’s breathing and other manifestations indicates an upper respiratory infection. The patient’s parents are chronic heavy smokers and the child is exposed to second-hand smoke in the home environment.

**History:** The patient has recurrent episodes of middle ear infections.

**Assessment:**
- Acute recurrent serous otitis media
- Upper respiratory infection (presumed of viral origin)
- Chronic secondary smoke exposure

In this example, otitis media was the primary diagnosis and the other two diagnoses were secondary diagnoses. Although the participants were given this listing they were not instructed on how many codes to enter. Three scenarios did not include a clinical assessment (as in the example above) and only contained the narrative. The full wording of all scenarios and examples of coding are available on the Road to Ten website maintained by the CMS.

Analysis

Analyses consisted of enumerating the entered codes and evaluating whether they were appropriate or not for the given scenario and whether any codes expected for complete coding of all implicit diagnoses were missing. We also analyzed free-text search terms entered in the query field for variation and the number of results returned by the algorithm. Group comparisons included type of scenario (with vs. without included assessment), type of diagnosis (primary vs. secondary) and electronic health record system (EHR 1 vs. EHR 2). Chi-square or Fisher’s Exact test were used where appropriate to compute group differences and statistical significance with SAS 9.4 software.

Results

We have analyzed three aspects of the diagnostic coding process: a) the appropriateness and completeness of codes for each scenario, b) variation and patterns of similarity of free-text search terms the participants used to initiate queries and c) the number of returned search results.

Accuracy and completeness of coding

The unit of observation was a single ICD-10 code in the context of one standardized scenario. The number of diagnostic codes required for a fully qualified (complete) description varied between 2 and 4 per scenario. We therefore expected 356 codes to be entered if all participants coded all scenarios completely (22 participants x 8 in Set
A plus 18 participants x 10 in Set B) Diagnoses for each scenario and the distribution of appropriate and omitted entries are shown in Table 1. Scenarios that included an explicit assessment are identified.

Just over a half (56%) of all entered diagnostic codes were rated as appropriate and about one quarter were omitted. Diagnoses with the highest accuracy rates, 90% or above, were essential hypertension, acute upper respiratory infection and streptococcal tonsillitis. Two diagnoses, type 1 diabetes mellitus with diabetic polyneuropathy and Crohn’s disease of large intestine with abscess had the greatest proportion of inappropriate codes entered than appropriate (52% and 58%, respectively). The most often omitted codes were for immunization not given (omission rate 91%), dependence on renal dialysis (78% omitted), and personal history of nicotine dependence that was omitted by two thirds of participants.

We also compared separately scenarios where an assessment was included with the narrative as it could serve as a cue to both the specificity of the diagnosis as well as the number of diagnoses that required coding. We computed their respective rates of accuracy and completeness. Results are shown in Table 2.

</table>
Primary diagnoses were significantly less likely to be omitted than secondary diagnoses. Only 5 out of 125 expected primary diagnoses were not entered. These omissions were all for the same diagnosis: type 1 diabetes with diabetic kidney disease. The omission rate for secondary diagnoses was 38%, with only a half coded appropriately. There was no significant effect of the EHR used to enter the codes on the main outcome measures and the proportions in each category were similar. However, when we analyzed primary diagnoses separately we found that significantly more appropriate codes were entered with EHR 2 (79%) than with the commercial EHR 1 (59%). The proportion of omitted codes was equally low for both systems (4%). Scenarios that included clinical assessment with the narrative showed higher rates of appropriate codes (73% vs. 40%) and reduced rates of codes that were omitted by three quarters (41% to 11%).

We next assessed the frequency and distribution of ICD-10 codes for every diagnosis in the scenarios (Table 3). The distribution pattern was typically a majority of entries in one or two appropriate codes and a few other codes with frequencies of one or two. For example, out of the 17 codes entered for paroxysmal atrial fibrillation, 13 (76%) were the correct I48.0 codes, two were I48.2 and two I48.9. Seven diagnoses had between 2 and 4 codes, five between 5 and 7 and two had nine and ten different codes, respectively. Two scenarios showed markedly different distribution: type 1 diabetes with diabetic polyneuropathy and Crohn’s disease of large intestine with abscess. In the diabetes case, only 4 out of the 15 codes entered (27%) were appropriate and the rest was distributed over 8 other diagnoses, each used by just one participant (by two in one case). For Crohn’s disease, 13 (48%) codes were the appropriate K50.114 and 8 other codes were also entered. There were three diagnoses with a complete agreement in coding among all participants: end-stage renal disease (N18.6), essential (primary) hypertension (I10) and acute upper respiratory infection (J06.9).

**Search terms and selection of codes**

We found no systematic differences in the type of search terms used, such as preference for different abbreviations, character sequences or full query terms that appeared to be EHR-specific. Table 4 shows the combined results for both systems, in descending order of use frequency. Terms with frequencies of 1 are grouped together and their cumulative proportion is shown. Relatively few terms were common to the queries of multiple clinicians. The proportion of common terms was typically 20%-40%, rarely exceeding 50% for each diagnosis while those that were unique and used only once comprised the largest group, often 40%-50% of all terms. For example, unique search strings such as ‘secondary’, ‘smoker’, ‘passive smoke’ or ‘parent smoke’ made up 40% of all search terms for the diagnostic code Z77.22 “Contact with and (suspected) exposure to environmental tobacco smoke”. The term ‘smoke’ by itself was used by only 6 participants (21%). Terms that appeared repeatedly in the search queries of multiple clinicians were either single-word disease

names such as asthma (used in 78% of all queries for ‘moderate persistent asthma’) or neuropathy (40%), or common abbreviations such as ‘cad’ (50%), ‘uri’ (59%), or ‘esrd’ (70%).

We also examined the interactive behavior of clinicians with respect to repeated formulation of search queries. The mean number of search terms, that is, instances when participants entered a new search string into a free-text field, is shown in Table 5.

</table>

Participants typically entered only one initial search term. Almost 80% selected a code after first search attempt. Only a small minority (less than 15%) needed to or were willing to change the query term and repeat the search cycle, and fewer still (under 10%) tried more times. Several clinicians repeated the search up to nine times but they acknowledged during the test session that they would not have gone to this length under the time constraints of actual practice. The average of the number of queries per diagnosis was almost equal for the two systems although there was a large difference in the number of returned results. The commercial EHR 1 displayed on average six times as many results as EHR 2.

**Discussion**

We found a large variability in the accuracy of ICD-10 diagnostic codes in a simulation of six clinical scenarios by clinicians using two EHRs. This varying level of diagnostic accuracy (the use of appropriate codes) seemed to increase when the code could be searched for with relatively ubiquitous and intuitive terms and abbreviations. For example, diagnoses with the rate of appropriate coding close to 80% or higher, such as streptococcal tonsillitis, asthma, rhinitis, upper respiratory infection or atrial fibrillation (Table 1) also had a high proportion of initial search queries repeatedly formulated with the same or similar terms by many clinicians (Table 4). Search terms such as ‘strep’, ‘pharyngitis’, ‘asthma’, ‘rhinitis’ or ‘uri’ likely produced a list of results that included the target code. Conversely, the largest variation in search terms was for diagnoses related to nicotine dependence or tobacco smoke exposure that could be expressed in many ways and do not lend themselves easily to one highly specific word. Terms with relatively low specificity are more difficult to map in reference terminologies to related codes and therefore clinicians were likely looking at different sets of results when completing the same search task with very different initial query terms.

The large number of results that search queries often returned had to be further refined and this extra series of steps was a common source of frustration for many participants. For example, some clinicians pointed out that they had to read through a dozen or more variations on gestational hypertension and preeclampsia included in the results for a male patient before they found the appropriate code for primary hypertension. This low efficiency of the query and entry process may lead over time to adopting a satisficing strategy – a decision-making heuristic in which the first option that seems to address most needs is selected rather than the most optimal choice. The tendency of clinicians to initiate only one or two different queries per diagnosis (Table 5) also seems to support the notion that there is a practical (likely time) limit on every query and that clinicians may need to tradeoff accuracy or completeness for efficiency.

The omission rate, while minimal for primary diagnoses, reached almost forty percent for secondary diagnoses. The non-coded conditions, if otherwise documented in notes, may not substantially affect the treatment of individual patients but would provide a distorted view of the patient population with underestimates of disease severity and comorbidity. For example, old myocardial infarction, dependence on dialysis and personal history of nicotine dependence were more often missing (up to almost 80%) than coded (Table 1). Leaving out such key clinical information in the diagnostic codes may have financial implications for the clinicians and may have research repercussions for those using such data for investigations.
Conclusion

We demonstrated significant deficiencies in documented diagnostic codes using clinical simulations of two different EHR systems. The promise of improved clinical documentation with ICD-10 may not be quickly realized due to three main factors. First, clinicians entering codes are not adequately trained to understand the requirements and nuances of the ICD-10 coding system. Additional training and specialized resources may be necessary at many institutions. Second, the design of query systems in EHRs may negatively affect the code selection process and lead clinicians to choose a less specific or less desirable code. Lastly, accurate understanding of the meaning of a particular code, especially those that indicate “unspecified,” is often possible only within the context of the code hierarchy. Clinicians therefore may need to have a good working knowledge of the ICD-10 structure to correctly identify what is unspecified and what may need to be specified. The core objective of decision support interventions is to assist them with this comparison by clearly contextualizing the returned candidate entries as the code set is too large and complex to be effectively learned in its entirety. The lack of appropriate coding may also affect reimbursement rates, especially with increased adoption of alternate payment models that rely on case-mix analysis to adjust financial reimbursement, as well as on potential utility of ICD-10 codes for research and other purposes.

ICD-10 will improve national healthcare initiatives such as Meaningful Use, value-based purchasing, payment reform and quality reporting. Without ICD-10 data, there will be serious gaps in the ability to extract important patient health information needed to support research and public health reporting, and move to a payment system based on quality and outcomes.14 These goals can be achieved if HIT better supports clinicians in making adequately informed choices by providing decision support, guidance and effective tools.

Abstract

Improving the efficiency of outpatient clinics is challenging in the face of increased patient loads, decreased reimbursements and potential negative productivity impacts of using electronic health records (EHR). We modeled outpatient ophthalmology clinic workflow using discrete event simulation for testing new scheduling templates that decrease patient wait time and improve clinic efficiency. Despite challenges in implementing the new scheduling templates in one outpatient clinic, the new templates improved patient wait time and clinic session length when they were followed. Analyzing EHR data about these schedules and their adherence to the template provides insight into new policies that can better balance the competing priorities of filling the schedules, meeting patient demand and minimizing wait time.

Introduction

Physicians today are pressured to see more patients in less time for less reimbursement due to persistent concerns about the accessibility and cost of healthcare.\textsuperscript{1,2} Furthermore, clinicians are concerned that the adoption of electronic health records (EHRs) has negatively impacted their productivity.\textsuperscript{3–5} For example, at Oregon Health & Science University (OHSU), which completed a successful EHR implementation in 2006 that received national publicity, ophthalmologists currently see 3-5\% fewer patients than before EHR implementation and require >40\% additional time for each patient encounter.\textsuperscript{6}

Clinic inefficiencies result when patients arrive and clinic resources (staff, exam rooms, and providers) are not available to serve them. This mismatch of arrivals and availability can be caused by ad-hoc scheduling protocols that increase patient wait time.\textsuperscript{7} Previous work has demonstrated that EHR timing data can be used for building clinic simulation models for studying scheduling templates before implementing them in the clinic.\textsuperscript{8} These models, along with prior research, confirm that scheduling longer encounters with higher variability at the end of the day helps reduce wait time.\textsuperscript{9}

While simulation models can predict improvements with new scheduling templates, implementing them in clinic faces real-world challenges such as competing clinic priorities, and established scheduling practices. While efficient workflow is a priority in outpatient clinics, so is filling all appointment slots and serving urgent walk-in patients. Clinic staff become adept at navigating clinic schedules, ensuring that all urgent patients are scheduled and appointment slots are filled, including those that are last-minute cancellations. New scheduling templates disrupt these practices and priorities, which can make following new schedules challenging.

We implemented a new scheduling template in one outpatient ophthalmology clinic (LR) at OHSU starting in September 2016 after preliminary studies demonstrated its effectiveness.\textsuperscript{10} As expected, there were challenges in implementing the new template, but when it was followed, there were reductions in average patient wait times and clinic session lengths. The purpose of this paper is to analyze challenges in a real-world implementation of simulation model based workflow improvements. Analyzing data about adherence to the new template will provide insight into new policies that can better balance the competing priorities of filling the schedules, meeting patient demand, and minimizing wait time, ultimately improving the clinic workflow. We found that 1) complex templates that the simulation predicts as optimal can be challenging to follow, 2) secondary use of EHR data allowed for a thorough analysis of a complex scheduling template and suggested ways to simplify it, 3) when the template was followed, scheduling according to exam length significantly improves patient wait time and session length, especially when short exams are scheduled at the start of the clinic, 4) these insights have impacts for developing new scheduling policies and strategies, and 5) EHR timing data enables detailed evaluation and improvement of clinic workflow modifications.
Methods
This study was approved by the Institutional Review Board at Oregon Health & Science University (OHSU).

Study Environment
OHSU is a large academic medical center in Portland, Oregon. The ophthalmology department includes over 50 faculty providers, who perform over 90,000 annual outpatient examinations. The department provides primary eye care, and serves as a major referral center in Pacific Northwest and nationally. We studied one provider’s outpatient clinic in pediatric ophthalmology (LR).

Over several years, an institution-wide EHR system (EpicCare; Epic Systems, Madison, WI) was implemented throughout OHSU. This vendor develops software for mid-size and large medical practices, is a market share leader among large hospitals, and has implemented its EHR systems at over 200 hospital systems in the United States. In 2006, all ophthalmologists at OHSU began using this EHR. All ambulatory practice management, clinical documentation, order entry, medication prescribing, and billing tasks are performed using components of the EHR.

Clinic Workflow
Interviews and clinic observations determined the basic clinic workflow of the majority of patient appointments as shown in Figure 1. Patients check in and wait to be seen. An ancillary staff member (an ophthalmic technician or orthoptist) performs an initial exam in an exam room. At the end of this exam, the patient’s eyes may be dilated. If this is the case, the patient returns to the waiting room while waiting for the dilation to take effect. After the dilation occurs (approximately 25 minutes), the patient is returned to an exam room and waits for the physician exam. If the patient’s eyes were not dilated, the patient remains in the exam room and waits for the physician. After the physician’s exam, the patients check out and leave. Waiting occurs before each of the two exams if a staff member (2 total) or physician (1 total) is not available.

Simulation Model Using EHR Timestamp Data
To build models for studying the clinic’s efficiency, we first had to collect large amounts of timing data for each step of the clinic workflow. In prior studies, we identified sources of timestamp data within the EHR and verified them against timing data from in person observations. We used the clinical data warehouse and ophthalmology datamart for OHSU’s EHR (EpicCare; Epic Systems, Madison, WI). While these timestamps are specific to OHSU’s implementation in ophthalmology, comparable timestamps are available for other vendors, installations and specialties. We used this timing data in our models, and for measuring the average patient wait time before and after we changed the scheduling templates.

We used Arena simulation software to build a discrete event simulation model of a pediatric outpatient ophthalmology clinic’s (LR) workflow using the EHR timing data. Previous studies validated this model and used it to test different scheduling templates. Schedules with the longest appointments near the end of the clinic session minimized average patient wait time, but could also lengthen clinic sessions. As a compromise, scheduling long patients near the end of the clinic, but not at the very end, still reduces wait time without unduly lengthening the clinic.

New Schedule Template
Based on the results of the simulation studies and input from the clinic provider and staff, we created a new scheduling template to be used within the pediatric provider’s clinic. Patients’ appointments were scheduled according to their anticipated length and dilation status: shortest appointments were earliest, with the longest appointments near the end of the clinic to minimize patient wait time. We classified the short appointments as roughly the shortest quarter of
appointments and the long appointments as the longest quarter. The remaining appointments were designated as medium. Each clinic session was a half-day with patients scheduled in 15 minute blocks. Because of OHSU’s scheduling policies, all appointment blocks must be the same length. The morning clinic schedule is given in Figure 2; the afternoon schedule was similar, but without the empty block and one each fewer of short and medium blocks. Morning clinics ran from 8:00 am until about 12:00 noon with 15 total patients; afternoon clinics began at 12:45 pm or 1:00 pm and ended by 5:00 pm. To ensure that afternoon clinics ended on time, there were usually fewer patients scheduled (13). In both clinic sessions, we scheduled the long patients near the end of the clinic, with 3 non-long patients after them to avoid clinic sessions ending late. In the morning clinic, the staff wished to include an empty slot in the middle of the long patient appointment slots to allow for catchup. The first appointment slot was double booked with one dilated patient and one not. This allowed the provider to get started quickly with the non-dilated patient.

Previous studies identified which exams were expected to be shorts and longs, but also found that there was quite a bit of variability among appointment lengths that was not easy to predict (Spatar D, et al. IOVS 2016;57:ARVO E-Abstract 5566). Fortunately, the provider was very good at assessing the length of the exam. For this reason, the provider documented her prediction (short, medium, or long) for the next appointment in the followup notes for the encounter, which are viewed by the scheduler when scheduling the next appointment. New appointments are always long.

Finally, the provider and staff wished to try alternating dilated and non-dilated appointments for preventing multiple patients waiting for the provider at the same time. Appointment slots on the schedule were designated as dilated or non-dilated exams, which required schedulers anticipating which type of exam the patient required at time of scheduling. Again, the provider documented her preference in the notes and other information about the appointment helped with this prediction.

The new scheduling templates were put into place starting in April 2016 for appointments scheduled September 1 or after. The provider started documenting her exam length and dilation predictions in her followup notes at this time. Even with a lead time of 5 months, there were still appointments already scheduled after September 1 using the old templates; the clinic decided to leave them as scheduled, regardless of whether they followed the new scheduling template.

New Schedule Template Evaluation Metrics

To assess the performance of the new scheduling template, we used two metrics: patient wait time and clinic length. The patient wait time was calculated using EHR timestamps and data about the appointment from the OHSU datamart. Exam lengths were determined by EHR audit log timestamps recorded between the appointment’s check in and check out times. Wait times are calculated by subtracting the exam length and dilation length (25 minutes for dilated exams, 0 for non-dilated exams) from the entire time the patient was checked in for their appointment.

We found that we needed to adjust this wait time since many patients arrived significantly early for their appointments. Because OHSU provides care for a large geographic region throughout the Pacific Northwest, many patients arrive early because of concerns about traffic and/or with the hope of being examined earlier. Often the patients are seen before their appointment times, so it was not meaningful to count only the wait time that occurred after their scheduled appointment time. Instead we eliminated any wait time that occurred before the exam started that was also before their scheduled appointment time. Once the patient started the exam, all subsequent wait time was counted. Clinic length is calculated as the difference between the first timestamp recorded during an exam in the clinic and the last timestamp recorded for the last exam of the clinic.
New Schedule Template Evaluation

To evaluate the impact of the new schedule in October – December 2016, we first compared the average patient wait times and clinic lengths to baseline sessions for the same clinic from July 2015 – June 2016, when the old scheduling templates were used. We used a t-test to compare our two metrics and investigated differences between the two groups with respect to new patient appointments, adult patients, dilated patients, early and late patients, double booked appointments, unfilled appointment blocks and known long exams at the start of the clinic session.

To further analyze the new schedule, we compared the scheduled appointments with the scheduling template to determine when and how well the templates were followed. Again, we used data from the EHR to assess the adherence to the scheduling template: the followup notes from the previous exam, the date of the previous exam, the type of scheduled encounter, and the age of the patient. The followup notes, when available, provided the provider’s predictions for exam length and dilation. When the notes weren’t available, we used our previously determined rules for predicting exam length based on encounter type and patient age (new vs. return, adult vs. child, pre-op, post-op or followup). The date of the previous appointment determined the dilation status (most patients require dilation once annually). We coded each appointment block according to its predicted exam length and dilation along with the corresponding template block’s exam length and dilation. We used linear regression to determine the wait time and session length impacts of following the schedule according to exam length and dilation.

Results

New vs. Old Scheduling Templates

We compared the performance of the new scheduling templates (Oct – Dec 2016) to our baseline (July 2015 - June 2016), which used the old templates. For our two main metrics, average patient wait time and clinic session length,

* Unfilled blocks represent any appointments where a patient canceled or didn’t show, and/or the staff was unable to fill the block
† Blocks that had 2 patients scheduled and both showed.

**Table 1: Comparison of New and Old Scheduling Templates.** For both patient wait time and session length, the new schedule was not significantly different from baseline (p > 0.05 for both). All other clinic characteristics were similar for both the new schedule and baseline.
the new template was not significantly different from the old template as shown in Table 1. The means for wait time (20.6 minutes for new and 22.1 minutes for old) and the means for session length (242.3 minutes for new and 232.1 minutes for old) were not significantly different when compared using a t-test ($p = 0.09$ and $p = 0.08$, respectively).

We also measured other characteristics relating to the schedules for both the old and new template periods in Table 1. Both groups were similar with respect to the number of dilated, new, adult, early and late patients per session. They also had similar numbers of unfilled blocks and double-booked blocks. Finally, because the new template does not schedule long patient appointments at the start of the clinic session, we compared the number of adult and new patients (always long appointments) at the start of the session. Both were similar, with slightly more new patients at the start of the baseline clinics.

**Scheduling Errors**

Since the wait times, clinic lengths and clinic characteristics for the new schedule test period were similar to the old templates in the baseline, we analyzed the new schedule test period for adherence to the new schedule template.

**Figure 3** shows the impact of schedule adherence on average patient wait time and session length. For each clinic session, the percentage of correct blocks for exam length and dilation was plotted versus the average patient wait time and session length for that clinic session. As the percentage of correctly scheduled exam length blocks increased, the wait time decreased significantly: 3.7 minutes per 10% increase in correct exam length blocks ($p < 0.0001$). Similarly, the session length decreased by 7.7 minutes per 10% increase in correct exam length blocks ($p = 0.008$), according to the linear regression models shown in the figure. Correctly scheduling the dilation blocks did not significantly decrease the wait time or session length.

To understand how the clinic adhered to the template, we analyzed the scheduling errors. **Table 2** outlines the different types of appointment blocks and the errors made in scheduling them; 240/677 (36%) appointment blocks were not scheduled correctly with respect to exam length and 270/677 (40%) were incorrect with respect to dilation. Breaking the appointment blocks down according to exam length shows that similar percentages (31% - 39%) were scheduled incorrectly. Finally, 14/24 (58%) blocks intended to be blank were scheduled with appointments. Since errors with were occurring frequently—30 – 40% of the time—it was important to determine which errors had the biggest impact.
Figure 4 shows the impact of scheduling errors for short, medium and long exam block errors. The most significant impacts were for short block errors: they increased wait time by 1.5 minutes for each 10% increase in errors (p = 0.008) and they increased clinic length by 4.8 minutes per every 10% increase in errors (p = 0.005) as predicted by the linear regression models shown in the figure. The only other significant impact was on clinic length for medium block errors: those decreased the session length by 5.5 minutes for each 10% increase in errors (p = 0.01).

Looking at just the short scheduling errors, we see that scheduling longs in a short exam block had the most significant impact as shown in Figure 5. For every 10% increase in the number of long exams in short blocks the wait time increased by 1.5 minutes (p = 0.01). There wasn’t a significant increase in session length for long exams in short blocks, nor was there a significant impact of scheduling medium exams in short blocks on wait time or session length.

Discussion

The new clinic schedule did not significantly decrease patient wait time or clinic session length over baseline for the entire 3 months we evaluated, presumably because the schedule was not followed for all clinic sessions. This highlights the difficulty in implementing scheduling changes predicted to be optimal based on simulation models. Analyzing the clinic sessions’ schedules for errors gives us insight into improving the scheduling process in the future. In particular, we found:

Table 2: Scheduling Errors. The schedule was not followed for both exam length and dilation: 39.9% of blocks were incorrectly scheduled for dilation and 36.2% of blocks were incorrectly scheduled for exam length.

Figure 4: Impacts of Short, Medium, and Long Block Scheduling Errors. Scheduling short blocks incorrectly had the most significant impact on wait time and session length (p = 0.0009 and p=0.005, respectively). Scheduling medium blocks incorrectly also significantly impacted session length (p = 0.01), but not patient wait time. Long block scheduling errors did not significantly impact patient wait time or session length.
1. Complex templates that simulation predicts as optimal can be challenging to follow. At best, 60% of blocks were correct for dilation and 64% were correct for exam length. From our discussions with schedulers, we determined the new template was too difficult to schedule for both exam length and dilation, there weren’t enough dilation blocks (only 277 were designated as dilated blocks, but there were 383 actual dilated patients), not all patients had provider predictions, and there are competing priorities for maintaining clinic volume. When patients cancel, the appointment blocks must be filled, usually with new patients who require long exams. This highlights the substantial challenges for implementing new scheduling templates and the importance of evaluation for determining their benefits.

Table 3 provides a breakdown of the potential sources for scheduling errors. Some appointments were scheduled prior to the implementation of the scheduling template in April of 2016 and these appointments weren’t changed if they violated the schedule. For example, 14.5% of the errors in short blocks were due to this. Also, when patients canceled close to the appointment time, there is pressure to fill the appointment block; this caused 29.1% of the short block errors. Missing provider predictions for appointments also results in errors; this caused 78.2% of the short block errors. Some of these were new patients who didn’t have predictions (Schedulers know they are always longs) or patients whose previous appointment was prior to April of 2016, before the provider started documenting her predictions. The remainder were appointments that should have had predictions, but were missing. Nevertheless, even with predictions, there were still scheduling errors. This highlights the need for more provider predictions and better training for schedulers to follow them. It also motivated us to find ways to simplify the schedule.

2. Secondary use of EHR data allowed for a thorough analysis of a complex scheduling template and suggested ways to simplify it. We determined dilation block scheduling errors do not appear to worsen wait times or session length and it is difficult to schedule for both dilation and exam length. For both of those reasons, we simplified the template to exclude dilation, which we hope eases the schedulers’ burden.

3. When the template was followed, scheduling according to exam length significantly improves patient wait time and session length, especially when short exams are scheduled at the start of the clinic. Wait time decreases by 3.7 minutes per 10% increase in correct exam length blocks and session length decreases by 7.7 minutes per 10% increase in correct blocks. Further, scheduling short patients at the start of the clinic helps the clinic stay on time and reduce patient wait times for subsequent patients. It is most significant to avoid scheduling long exams in the short exam blocks, but even medium exams can have an impact. This result is important since it validates our simulation models and previous studies⁸,⁹ and confirms that our schedule can improve clinic efficiency if it is
4. These insights can lead to better scheduling and potentially innovative dynamic scheduling strategies. There are currently many opportunities and possible innovations for improving scheduling in healthcare. For example, because scheduling long patients at the start of the clinic has the biggest impact on patient wait time, all attempts should be made to avoid doing this, even when an early block becomes available for a long patient (e.g. a new patient). Schedulers should attempt to shift shorter exams to this block or double book the new patient later, leaving the short block empty. The unfilled blocks (typically 1-2 per clinic session) due to no shows or late cancels can help offset this double booking. Also, since the clinic has a high number of early patients, any that have short or medium exams can be worked in to fill that early blank spot. Other possibilities include innovative dynamic scheduling strategies where patients are scheduled for a given clinic session, but not assigned an appointment time until just prior to the session. That way, patients could be arranged so that the shortest appointments were first, followed by the mediums and longs.

5. EHR timing data allows for detailed evaluation and improvement of clinic workflow modifications. EHR data can be used to measure metrics such as average patient wait times, session lengths, and adherence to scheduling templates which allows for a detailed evaluation of a new scheduling strategy. While this study focuses on a new scheduling template in an outpatient ophthalmology clinic, EHR timing data can be used to analyze any workflow modification in any setting. This timing data can determine if a new modification is having the desired impact and why, leading to potential improvements. Without using EHR data, metrics would be gathered manually through observations, which is prohibitive for any extended test period and may not provide as rich of insights.

Limitations

This study has the following limitations: 1) It uses EHR timestamps for measuring exam times, calculating patient wait times, and session lengths. If the provider’s or staff’s EHR use doesn’t coincide with their exams, the wait time and session length calculations could be wrong. Previous studies have validated this approach, but errors may still occur. 2) The new schedule was studied for a 3 month time period—its performance may vary if a longer test period including multiple seasons was used. We plan to evaluate the schedule again, particularly after more scheduler training and after relaxing the dilation criteria. 3) We focused our evaluation to quantitative methods, but qualitative evaluation will provide more insight into the benefits and challenges of the new schedule implementation. A followup qualitative study is planned to address this limitation. 4) OHSU’s policy of equal length scheduling blocks eliminates other potential optimal scheduling policies, such as variable length appointments. 5) We assume that long appointments can be scheduled near the end of the clinic; if this is not the case, then other strategies would need to be used to mitigate the potential delays incurred by long patients at the start of the clinic. Future studies are needed to investigate strategies such as variable length appointments or empty “catchup” blocks for early long appointments.

Table 3: Sources of Scheduling Errors. A few scheduling errors occurred because of appointments that were scheduled prior to the new template’s implementation: it accounts for 14.5% of the short block errors. Others occurred because of late scheduling, but the majority of errors happened without provider predictions (78.2% of the short block errors), but even with predictions there were still errors (21.8% of the short block errors).
Conclusions

Simulation models predict that scheduling according to length—short appointments first, followed by longer appointments—significantly decrease patient wait times and session length. Real world implementations of these scheduling rules, however, can be challenging, but using EHR timing data can evaluate the effects of compliance. Secondary use of EHR data allows for a detailed analysis of a new scheduling template, with the goal of identifying critical aspects of the modification and those that can be eliminated. This study focuses on a scheduling template in outpatient ophthalmology, but the data analysis techniques apply to the evaluation of any workflow modification in any setting.

Abstract
Psychological stress is a major contributor to the adoption of unhealthy behaviors, which in turn accounts for 41% of global cardiovascular disease burden. While the proliferation of mobile health apps has offered promise to stress management, these apps do not provide micro-level feedback with regard to how to adjust one’s behaviors to achieve a desired health outcome. In this paper, we formulate the task of multi-stage stress management as a sequential decision-making problem and explore the application of reinforcement learning to provide micro-level feedback for stress reduction. Specifically, we incorporate a multi-stage threshold selection into Q-learning to derive an interpretable form of a recommendation policy for behavioral coaching. We apply this method on an observational dataset that contains Fitbit ActiGraph measurements and self-reported stress levels. The estimated policy is then used to understand how exercise patterns may affect users’ psychological stress levels and to perform coaching more effectively.

Introduction
Psychological stress has long been shown as the source of unhealthy behaviors and in turn contributes to the increase of cardiovascular disease risk [1]. Public health experts have been advocating on the importance of behavioral factors on cardiovascular risk, which account for 41% of global cardiovascular disease burden [2, 3]. Improving on exercise behaviors, in particular, has been shown as a cost-effective solution compared to pharmacological treatments. Recent research has demonstrated the benefit of regular exercise and physical activities on reducing stress and improving emotional well-being [4, 5]. Yet its implementation often fails due to the lack of systematic monitoring for effective coaching. Early research in clinical decision support systems has attempted to integrate multimodal sensor input to start guiding the management of psychological stress. However, its clinical uptake has been slow due to the lack of intuitive reasoning and explanation capability [6].

In fact, the stress-behavior mechanistic pathway is a process that is highly individualized, in which interpretations of the environmental demand and adaptive capacity ("appraisals") are important in determining psychological, behavioral, and physiological responses to stress [7]. Previous clinical trials have demonstrated the effectiveness of individualized stress management for obtaining certain goals, e.g., hypertension control [8]. The recent proliferation of mobile health and self-tracking mobile apps has offered new promise to further integrate daily monitoring data into the process of individualized stress management. However, a most recent review of existing stress management apps [9] has shown that there is still a lack of apps that can provide user behavior-oriented feedback such as prompting for a specific goal. Therefore, how to leverage individual observations to provide incremental micro-level feedback has been a key challenge to the development of behavioral coaching systems.

In many other domains, recent technological advances in mobile health have used smart phones and wearable devices to collect data and deliver interventions over time. Evidence has emerged for the potential of drawing sequential patterns from patient-reported outcomes (PRO) [10] and Ecological Momentary Assessments (EMA) [11] to make predictions and recommendations. This is favorable by behavior scientists and healthcare researchers, since mobile devices provide an interactive platform that has great potential to promote health behaviors and achieve better health outcomes [12, 13]. Despite that simply measuring users’ calories intake and exercise patterns has only limited effect on outcomes, such as long-term weight loss [14], it still has been expected that the development of mobile-based behavioral coaching systems would be beneficial to understand the implicit user preferences and barriers so as to guide users for goal attainment with personalized training plans. In addition, behavior interventions can be tailored based on users’ changing needs and ongoing performance. The delivery of such interventions has started being attempted in the area of substance use disorder [15], physical activity [16], mental health [17, 18] and diabetic self-management [19]. Yet the methodology is under development for these behavior intervention studies.
As a first step towards an interactive and personalized behavioral coaching system for stress management, we need to build on the observations of actions and self-reported outcomes over time to derive recommendations of beneficial behaviors and to guide users to achieve healthy outcomes. Intuitively, this can be represented as a sequential decision-making problem. Under similar problem specifications, reinforcement learning algorithms [20], for example Q-learning, can be applied to solve this problem by estimating an optimal policy, i.e., a set of decision rules for selecting actions that maximize long-range cumulative reward. However, the “black-box” nature of reinforcement learning algorithms makes it less appealing for stress management coaching systems that require explicit explanations for recommended actions -- as demonstrated in the previous clinical decision support research [6]. In many other fields, such as clinical trials, explicit explanations are also preferred for decision-making. Statistical methods have been developed for prescribing adaptive treatment regimes in clinical trials [21, 22, 23]. In this paper, we apply a Multi-stage Threshold Q-learning (MTQL) method and construct interpretable policies that map from subjects’ up-to-date observations to recommend actions adaptively for stress reduction coaching. We make model assumptions for the Q-learning algorithm and incorporate a threshold-finding step to identify optimal sub-goals for recommendation. In the rest of this paper, we will first introduce the stress data used in the study and describe the MTQL method. Then we will demonstrate and discuss the interpretable policies derived from the MTQL method on the dataset.

Method

Data Collection

In this paper, the stress dataset used was collected in a longitudinal study during Jan 2014 to July 2015 from 79 subjects. The observations used to evaluate the MTQL method were from the first twelve weeks of the study. 75 subjects had complete data for that period of time.

Subjects in the study were healthy individuals aged 18 or older who responded to fliers posted throughout the buildings of Columbia University Medical Center and who on phone screening reported only intermittent engagement in exercise (exercise 6-11 times per month, not on a regular basis), had daily access to a computer with Internet, and had an iPhone or Android phone. Excluded were individuals who had previously been told by a healthcare professional to restrict physical activity, were deemed unable to comply with the protocol (either self-selected, by indicating during screening that he/she could not complete all requested tasks), were unavailable during the following continuous twelve months, had serious medical comorbidity that would compromise their ability to engage in usual physical activity, had occupational work demands that required rigorous activity or would make responding to the EMA dangerous, or were unable to read and speak English.

Physical activity was continuously and objectively measured using a wrist-based model of the Fitbit (Fitbit Flex; Fitbit, Inc., San Francisco, CA) [24]. The Fitbit Flex is a microelectromechanical triaxial accelerometer that tracks the wearer’s daily physical activity including steps, intensity of activities (sedentary, light, moderate, or vigorous) and energy expenditure. We and others have shown that the Fitbit Flex is a valid and reliable device for measuring physical activity in adults [25, 26].

Minute-by-minute activity data were extracted using Fitabase (Small Steps Labs, San Diego, California). We defined a “social day” as the period from 3am one day until 2:59am the next day. Non-wear was defined as greater than 60 consecutive minutes with fewer than 10 steps. Only days with a minimum of 10 hours of wear time were included in analyses. Each valid day was then classified as an exercise or non-exercise day. Our objective measure for exercise was defined as at least 24 minutes of moderate or vigorous physical activity (MVPA) within any consecutive 30-minute period, thereby allowing for up to 6 minutes of below threshold physical activity (e.g., rest). Such an instance is referred to as an “MVPA bout”. This definition was adapted from conventional accelerometer processing approaches used in many population-based studies [27, 28, 29] and suggested by best practice recommendations [30] wherein a healthful bout of physical activity is defined as a 10-minute or longer bout of MVPA with an allowance of 2 minutes below threshold (e.g. 8 out of 10 consecutive minutes). The 8 out of 10-minute bout was extrapolated to 30 minutes for the purposes of this study to be consistent with physical activity guidelines which recommend exercise in bouts of 10 minutes or more for at least 30 minutes a day, while accommodating interruptions.

An electronic diary that used the subject’s own iPhone or Android phone was used to capture momentary and summary aspects of their perceived stress. Each morning upon rising, the subject responded to a question on a browser asking them, “Overall, how stressful do you expect today to be?”, answered on a scale from 0 (Not at all) to 10 (Extremely). Similarly, each evening, the subject responded to a question on a browser asking them, “Overall, how stressful was your day?”, answered on the same scale. In addition, the diary system was programmed to query
the subject via text message or email 3 random times per day over their preset hours of wakefulness (e.g., 7am-10pm), with the specific time period programmed individually according to the subject’s own sleep schedule. Notifications were separated by at least 1 hour. Each of the 3 daytime momentary assessments included questions concerning key sources of stress (one screen listing sources of stress including work, argument, traffic, deadline trouble, paying bills, running late, none, or other, with the subject checking all that apply) [31], stress appraisal using the four-item Perceived Stress Scale [32]. Before each prompt, the subject responded to a question asking “how stressful did you feel?”, answered on the scale specified before. Data transmission was secured via SSL (i.e., https) and sent to a managed server.

The data used for the analyses includes duration of daily MVPA bouts, perceived stress levels, exogenous and environmental factors (such as day in a week, daylight time, temperature and precipitation).

Problem Formulation for the Multi-stage Threshold Q-learning Method

We observed a sequence of data discussed in the last section and aim to maximize the mean stress level reduction from baseline over a given time period. At baseline, the subjects’ characteristics and stress information were collected. We defined the baseline stress level as the mean stress level over the first four-week of the study. After four weeks, daily actions (e.g., MVPA pattern) and daily health outcomes (e.g., stress level) were observed at each stage. The action was binary and defined as if the mean duration of daily MVPA bout over the time period of the stage was greater than 30 minutes then the action was denoted as 1 otherwise 0. Mean stress level was used as the health outcome of interest, which was a continuous value ranging from 0 to 10. Everyday the stress level was assessed three times during the wakefulness time of the subjects and the overall stress level was assessed at the end of the day. If the value of the overall stress level was not missing, then the daily stress level was defined as the overall stress level. Otherwise, it was defined as the average of the stress levels assessed during the wakefulness time. The stress level at each stage was calculated by averaging over the daily stress level during the time period of the stage. In a T-stage study for each subject $i$, we observe the data:

$$\{O_{it}, A_{it}, O_{it+1}, \ldots, O_{iT}, A_{iT}, O_{(T+1)}\}$$

$O_{it}$ is a baseline stress level, $O_{it}$, where $1 < t \leq T + 1$, is a stress level at the $(t-1)$-stage, and $A_{it}$ is a binary action at the $t$-stage. Since stress levels were self-evaluated, subtracting the baseline stress level from the following stress levels evaluated helps to adjust for heterogeneity of self-evaluation across subjects. We define $R_{it} = O_{it} - O_{it+1}$ as the stress reduction from baseline at the $t$-stage, which is also the reward at the $t$-stage. We use $H_{it}$ to denote historical information for subject $i$ before the $t$-stage, for example $H_{i1} = \{O_{i1}\}$ and $H_{i2} = \{O_{i1}, A_{i1}, O_{i2}\}$.

Q-learning is a commonly used method of reinforcement learning introduced by computer scientists to construct high quality policies [20]. Q-learning models the interaction between an agent and environment. In our setting, the agent refers to each subject in the study, and environment refers to the system of human body and external source of observations. The Q-learning algorithm uses a backward induction to estimate the optimal policy $\pi$, which consists of a sequence of decision rules $\pi_1, \ldots, \pi_T$, under which the cumulative reward is maximized. At the $t$-stage, a decision rule $\pi_t$ takes the historical information of a subject $H_{it}$ as an input and outputs a recommended action $A_{it}$. The $t$-th subject with historical information $H_{it}$ takes an action $A_{it}$ and gains a reward $R_{it}$. In the computer science field, researchers focus on solving infinite time horizon decision-making problems [20], while in the statistical field, methodologies were developed to solve finite time horizon problems using statistical models [21-23, 33-36]. The MTQL method combines statistical methods with the Q-learning algorithm to construct interpretable decision rules. In the following, we use lower-case variables to denote the realizations of the corresponding upper-case random variables. We define a value function at the $t$-stage:

$$V_t(h_t) = E_\pi \left( \sum_{k=0}^{T} r_{t+k} | h_t \right)$$

Then the optimal value function is the one maximized over all possible policies $\pi$ in the policy space $\Pi$, i.e., $V_t^\ast(h_t) = \max_{\pi \in \Pi} V_t(h_t)$. We define the optimal Q function at the $t$-stage:

$$Q_t^\ast(h_t, a_t) = E[r_t + V_{t+1}(h_{t+1}) | h_t, a_t]$$

By definition, the relationship between a value function and a Q function is $V_t^\ast(h_t) = \max_a Q_t^\ast(h_t, a) = E[r_t + \max_{a_{t+1}} Q_{t+1}^\ast(h_{t+1}, a_{t+1}) | h_t, a_t]$. 

932
The optimal Q function $Q^*_t$ (referred to as the Q function in the following) is estimated based on the Bellman equation [37] backwards through time. The optimal policy is defined as $\pi^*_t(h_t) = \arg\max_{a_t} Q^*_t(h_t, a_t)$.

In our proposed MTQL method, we assume a regression model for the Q function. The benefit of assuming a regression model is to make the estimated Q function and policy interpretable. A threshold-selection step is added into the learning process. The thresholds are set for the health outcome variables and selected by maximizing the expected cumulative reward. The estimated thresholds are considered as goal-setting options of the health outcome. Our goal is to estimate a sequence of optimal decision rules that maximizes the expected health outcome.

We illustrate the proposed method in multi-stage studies and discuss the effect of setting different numbers of stages on the expected health outcome. Our goal is to estimate a sequence of optimal decision rules that maximizes the mean stress reduction from baseline over a four-week period. This can be formulated as a four-stage study ($T=4$) with one week for each stage, or a two-stage study ($T=2$) with two weeks for each stage, or a one-stage study ($T=1$) with four weeks for one stage. We describe the variables used in modeling Q functions in Table 1.

Table 1. List of variables used in modeling Q functions.

The Q function consists of the main effect and the interaction effect. The interaction effect assesses the association of the historical information and the value of the Q function under different actions. We use $H_{10} = (1, R_1, A_1, R_2, A_2, \ldots, R_T)$ to denote the design matrix for the main effect and use $H_{11} = (1, I_{t-1}, A_{t-1}, I_t, I_{t-1}I_t, I_{t-1}A_{t-1}, A_{t-1}I_t)$ to denote the design matrix for the interaction effect. Let $\theta_t$ be a vector of regression coefficients which consists of the coefficients of the main effect $\theta_{t0}$ and the coefficients of the interaction effect $\theta_{t1}$, i.e., $\theta_t = (\theta_{t0}, \theta_{t1})$. The model of the Q function at the $t$-stage, for $t = 2, \ldots, T$, is of the form:

$$Q_t(h_t, a_t; \theta_t, c_t) = h_{t0}\theta_{t0} + (h_{t1}a_t)\theta_{t1}$$

For the first stage ($t = 1$), let $H_{10} = (1, O_1)$ and $H_{11} = (1, 1(O_1 > c_t))$, thus

$$Q_1(h_1, a_1; \theta_1, c_1) = h_{10}\theta_{10} + (h_{11}a_1)\theta_{11}$$

The optimal policy is estimated from the last stage to the first stage using a backward induction. The optimal policy at the $t$-stage is of the form:

$$\pi^*_t(h_{t1}; \theta_{t1}, c_t) = \arg\max_{a_t} Q^*_t(h_{t1}, a_t)\theta_{t1}$$

The parameters of a policy consist of the regression parameter $\theta_t$ and the threshold parameter $c_t$. $\theta_t$ is estimated as a least square estimator. More specifically, at final stage $T$ given an estimated threshold parameter $\hat{c}_T$,

$$\hat{\theta}_T = \arg\min_{\theta_T} \sum_{i=1}^{n} (R_{iT} - Q_T(h_{iT}, a_{iT}; \theta_T, \hat{c}_T))^2$$

At a previous stage $t$:

$$\pi^*_t = R_{it} + \max_{a_{i(t+1)}} Q_{t+1}(h_{i(t+1)}, a_{i(t+1)}; \hat{\theta}_{t+1}, \hat{c}_{t+1})$$

933
The estimated threshold parameter $\hat{c}_t$ is chosen as the one that maximizes the mean stress level reduction from baseline $Y$. We introduce an inverse probability weighting estimator (IPWE) [34], which is an expected outcome under a given policy. IPWE does not depend on model assumptions, thus is robust to model misspecification. It is used to evaluate the estimated parametric policies. IPWE is defined as

$$\frac{\sum_{i=1}^{n} W_i Y_i}{\sum_{i=1}^{n} W_i}$$

where the weight

$$W_i = \frac{\prod_{k=1}^{T} 1(a_{ik} = \pi_k(h_{ik}; \theta_t, c_t))}{\prod_{k=1}^{T} p_k(a_{ik} | h_{ik})}$$

$p_t(a_{it} | h_{it})$ is a propensity score estimated using logistic regression. The logistic regression model is built based on variable selection using P-value less than 0.2 as a criterion, and it contains the variables of stress level, action, gender and mean precipitation. The threshold parameter $c_t$ is estimated using the genetic algorithm [38] to maximize the mean stress reduction from baseline. Genetic algorithm is a heuristic searching algorithm and has computational advantages for solving optimization problems.

**Policy Estimation from the Observational Data**

In the observational study, we consider a binary action of whether exercising more than 30 minutes daily on average (i.e., daily MVPA bout on average is greater than 30 minutes) over the time period of a stage, and define “active” as exercising more than 30 minutes daily on average, and “inactive” otherwise. The health outcome of our interest is the self-evaluated stress level on average over the time period of a stage. We use the data of the first four weeks of the study for assessing the baseline information, the data of the second four weeks as the training data and the data of the third four weeks as the test data. We apply the MTQL method on the training data to estimate the optimal policy and evaluate it on the test data. The estimated tree-structured policy is presented below in Figure 1-3 respectively. Our goal is to compare the expected outcomes estimated in a one-stage study, in a two-stage study and in a four-stage study in order to evaluate the effect of setting different numbers of intervention stages.

**Results**

![Figure 1. Estimated optimal policy for the one-stage study.](image-url)
Figure 2. Estimated optimal policy for the two-stage study.
Figure 1 shows the estimated optimal policy in a one-stage study over the time period of four weeks. That is, if a subject has perceived baseline stress level higher than 4.4 (on a scale of 0-10), then for obtaining the optimal stress reduction outcome, this subject should be recommended to stay “active” (i.e., exercising more than 30 minutes daily on average) in the next four weeks. This recommendation is similar to what has been offered by the existing stress management apps (as surveyed in [9]). The threshold learned here can help subjects and their care team to understand whether keeping active would be expected to yield a positive impact on the overall stress reduction for them.

As we expect that a fine-grained level of policy will reveal more actionable micro strategies for subjects and their care team, we further derive the optimal two- and four-stage policy from the data. Figure 2 shows the optimal policy estimated using the data of the first two weeks as one stage and the second two weeks as the other stage. The stress level 3.7 is learned as the baseline threshold to decide if we should recommend being active in the first two weeks, and 1.3 is learned as the threshold for the mean stress level increased from baseline to differentiate whether a target subject can potentially obtain an optimal outcome by adopting a sequential active-to-inactive strategy: i.e., staying active in the first two weeks, and then take a break in the next two weeks. For those subjects who have baseline stress level lower than or equal to 3.7, it would be important to observe whether being active in the first two weeks followed by an increase of mean stress level in the next two weeks. If the mean stress level increases greater than 1.3, then it is better not to suggest the active action any further to accommodate the individual behavioral preferences and barriers.

Figure 3 shows the finer-grained policy (one week as one stage) learned for making recommendations for subjects. It is important to know whether the target subject starts with a perceived mean stress level higher than 5.4, whether the subject is active during the first week and whether exercising helps reduce the subject’s mean stress level. The observed intermediate outcomes and actions would be important to determine whether to recommend being active or not in the next stage. To make the fourth stage recommendation, it is critical to keep observing for the mean stress level change in the second week and whether the user is active or not in the third week.

In addition to the empirical interpretation of the learned policy for curating actionable micro strategies, we are also interested in learning the quantifiable impact of a finer-grained policy on the overall outcome (i.e. the mean stress reduction from baseline). Applying the learned policies on the test data, the mean stress level reduction from baseline in the one-stage study is 0.04, the one in the two-stage study is 0.58, and the one in the four-stage study is 0.97. The distribution of the mean stress level reduction among the study subjects is shown in Figure 4. The estimated values of the mean stress level reduction based on different numbers of stages are indicated in Figure 4. The results show that dividing the study period into multiple stages and incorporating more sub-goals for micro-level feedback potentially help subjects achieving better stress reduction.
Discussion

There exist needs to propose new methods that can support the building of simple but interpretable decision making models and the discovery of optimal sub-goals so as to facilitate decision-making processes, instead of dictating interventions to subjects. In addition, a concern frequently raised for applying behavioral coaching is often that the evidence may not adequately reflect individual differences among users. In the past, psychologists and behavioral scientists have developed a variety of ideographic approaches for single-case experimental designs [39]. To extend the ideographic approach in experimental designs of intervention, researchers have further developed N-of-1 trials to help patients make health decisions that are informed by highly relevant, evidence-based information [40, 41, 42]. In this paper, we extend this school of thoughts to investigate how to further tie the insights learned from user-generated health data into an adaptive decision-making process. In particular, we develop a MTQL method to learn how to curate effective micro strategies for recommendations, with an implicit consideration of user preferences and barriers. The proposed method uses a simple form of regression models to approximate Q functions, and constructs an interpretable form of policies using the Q-learning algorithm. The policy learned using the MTQL method provides sub-goal setting options, which may affect the intervention process. In many other domains, such as tutoring, micro-level strategies have been validated to be beneficial in pragmatic settings [43, 44]. The proposed method in this paper provides a novel way to start exploring a more systematic monitoring and self-experimentation framework to derive sequential micro-level strategies for behavioral coaching.

Conclusion

In this paper we described a MTQL method to estimate the optimal policy in order to maximize the mean stress reduction for healthy adults over a four-week period. We implement the MTQL method on the stress data to illustrate the interpretability of the estimated policies and the way to provide recommendations based on the policies. The insights we gain from the stress data are three-fold: First, tracking whether intermediate stress reduction is achieved and what actions have been taken by a target user are important; the observations will affect the choice of different strategies of stress reduction in a longer term. Second, individualized stress management can benefit from the agility introduced by micro-level strategies. When we assume a finer-grained observation time unit, the system derives more effective micro-strategies that in turn lend support to subjects for achieving better stress reduction in a longer term. Moreover, when the system observes that a user has started going astray from his usual path, the system is still capable to find corresponding recommendations for this user for quick adaptation. Instead of insisting on the same recommendation for target users, the proposed approach is expected to be more flexible and effective in pragmatic settings. Last but not least, personal behavioral coaching recommendations have the potential to help managing people’s stress better by enabling more informed decision making. The derived insights are expected to benefit future collaborative care and self-care applications, such as sense making [19] and persuasive reminders [45]. These insights can also be used to provide feedback into adaptive N-of-1 trials [40, 41, 42] and self-experimentation [46]. Our work is a first step towards a behavioral coaching system, which can help consume systematic monitoring

Figure 4. Histogram of the mean stress level reduction from baseline over a four-week period. data of target users and transform the curated insights into micro-level feedback that can sequentially guide users through the care management process (or self-experimentation when applicable) to obtain the best possible outcome.

Framing Electronic Medical Records as Polylingual Documents in Query Expansion

Abstract

We present a study of electronic medical record (EMR) retrieval that emulates situations in which a doctor treats a new patient. Given a query consisting of a new patient’s symptoms, the retrieval system returns the set of most relevant records of previously treated patients. However, due to semantic, functional, and treatment synonyms in medical terminology, queries are often incomplete and thus require enhancement. In this paper, we present a topic model that frames symptoms and treatments as separate languages. Our experimental results show that this method improves retrieval performance over several baselines with statistical significance. These baselines include methods used in prior studies as well as state-of-the-art embedding techniques. Finally, we show that our proposed topic model discovers all three types of synonyms to improve medical record retrieval.

Introduction

The Obama administration made electronic medical records (EMR) a high-priority initiative, devoting significant amounts of resources to improve their adoption rate in healthcare practices1. As EMR databases are further introduced into daily usage, retrieval systems are increasing in importance. In particular, one important application of an EMR retrieval system is to efficiently parse medical records and identify those that are most relevant to a new patient. Standard information retrieval systems receive string queries as input, compute numeric scores that determine how well each database document matches the query, and output a ranked list of documents. Ideally, a doctor can query a system with a new patient’s symptoms and receive a set of relevant patient records. These records can serve as an informative baseline to prescribe suitable treatments for the new patient.

However, due to synonyms that occur in the medical vocabulary, the original search query may not be complete, and thus may not retrieve optimal results. There are three categories of synonyms of interest to medical record retrieval:

1. **Semantic synonyms** are medical terms that have identical meanings. For instance, “halitosis” and “fetor oris” are semantic synonyms because they are different terms that refer to the same symptom. Because doctors will typically record only one of these, queries that contain “halitosis” will not properly match records that contain “fetor oris”, and vice versa. Semantic synonyms can be mined with natural language processing techniques and straightforward statistical measures2.

2. **Functional synonyms** are terms that are not identical, but co-occur more frequently than random. “Arthritis” and “hypertension” are functional synonyms due to their comorbid relationship (a decade-long study showed that nearly half of elderly arthritis patients also suffered from hypertension)3. Thus, if a hypothetical query consists of only the term “arthritis” to describe an elderly arthritis patient with hypertension, the retrieved patient records may not contain treatments optimally suited for the query patient. Functional synonyms can be inferred from treatment synonyms, which are described next.

3. **Treatment synonyms** are drug-symptom pairs in which the drug treats the symptom. For example, “ibuprofen” and “fever” are treatment synonyms. Treatment synonyms can be obtained by mining medical publications4.

If a query consists entirely of symptoms, then semantic and functional synonyms are also symptoms. We show that augmenting an original patient query with all three synonym types can capture relevant but mismatched documents, thus improving retrieval performance.
In prior work, Zeng et al. performed query expansion in a similar medical record retrieval setting using synonyms and topic models. Their synonym-based query expansion utilized the Unified Medical Language System (UMLS), which is a compendium of biomedical vocabularies, to map query terms to their semantic synonyms. We refer to this method as the dictionary-based query expansion to avoid confusion. On the other hand, their topic-model-based query expansion trained on patient records to jointly find all three synonym types. However, using this standard topic model, symptoms and treatments are grouped together with no distinction in the medical records, which may decrease performance.

Rather than jointly mine these three types of synonyms, we separately modeled the symptom and treatment synonyms. Our approach is based on traditional monolingual topic models, but instead views the symptoms and treatments of a medical record as generated by distinct languages. Thus, outputted topics will be aligned across the two languages and will contain synonyms of all three types. This is because symptoms in the same topic are likely to be semantic or functional synonyms, while symptoms and treatments in aligned topics are likely to be treatment synonyms. Synonyms of query symptoms can then be used to augment the original query during retrieval. To the best of our knowledge, our proposed method is the first to model symptoms and treatments as separate languages in electronic medical records. We also compare with two embedding methods that jointly mine all three synonyms.

We evaluated our approach on a traditional Chinese medicine (TCM) medical record collection. We chose this dataset because functionally synonymous symptoms are even more prevalent in the TCM field. Thus, if our method could improve retrieval performance on this dataset, it would also work well for EMR datasets in other domains. We show that our method can improve over baseline methods, as well as state-of-the-art embedding methods, in query expansion.

Problem Formulation

Given a database of patient records \( R = \{r_1, \ldots, r_n\} \), the \( i \)th patient record \( r_i \) consists of a set of diseases \( D_i \), a set of symptoms \( S_i \), and a set of treatments \( T_i \). From this database, we wish to retrieve the set of patient records most relevant to some new patient \( p_{\text{new}} \) who is not in the database. To achieve this, we first reformulate \( p_{\text{new}} \)'s symptoms as a query. Thus, given \( p_{\text{new}} \)'s set of symptoms \( S_{\text{new}} = \{s_1, \ldots, s_j\} \),

\[
Q_{\text{new}} = S_{\text{new}} = \{s_1, \ldots, s_j\}
\]  

By performing query expansion on \( Q_{\text{new}} \), we add query terms to better match relevant records and thus improve the retrieval performance:

\[
Q'_{\text{new}} = \{s_1, \ldots, s_j, q_1, \ldots, q_l\}
\]

Here, \( \{q_1, \ldots, q_l\} \) is the set of expansion terms that are added to the original query. Although the original query \( Q_{\text{new}} \) only contains symptoms, the expansion terms can contain both symptoms and treatments. Expansion terms can be obtained with a variety of methods, which we discuss in the next section.

We hypothesize that the expanded query, \( Q'_{\text{new}} \), will retrieve more relevant documents because in practice, \( Q_{\text{new}} \) is usually not comprehensive. In our medical setting, this is analogous to situations in which the list of symptoms that a doctor identifies in a new patient is incomplete, which may be due to a combination of two major factors.

1. The doctor uses one of many possible synonyms, including semantic, functional, and treatment synonyms, to describe a patient’s condition.
2. The database is incomplete, so a query symptom may simply not appear in existing medical records, resulting in poor query matches.

We expect the first factor to have a larger impact on query quality, particularly due to unique variations of symptoms that are prevalent in TCM.

Methods

With each technique that we used in our experiments, we conducted query expansion, which is a form of pseudo-relevance feedback, to improve retrieval performance. We augmented each query with synonym terms selected by
each method, and then performed the retrieval on the existing database of medical records.

Overall, we used five different methods of query expansion. First, we addressed two baselines used in previous work\(^5\): the dictionary-based query expansion and the topic-model-based query expansion. In our dataset, the dictionary-based method incorporated an external treatment-symptom knowledge graph to add manually curated treatment synonyms. The topic-model-based method trains topics on the patient record database to add expansion terms that co-occur in the same topics as the given query. Although the previous study used a third method, predicate-based query expansion, we did not utilize this method due to a lack of high-quality TCM ontology databases. Furthermore, the predicate-based method was unable to outperform the topic-model-based method in prior work.

Next, we explored two network embedding techniques, Med2Vec and diffusion component analysis (DCA). Med2Vec is an embedding algorithm that learns efficient representations of medical records and concepts by using EMR datasets. On the other hand, DCA performs network embedding on the knowledge graph utilized in dictionary-based query expansion to obtain vector representations of nodes in the graph. The key difference between these two methods is that Med2Vec does not depend on expert medical knowledge, while DCA does.

Lastly, we discuss our method, which mines semantic, functional, and treatment synonyms by considering symptoms and treatments to be separate languages in a topic model.

**Dictionary-Based Query Expansion**

Dictionary-based query expansion utilizes a ground-truth, treatment-symptom TCM dictionary. This dictionary was curated from a TCM textbook containing known relations, interactions, and treatments. For example, the “crow-dipper” herb has multiple entries, treating symptoms from vertigo to breathing difficulties. We constructed a knowledge graph, in which an undirected edge \(\{t, s\}\) indicates that a treatment \(t\) treats a symptom \(s\) in the dictionary. There are 1,995 treatments, 1,635 symptoms, and 27,824 treatment relations in the dictionary, which translated to a total of 3,630 nodes and 27,824 edges in the resulting knowledge graph. There are no treatment-treatment or symptom-symptom edges. To perform query expansion on a query \(Q_{new}\), we add all treatments from the knowledge graph that are directly connected to at least one symptom in \(Q_{new}\).

**Topic-Model-Based Query Expansion**

In prior work, topic-model-based query expansion performed the best in a similar medical record retrieval task in terms of recall and F-measure\(^5\). Specifically, the authors used latent Dirichlet allocation (LDA)\(^7\) to derive topics from their database of EMRs. With LDA, each document is characterized by a mixture of topics. In turn, each topic consists of mixtures of words. In our study, we also used LDA to train topics from the dataset.

After training \(k\) topics, from topic \(i\)’s per-word distribution \(\phi_i\), we refer to the set of 100 words with the highest probabilities as \(H_i\). For a query \(Q_{new}\), we then perform the following multiplication:

\[
\phi'_i = |Q_{new} \cap H_i| \cdot \phi_i
\]

With this operation, we scale each word’s probability in \(\phi_i\) by the number of query terms that are in the top 100 words of \(\phi_i\). Finally, we sum each word’s probabilities across the scaled distributions, \(\sum_{i=1}^{k} \phi'_i\), and receive a new weight for each word. We experimentally chose to identify five topics from our dataset. The top five words with the highest weights were designated expansion terms.

**Med2Vec-Based Query Expansion**

Med2Vec is a state-of-the-art embedding method designed specifically for EMRs\(^8\). It discovers efficient representations of “medical codes” (symptoms and treatments, in the case of our dataset). To learn embedding from patient records, Med2Vec’s optimization function is similar to that of word embedding methods that use the skip-gram model, such as word2vec\(^9\). The authors stated three major reasons for word2vec’s failure to accommodate medical data:

1. Healthcare datasets have unique structures in which the visits are temporally ordered, but the medical codes
within a visit form an unordered set.

2. Learned representations should be interpretable.

3. The algorithm should be scalable to handle real-world datasets of millions of patients.

In particular, the first reason is of greatest relevance to our experiment setting. Med2Vec maximizes the likelihood of observing a medical code (symptom or treatment) given the codes in the same visit. In other words, a medical code’s vector representation predicts its neighboring medical codes. By obtaining vector representations of all medical codes as well as computing their pairwise similarities, Med2Vec jointly discovers semantic, functional, and treatment relationships.

We ran Med2Vec on our training corpus and obtained a set of low-dimensional vector representations for each symptom and treatment in the dataset. Given a query \( Q_{new} = \{s_1, \ldots, s_j\} \), we computed the cosine similarity between each query term \( s_i \)’s Med2Vec representation and every non-query term’s Med2Vec representation. Thus, for each candidate expansion term, we summed \( j \) similarity scores, one for each query term. We took the five terms with the highest score sums as expansion terms.

**DCA-Based Query Expansion**

DCA is a network embedding technique that takes a network as input and then learns low-dimensional vector representations of the input’s nodes\(^{10}\). DCA has been shown to achieve excellent results in learning network structure for gene function prediction\(^{11}\).

DCA ensures that two nodes have very similar low-dimensional representations if they are topologically close in the network. Thus, related medical concepts tend to have similar output vectors. Like Med2Vec, DCA jointly mines all three synonym types. We used the network constructed in dictionary-based query expansion as the input to DCA. After learning vector representations for each node in the network, we computed cosine similarity scores as in Med2Vec-based query expansion, again taking the top five terms with the highest score sums as expansion terms.

**BiLDA-Based Query Expansion**

In our data, symptoms and treatments are labeled and separated in each patient record. We hypothesize that a topic model that explicitly captures this structure will improve performance over standard, monolingual topic models.

Polylingual topic modeling (PLTM) finds latent cross-lingual topics in a multilingual corpus\(^{12}\). These text collections can either be direct translations or theme aligned\(^{13}\). Direct translations occur in sentences of two documents that are meant to be translations of one another. An example of a direct translation is “Romeo and Juliet” in English and Chinese. On the other hand, theme alignment occurs in documents that are not necessarily direct translations, but discuss the same topics in similar sections. An example of theme alignment is the Wikipedia pages on “Romeo and Juliet” in English and Chinese.

Our method considers EMRs to consist of two separate “languages”: symptoms and treatments. Thus, patient records are theme aligned in the sense that a patient’s symptoms and treatments are generated by the same set of diseases. Furthermore, the symptoms and treatments are varied according to the same syndromes, which are latent factors not explicitly stated in the records. Standard monolingual topic models are unable to represent these separate “languages”, since symptoms and treatments are grouped together. This removes the ability to differentiate, and therefore translate, between the two.

The output of the PLTM is a set of cross-lingual topics, including per-document topic distributions and per-topic word distributions in each of the languages. This model assumes that each topic consists of a discrete distribution of words for each language. Thus, there are two language-specific topics, \( \Phi^S \) and \( \Phi^T \), each of which is drawn from its own symmetric Dirichlet distribution with parameters \( \beta^S \) and \( \beta^T \), respectively.

Next, we discuss the generative process. Each EMR is represented as a mixture over topics, and is generated by first sampling from an asymmetric Dirichlet prior with concentration parameter \( \alpha \) and base measure \( m \):
Figure 1: The plate notation of our proposed model, framing electronic medical records as bilingual documents. A variable’s superscript $S$ indicates symptoms and $T$ indicates treatments. $\alpha$ and $\beta$ are the parameters of the Dirichlet priors on the per-document topic distributions and the per-topic word distributions, respectively. $\theta_d$ is the topic distribution for document $d$. $\phi^S_k$ and $\phi^T_k$ are each language’s corresponding word distributions for topic $k$. $z$ is the latent topic assignment for each observed word $w$.

$$\theta \sim \text{Dir}(\theta, \alpha m)$$  \hspace{1cm} (4)

Then, a latent topic assignment is drawn for each word in the corresponding “language” (i.e., symptoms and treatments).

$$z^S \sim P(z^S | \theta) = \prod_r \theta_{z^S_r}$$  \hspace{1cm} (5)

$$z^T \sim P(z^T | \theta) = \prod_r \theta_{z^T_r}$$  \hspace{1cm} (6)

The individual symptoms and treatments are then drawn using language-specific topic parameters.

$$w^S \sim P(w^S | z^S, \Phi^S) = \prod_r \phi^S_{w^S_r | z^S_r}$$  \hspace{1cm} (7)

$$w^T \sim P(w^T | z^T, \Phi^T) = \prod_r \phi^T_{w^T_r | z^T_r}$$  \hspace{1cm} (8)

With two languages, PLTM reduces to Bilingual Latent Dirichlet Allocation (BiLDA) (Figure 1). We obtained $k$ joint topics that align $k$ symptom topics and $k$ treatment topics. As with monolingual LDA, we experimented with different values of $k$, finding $k = 5$ to yield the best results. To train topics with BiLDA, we used the MAchine Learning for Language Toolkit (MALLET)\textsuperscript{14}, which performs inference with Gibbs sampling. We conducted query expansion the same way we performed LDA-based query expansion, selecting the five terms with the highest sums.

Evaluation

We evaluated and compared the five different query expansion methods, as well as the baseline with no query expansion, by performing retrieval on our dataset. We first describe our dataset, then discuss the evaluation process in the following two sections.

Data Description

We used a large, real-world EMR database containing 7,553 anonymous patient visits, obtained from the department of gastroenterology at Guang’anmen Hospital in Beijing, China. The same doctor treated all patients in the record,
which has the advantage of consistent treatment, but the simultaneous disadvantage of potentially systematic errors or incompleteness. All patients had some variety of stomach illness. Each record contains a detailed list of symptoms, treatments, and diseases. Each patient had an average of 9.08 symptoms and 1.63 diseases. The disease information was used as ground truth labels in the evaluation stage, and was therefore not included when finding query expansion terms. We elected to use only the first visit for each patient to prevent cases in which a patient’s query returns other visits of the same patient. This left us with 3,750 patient visits.

Cross-Validation

We split our dataset into ten random training and test sets as per $k$-fold cross-validation. Thus, the training records were functionally a database of EMRs. Each held-out test patient was then regarded as a new, unseen patient. For each of the test patients, we retrieved relevant patient documents from the training set.

Each test set contained 375 patient records. We excluded all details from the test set except for symptoms. Using a given test patient’s symptom set as a query, we performed each query expansion method in three ways: adding symptoms, adding treatments, and adding both. We refer to these methods as “symptom expansion”, “treatment expansion”, and “mixed expansion”, respectively. The only exception to this was the dictionary-based query expansion, which is only capable of treatment expansion.

Retrieval Tests

For each query in the held-out test set, we performed medical record retrieval. To score a document in the training corpus given a query patient, we used Okapi BM25 as our ranking function, which is one of the most effective retrieval methods. The Okapi BM25 score of a document $D$ given a query patient $Q = \{q_1, \ldots, q_n\}$ is defined as

$$\text{Score}(D, Q) = \sum_{i=1}^{n} \text{IDF}(q_i) \cdot \frac{f(q_i, D) \cdot (k_1 + 1)}{f(q_i, D) + k_1 \cdot \left(1 - b + b \cdot \frac{|D|}{\text{avgdl}}\right)}$$

In our experiments, $f(q_i, D)$ was always 1 if $q_i$ appeared in $D$, since no patient record contained duplicate symptoms or treatments. $|D|$ is the length of document $D$, and avgdl is the average document length in the training corpus. For the symptom expansions and the baseline with no query expansion, $D$ contained only symptoms. For treatment and mixed expansions, $D$ contained all symptoms and treatments of the patient. In the absence of parameter optimization, we chose the default values of $k_1 = 2$ and $b = 0.75$. Additionally, the inverse document frequency is defined as

$$\text{IDF}(q_i) = \log \frac{N - n(q_i) + 0.5}{n(q_i) + 0.5}$$

where $N$ is the total number of documents in the training corpus, and $n(q_i)$ is the number of training documents containing the term $q_i$. With this ranking function, we returned a ranked list of retrieved documents given a query $Q$.

Relevance Measure

To evaluate the performance of each retrieval task, we assigned an objective measure of relevance to a retrieved patient given a query patient. Conveniently, the list of diseases the doctor assigned to each patient was recorded in our dataset. We used these disease lists as ground truth labels for the corresponding patients. Thus, we define the gain of a document $D$ given a query patient $Q$ to be the following:

$$\text{Gain}(D, Q) = \frac{|D_{\text{disease}} \cap Q_{\text{disease}}|}{|D_{\text{disease}}||Q_{\text{disease}}|}$$

Here, $D_{\text{disease}}$ and $Q_{\text{disease}}$ refer to the set of diseases belonging to $D$ and $Q$, respectively. In the traditional vector space model, this gain is the cosine similarity between the document and query vectors, which is a useful metric for determining similarity between two documents. Thus, we can use normalized discounted cumulative gain (NDCG),
Table 1: Retrieval results for various query expansion methods. Bolded values indicate the highest NDCG@k. BiLDA mixed expansion performed best for all choices of k.

A standard method of evaluating search engines,[17] to compute the quality of our ranked list. The DCG at a particular rank k, for query Q, which returns a ranked list of D_1, ..., D_N is defined as

$$DCG@k = \sum_{i=1}^{k} \frac{Gain(D_i, Q)}{\log_2(i + 1)}$$  \hspace{1cm} (12)$$

where Gain(D_i, Q) is defined in Equation 11. NDCG@k is defined as DCG@k divided by the DCG of the ideal ranked list for query Q, thus making it a metric comparable across queries and suitable for our 10-fold framework. We show results for k ∈ {5, 10, 15, 20}. We exclude precision, recall, and the F-measure due to their inability to incorporate rankings.

Results and Discussion

The results of the evaluation are shown in Table 1. In order to analyze the significance of the NDCG values, we performed the paired t-test on the ranking metrics between pairs of expansion methods.

BiLDA-based mixed query expansion achieved the best retrieval performance among all expansions. For NDCG@5, 10, 15, and 20, it performed better than the baseline with no query expansion with p-values of 2.842 × 10^{-3}, 4.784 × 10^{-3}, 6.852 × 10^{-7}, and 1.929 × 10^{-6}, respectively. Furthermore, BiLDA mixed expansion performed better than all of the runner-up methods at the 5% significance level.

Mixed expansion was only the best-performing expansion type for BiLDA. This is due to the fact that all other methods do not separately mine symptom and treatment synonyms. On the other hand, BiLDA-based query expansion considers symptoms and treatments to be from separate topics, and therefore it successfully added in mixed query terms.

Dictionary-based expansion’s poor performance can be explained by the fact that it adds too many treatment synonyms, which dilutes the original query’s symptoms. On average, dictionary-based expansion nearly doubled each query in size.

We show an example of a mixed query expansion from BiLDA. In the patient query in Table 2, the five expansion terms include three symptoms and two treatment herbs. Fluttering pulse was an expansion term for this patient, and is indeed an indicative symptom of the patient’s disease, chronic gastritis.[18] Dark, red tongue is a functional synonym of yellow, greasy tongue coating, both of which commonly appear in patients with chronic gastritis.[19] Fullness is a
Table 2: Example of an expanded query created by the BiLDA method. Different query terms are separated by semicolons.

</tbody>
</table>

semantic synonym of bloating. Bitter oranges are known to treat abdominal bloating\textsuperscript{20}, and are furthermore known to treat chronic gastritis\textsuperscript{21}. Lastly, crow-dippers are also known to treat bloating in chronic gastritis patients\textsuperscript{22}. Indeed, crow-dipper was actually prescribed to this particular patient.

Related Work

Zeng et al. performed a study of synonym, topic model, and predicate-based query expansions. They used monolingual LDA as their choice of topic model and determined it to be the best-performing method\textsuperscript{5}. Our work builds upon their study in the context of traditional Chinese medicine, while also comparing additional methods, showing BiLDA to be an even more effective method. A major difference between their work and ours is that while both systems aim to return the most similar patients to a query, their experimental queries consisted of a single primary disease (“PTSD” and “diabetes”), while our query consists of the complete set of symptoms per patient. Furthermore, we refine the choice of evaluation from traditional measures of precision, recall, and $F_1$ to the more comparable metric of NDCG@$k$. Choi et al. developed a method of learning efficient representations of medical codes, Med2Vec, which we used as one of this study’s expansion methods\textsuperscript{8}. In a previous work, we also performed DCA on a prior knowledge dictionary, but in the context of patient record matrix enrichment for subcategorization of TCM syndromes\textsuperscript{6}. Jain et al. also performed medical record retrieval with query expansion on a patient’s symptoms\textsuperscript{1}. However, they used a knowledge base by integrating domain ontologies and automatic semantic relationship learning, similar to Zeng et al.’s predicate-based query expansion. Due to the lack of TCM ontologies, this method was infeasible.

Conclusions and Future Work

In this paper, we studied how medical record retrieval can improve with query expansion. Prior work showed topic-model-based query expansion to perform the best\textsuperscript{5}. We presented an improved topic model that frames symptoms and treatments as distinct languages.

We performed query expansion on EMR retrieval experiments with latent Dirichlet allocation (LDA), a treatment-symptom dictionary, Med2Vec, diffusion component analysis (DCA), and a polylingual topic model. LDA and dictionary synonyms were studied in prior work and thus used as baselines in this paper. Med2Vec is an EMR-specific embedding approach that learns interpretable representations of medical concepts. DCA is a network embedding method that incorporates prior TCM knowledge to also learn low-dimensional representations of medical concepts. Our experimental results showed that our method performs the best by normalized discounted cumulative gain, with significant $p$-values computed by paired $t$-tests.

Future work includes experimenting with other methods of query expansion. For instance, pointwise mutual information (PMI) has shown promising treatment-symptom pairings. Another potential method is the Weighted Exclusivity Test (WExT), which computes triples of medical concepts as an extension to PMI\textsuperscript{23}.

Lastly, a fundamental change to our problem would be to reframe the retrieval task as a treatment recommendation system. Like before, the system would take a test patient’s set of symptoms as the input query. However, instead of retrieving patient records relevant to the query, the system would recommend a set of drugs to treat the query symptoms. We can evaluate the new system by counting the number of recommended treatments that match the actual prescribed treatments for the test patient. With this framework, we can skip the step in which the doctor analyzes the set of returned patients in the retrieval task and instead directly recommend treatment. In fact, the embedding and knowledge graph-based methods, in addition to PMI and WExT outputs, already have explicit treatment-symptom relationships that would enable this new framework.

Extracting Actionable Recommendations for Modifying Enterprise Order Set Templates from CPOE Utilization Patterns

Abstract
As part of an enterprise-wide rollout of a new EHR, Intermountain Healthcare is investing significant effort in building a central library of best-practice order sets. As part of this effort, we have built analytics tools that can capture and determine actionable opportunities for change to order set templates, as reflected by aggregate user data. In order to determine the acceptability of this system and set meaningful thresholds for actual use, we extracted recommendations for additions, removals, and change in initial order selection status for a series of thirteen order sets. We asked local clinical experts to review the changes and classify them as acceptable or not. In total, the system identified 362 potential changes in the order set templates and 186 were deemed acceptable. While further enhancement will sharpen the efficacy of the intervention, we expect that this type of utility will provide useful insight for content owners.

Introduction
Multiple studies in the medical informatics literature that have characterized CPOE system implementations have identified order sets, or standardized groupings of orders targeted to specific clinical conditions or scenarios, as a determining factor in driving user acceptance of CPOE1,2. Physicians often find benefit from using them in that the system can provide logical, pre-populated views of commonly grouped orders for routine procedures and scenarios that they face in the course of their work3. Users often find them quick, convenient and thoughtful in helping them remember all of the nuanced details that can accompany the ordering process for a clinical situation. In similar fashion, organizations have a unique opportunity through order set creation/customization to create value and standardize care by ‘making it easy to do the right thing’ in treating patients. They can build into these templates the kinds of practice elements that represent current best practice4-6. Order set templates often drive usage and adherence, potentially leading to lower overall variation in clinical care processes7.

These benefits, however, come with tradeoffs. Researchers have cited the difficulties of building up a comprehensive library of order sets1, keeping it current as medical knowledge evolves, and the management difficulties that can come with accommodating highly personalized derivatives of order set templates (sometimes known as ‘favorites’ or ‘personal order sets’)8. Clinical knowledge management systems are intended to help organizations identify, centralize, evaluate, refine, and share knowledge resources throughout a given company. Knowledge management strategy as it relates to Computerized Physician Order Entry (CPOE) systems poses a particularly complex challenge. A wide variety of knowledge components must be accounted for, ranging from orderable item libraries, drug databases, order set definitions, decision support rule bases and content dependency trees.

Compiling a centralized knowledge base of order sets has been described as a labor-intensive process. The amount of effort associated with building and maintaining this type of content has led previous research groups to explore methods of automating the creation and refinement of this content6,11. Whether an organization opts to purchase and customize third-party content or develop the order set content in-house, there are significant investments of time and expertise necessary to make it work. Not only are there up-front tasks to populate the catalog and customize it to local practice and availability, but there are ongoing costs associated with the effort such as a) regular review and update existing content to bring it into alignment with current knowledge, b) additions to the catalog to address gaps in coverage and c) removal of obsolete or low-utility content. Researchers have noted that with the exponential growth in medical knowledge, that there is a real risk that once implemented, order sets may be inadequately maintained; in essence, driving caregivers to practice outdated medicine on a widespread basis12. Experts have recommended standard, regular review processes before initial implementation of order set content, but also consistent, periodic review that involves the clinical sponsors as well as allied clinical services (nursing, laboratory, radiology, etc)13. In these reviews, committees should analyze variance from established clinical standards, consistency of care recommendations across order sets, potential for adverse events, and establish priorities for associated clinical decision support rules.
Background

Intermountain Healthcare is a not-for-profit integrated delivery network that serves the populations of the Intermountain West (Utah and southern Idaho). It has 22 hospitals, over 150 clinics, a medical group of over 700 employed physicians and an insurance plan that serves the needs of the people in the region. Collectively, it accounts for roughly half of the healthcare given in the region and insures a little more than a quarter of the population.

Intermountain Healthcare has an established legacy of informatics excellence, dating back to some of the earliest efforts at building electronic medical records in the United States. Recently, Intermountain has opted to transition over to a new EHR offering, in partnership with the Cerner Corporation. Our enterprise rollout of the Cerner EHR product is approximately two thirds complete, scheduled for completion by the end of the year. The change in strategy from building our own EHR to using one provided by a vendor has necessitated shifts in our clinical knowledge management strategy. In particular, many of the content authoring tools have shifted from homegrown solutions to that of using content builders and wizards afforded by the vendor. The two most immediate priorities that have come from the decision related to knowledge management are that of building up and providing visibility into usage patterns surrounding an enterprise library of order sets and decision support rules. In this manuscript, we will focus on the efforts of the former, specifically tooling and processes surrounding order set management.

The effort to create an enterprise repository of order sets has been conducted under the organizational structure of Intermountain’s Clinical Programs. These groups cover 10 specific domains of medical care at Intermountain including cardiovascular, intensive medicine, pediatric, and oncology. Clinical Programs have been in place at Intermountain since 1997 and have a primary charge to identify, develop, and deploy best practice protocols in the enterprise. Among the chief roles that they have is to set and drive towards specific clinical performance targets, and create enterprise content that supports these initiatives. As Intermountain has worked to prepare for and roll out a new EHR platform built on a vendor-supplied infrastructure, care teams of clinical champions, data managers and quality experts have collaborated in building out a library of over 2,000 order sets. (an example is given in Figure 1 below) Most of these order sets have been iterated upon and refined multiple times in the course of preparation and actual usage. This library continues to grow and iterative enhancements are regularly incorporated into the content as stakeholders give feedback and as the content adapts to changes in understanding of current best practice. The maintenance burdens that come with building and maintaining a library of this size are significant. At Intermountain, well over 100 authors have been personally involved in the creation and maintenance of this content, with hundreds of others giving feedback directly or in committee as to enhancement and refinement.

Figure 1- Order set example. This particular order set focuses on the treatment of dehydration in infants.
Rationale

As part of this effort, business and Clinical Programs leadership have prioritized the development of tools that give visibility into the order set catalog. Specific questions around the catalog, associated metadata (authors, review teams, publication dates, sponsoring departments) and usage patterns have been the focus of a tool known as DOT (Dashboard for Order set Transactions). The development and usage of this product has been previously described\(^\text{15}\).

As authors grew accustomed to this very granular level of visibility into the content usage and variation related to their order sets, they became increasingly interested in specific scenarios in which the prescribed order sets content and user behavior didn’t align well. In particular, four scenarios were identified in which they wanted the system to assist them by identifying particular opportunities for either change to the order set template or active education and change management processes to redirect user behavior. These included:

1. **Change to Unselected**: An order is pre-selected in the order set template (it shows up automatically selected upon loading) but users are actually ordering it infrequently. This would identify scenarios in which users are actively going out of their way to not order preselected content.
2. **Change to Preselected**: An order is initially unselected in the order set template, but a majority of users end up selecting and ordering it anyway.
3. **Additions**: An order that is not in the order set template at all is frequently added to the order list as part of the ordering encounter. This may identify scenarios in which thoughtful and clinically useful additions might be made to the order set template.
4. **Removals**: Orders that are in the order set template are never or very seldom used. Given that users can always revert back to looking up any individual order from the orderable item catalog, there is some benefit in considering removals from the order set template if they are seldom used. This can optimize users’ experience with the order set by reducing the number of items that they need to scan and process during the ordering episode.

While there are clearly other elements to utilization of order sets that could be approached in this type of optimization effort (order sentence detail, organization and co-location of order elements, etc.) these particular emphases were agreed upon as initial priorities. The overall effort behind this type of utility would be to reinforce the clinical review processes intended for systematic review of content with detailed, actionable feedback from the system that reflects usage patterns. Additionally, clinical sponsors recognized that in building this type of tool, not all feedback would result in template change. Ordering patterns that deviated from expected care might be just as useful for identifying specific areas where clinical leadership may need to build specific goals and education plans to bring ordering patterns closer to expected levels.

The process of navigating and using an order set has been previously described as a collective mathematical sum of both cognitive and physical costs.\(^\text{16}\) Cognitive costs involve the reading, scanning, and logical processing of the recommendations given by an order set. Physical costs involve the manual efforts of clicking checkboxes, dropdown menus, selection, and scrolling through the content itself to fully review and utilize it. In essence, the process of order set optimization is intended to account for both optimizing these costs while maintaining the clinical and operational effectiveness and utility that come from order set usage.

Methods

**Report Generation** – In order to balance these needs, we decided to build a content advisor utility that analyzes order set templates from the knowledge repository, associated usage data from the enterprise data warehouse and makes active recommendations for change along the four change ‘axes’ described above. Order set template data was extracted from Cerner’s database tables to Intermountain’s knowledge repository and organized into logical groupings by version. In similar fashion, encounters for which these order sets were used in clinical care were identified, and the orders derived from these sessions were grouped and aligned against the order set template. Under advisement from clinical partners, we set four initial thresholds for identifying actionable change items in the content.

1. Orders would be flagged as ‘candidates for unselected status’ if they were initially selected in the order set template, yet ordered in less than 50% of the encounters that used that order set template.
2. Orders would be identified as ‘candidates for preselected status’ if they were initially unselected in the order set template, yet ordered in more than 50% of the encounters that used that order set template.
3. Orders would be identified as ‘candidates for addition’ if they were not in the order set template at all, yet were added ‘ad hoc’ by ordering providers more than 5% of the time.

4. Orders would be identified as ‘candidates for removal’ if they were in the order set template, yet ordered 1% or less of the time.

We built database scripts that align the data from the sources described above, identifies order elements that match these thresholds and organized four lists in a document that details all recommended content changes per order set. These documents contain four sections, and in each section candidate orders for preselection, deselection, addition, and removal are detailed, along with the corresponding data that was intended to direct the users attention to the specific details of how the orders were used. In particular, the reports showed:

- Order set title and version
- Number of overall ordering instances for which the specific version of the order set template was used
- Orderable title
- Percentage of overall ordering instances for which the particular orderable item was used
- Actionable recommendation (change selection status to preselected/deselected, addition, removal)

**Report Validation** – In order to test the utility of these reports and understand whether these initial thresholds were optimal for this purpose, we sampled a series of thirteen order sets relevant to three separate clinical programs, and asked content and data managers to review the recommendations. These order sets were chosen as order sets of interest by three Intermountain Clinical Programs and are listed in Table 1 below.

**Report Selection & Creation Criteria** – This type of feedback mechanism is dependent upon a minimal threshold of content being in place. As the overall number of encounters for which a specific version of an order set increases, so does the sampling by which the recommendations are representative of general use. As a rule, we opted to analyze the most current version of the content in the system, unless there were fewer than 20 instances of use of the order set template. In this circumstance, we reverted to the version immediately prior the current version for analysis. Table 2 contains the # of ordering instances that correspond with each order set included in this analysis. It is noteworthy to mention that while it might be expected that the number of ordering instances of a hip replacement and hip replacement post-operative order set would be expected to be the same, the data does not bear this premise out. This is primarily due to the fact that these order sets are independently maintained and updated in the database. As such, some of the content was updated during this timeframe, affecting the overall number of ordering instances per version. The numbers reflected below are specific to one single version of the content in the database.

*Table 1 - Clinical Programs, Selected Order Sets and Corresponding Numbers of Ordering Instances for the Order Sets Analyzed in this Study*
From the metadata associated with each order set in the database, we contacted the main author and content stewards to see if they would be willing to review these system generated recommendations and provide us with feedback about the system-generated recommendations. They were given a spreadsheet in which they were asked to indicate whether they thought that the suggestion was acceptable as is, worthy of discussing in committee (but not yet implementing) or not acceptable. For those deemed not acceptable, we asked them to provide specific feedback as to why they felt that the feedback was not acceptable or useful. We then aggregated the results, tallied the responses, and stratified the results by suggestion type.

Results

Overall, the system made 53 recommendations for preselection, 23 recommendations for deselection, 32 candidate orders as ‘additions, and 255 candidates for removal. Given that both a response of ‘accept’ and ‘would consider in committee’ are positive indicators of how the suggestion was received, we aggregated those groups into a common category indicating that the respondents felt that the suggestion was reasonable. Table 2 contains the results of each of the suggestion categories made by the system, as well as the corresponding ratings from the owners and content managers.

Table 3 - Common reasons for deeming feedback to change order set elements as ’not acceptable’, along with change suggestion type and corresponding counts

Discussion

The content recommendation system produced a significant number of recommended changes across the order sets, with an average of just under 28 recommended changes per order set in the study. In total, just over 51% of the recommended 362 changes were deemed ‘accepted’ or ‘pending committee review’. Overall the system has exhibited higher rates of acceptable suggestions for suggesting changes to make orders preselected and additions to the order sets. Content owners were less likely to consider removals from the system (closer to 50%) and far less likely to consider unselecting currently-selected orders (only 13% of the time).

Opportunities for goal setting - One of the key findings of this effort is that the orders identified by the system may either be opportunities for change to the order set template itself or outliers from expected behaviors. Several of the orders flagged for ‘deselection’ came as surprises to the content owners and stewards. They were under the impression that users were ordering pre-selected orders close to 100% of the time, only to find out that they were in fact ordering them less than half the time. This serves as an important notice to the content author, even if it does not result in an immediate change to the order template. It represents a disconnect between the authors’ expectations around user behavior and the actual behaviors themselves. While individual reasons are different for each scenario, some possible reasons for these disconnects include a) different priorities between caregivers and content authors b)
presumed workflows that bear out differently in actual practice c) and local workarounds and user treatment behaviors that may deviate from centrally-designated best practice.

**Identification of broken components** - One of the suggestions for order set template change came from unexpectedly low rates for ordering head circumference measurements for pediatric patients. This suggestion showed up in three of the four pediatric order sets reviewed. Upon further inspection of the reasoning behind these low utilization rates, a knowledge engineer identified that an associated decision support rule intended to trigger and drive higher usage of these orders was currently not working. Although not a direct intent of the tool itself, the resultant suggestions from the tool helped to identify a different knowledge artifact in the system that was malfunctioning. Separately, in extracting data for the analysis process, it became clear that some of the order set definitions themselves pointed to orderables that were no longer active in the orderables library. While not considered a specific objective in this study, these particular points could also be brought forward to content authors in order to facilitate cleanup and maintenance of order set content.

**Facility-specific items** – Our recommendation system was not attuned for the fact that some orderable items are configured to only be available in specific locations. These types of orderables often correspond with a given location’s abilities to perform orders based on availability of equipment, specialized personnel, formulary, or other constraints. Since our system did not account for these variations, it sometimes recommended modifications that would not be universally useful in scope.

**Strength of suggestion** – There is some evidence in the data we gathered to indicate that the strength of the content recommendation is stronger with a greater overall ‘denominator’ of order set content usage. Content reviewers felt that a recommendation to remove an order that had not been ordered in a set of a few dozen episodes of care was far less impactful than a recommendation to remove an orderable that had not been ordered from the template from hundreds of order episodes. We may use this feedback to only present ‘candidates for removal with a lower threshold of usage (absolutely no usage) and with a required denominator of at least several hundred ordering instances before the recommendation was made. In similar fashion, recommendations to either preselect or deselect orders near the 50% threshold were less acceptable to users. Going forward, we may require 65-70% usage of a currently unselected order before recommending it for preselection, as users responses to those recommendations were more absolute. Several of the responses near the 50% threshold were deemed as too inconclusive to really make a change either way.

Overall, there appears to be more willingness on the part of content authors to preselect and add than there is to remove and unselect. This may be problematic if not tempered, in that overselecting and overloading any particular order set can make the order set more cumbersome to use. Overuse of preselection status within an order set may lead to overutilization of labs, imaging, and even medications. Our hope is that the approach taken by content authors to feed these recommendations back to a larger committee for review would temper and offset some of these concerns.

**Limitations**

**Size and scale** – In this study, we have only sampled thirteen order sets from our order set library of over 2,000 separate documents. We realize that this is a small sample and that it involves only a small number of reviewers. We hope to incorporate the lessons learned from this early sampler of content into the behavior of the system before rolling it out for broader use among the other Clinical Programs and content owners. Furthermore, our study has some real limitations in that we are bringing in data only from the sites that are currently live on our new EHR platform. Nearly half of the care delivery volumes at Intermountain Healthcare are not yet live on this platform and will undoubtedly impact both the usage numbers but also behavior patterns exhibited in the data set.

**Personalized order sets or ‘favorites’** – In our new EHR implementation, users do have the ability to derive personal order sets with modifications from the enterprise order set templates and save them as ‘favorites’ from which they can order. As of yet, our system does not account for either the definition of these templates, nor the usage patterns derived from their use. We do anticipate including both of these dimensions of content derivation and use in future iterations of the content recommendation tool itself. We feel that there is a rich amount of data stored in the definitions of these personalized order sets and that machine learning techniques will help us to identify clusters of user behaviors in this space.

**Consolidation of feedback recommendations across template versions** – In the current design of the content recommendation tool, we are not accounting for broader usage numbers that could be achieved with cleaner reconciliation of common orders across versions of order sets. While the content differences between versions of an
order set may be either subtle or substantial, we anticipate that we should be able to employ some grouping logic to allow the framework to more gracefully span order set versions and hopefully make recommendations that are more crosscutting as it relates to overall usage.

Next Steps

Going forward, we expect to extend the content recommendation tool to account for recommendations derived from the authoring of and usage surrounding personalized order sets. We expect to account for recommendations that span versions of the document, as detailed above. Further, we intend to pursue similar recommendation patterns for other portions of the knowledge captured in order set definition, including order sentence details (that often contain form elements specific to the orderable), sequence, redundancy (identical or similar orders placed in multiple locations in the template), and decision support integration.

In studying the acceptability of the recommendations themselves, we intend to pursue the recommendations that go to content committees and record how they are received there and whether the content changes eventually make their way into the order set definitions themselves. As described earlier, we plan to use altered ‘thresholds’ for triggering these recommendations, both in terms of the percentages and minimum number of ordering instances needed before the reports can be created.

Finally, we intend to conduct time-based studies to see if these types of changes affect the overall efficiency of our end-users. One of the main objectives of the research is to build a framework that can maximize efficiencies in users’ interactions without compromising the value and clinical quality that order set usage can bring.

Acknowledgments

We would like to acknowledge our colleagues at Cerner for their help in identifying data relevant to the order set templates, corresponding metadata, and the order set instance derivatives created from the use of these plans in the clinical data repository. Additionally, we would like to thank the authors, data managers, and clinical leaders who spent time reviewing suggested edits from the system and providing feedback.

Conclusion

As part of a broader initiative aimed at creation and effective use of clinical knowledge content inside our EHR, we have built a content recommendation system that is capable of identifying opportunities for optimizing order set definitions inside our system. Our preliminary testing has shown that the system produces recommendations that users generally find reasonable, although its performance in recommending additions and preselections is higher than that of deselections and removals. We expect that our efforts in trying to automate and summarize user-derived feedback systems will leave content owners better informed and more empowered to maintain their content in useful ways over time.

Replicability, Reproducibility, and Agent-based Simulation of Interventions

R. Stanley Hum, MD, MA1, Samantha Kleinberg, PhD2
1 Columbia University, New York, NY; 2 Stevens Institute of Technology, Hoboken, NJ

Abstract

Secondary use of medical data and use of observational data for causal inference has been growing. Yet these data bring many challenges such as confounding due to unobserved variables and variation in medical processes across settings. Further, while methods exist to handle some of these problems, researchers lack ground truth to evaluate these methods. When a finding is not replicated across multiple sites, it is unknown whether this is a failure of an algorithm, a genuine difference between populations, or an artifact of structural differences between the sites. We show how agent-based simulation of medical interventions can be used to explore how bias, error, and variation across settings affect inference. Our approach enables users to model not only interventions and outcomes, but also the complex interaction between patients with different risks of mortality and providers with different observed and latent treatment effects. Ultimately we propose that such simulations can be used to better evaluate the behavior of new methods with known ground truth and better calculate sample size for EHR-based studies.

Introduction

Electronic health records (EHRs) have made it possible to study large populations over longer timescales than has previously been feasible, yet the observational nature of these data lead to a number of challenges, including difficulties in both reproducing studies and understanding when we should expect results to be replicated in a new setting. While confounding due to unobserved variables is a known challenge for causal inference (and methods for inferring latent variables have been developed to address this), the effect of variation in medical processes and unobserved treatments on false positives and negatives is less appreciated and can lead to the same outcomes as selection bias – even without hidden common causes. The problem is further compounded when we repeat studies in multiple settings, whether as part of a multi-site trial or as an attempt at reproducing a particular finding. Standards of care, documentation, and variation in both treatments and patients may differ, and may all contribute to a failure to reproduce a genuine finding. Studies may also fail to show an effect due to being underpowered, and in some cases effective power may be lower than expected due to latent effects that are not accounted for.

For example, a study may aim to test the role of ventilators in treating pneumonia, but ventilators are combined with antibiotics in some cases, and this choice may depend on the population, a clinician’s background, and the patient’s treatment preferences. While ideally we will have data on all interventions so as to control for such differences, documentation practices and the nature of EHR data mean that such information may be systematically missing. That is, if only text-based data are used, and that is where interventions such as ventilation are documented, while medications are prescribed electronically and stored in a structured database, then work focusing solely on free text will not be able to capture the role of antibiotics.

However, it is difficult to tease apart the effect of each possible source of error and bias from EHR data directly, especially given the lack of ground truth for evaluating results. At the same time, replicability, or the lack thereof, is receiving increasing attention across many fields. We propose that simulations can be used to test algorithms for robustness in the face of these challenges, and to develop solutions to address the unique difficulties of reusing medical data. Here we present the results of an agent-based simulation of medical interventions, showing the individual and compounded impact of hidden interventions and process features. In particular, we examine how combinations of latent and observed interventions may lead to reduced study power, and show how agent-based modeling can help researchers explore these issues.

Background

Reproducibility and causal inference

A key part of the scientific method is that hypotheses should be falsifiable and results should be consistent. A protocol developed by one person should be able to be followed by another and should produce the same results under the same
circumstances. Yet recent articles have been raising concerns that many scientific results cannot be replicated, and that the problem may be getting worse. Attempts by pharmaceutical companies to replicate academic findings led to only 20-25% of findings being repeated and a review of 53 major findings in cancer biology found only 6 were replicable. Recent works such as the Many Labs project have investigated this in social psychology research by attempting large-scale replications. The Open Science Collaboration conducted detailed replications of 100 psychology studies, with only about half being replicable.

While much of the focus has been on the lack of reproducibility in experimental studies, much of the work in biomedical informatics relies on secondary use of observational data. Instead of prospectively collecting data to test a specific hypothesis, this research is primarily data driven, using massive EHR datasets and other sources to generate new hypotheses. Reproducing work is both more important (given the increased possibility for confounding and error in these observational data that were not primarily generated for research purposes) and more difficult in this case. One study looked at 52 claims from observational studies and found none were reproduced in later randomized controlled trials (RCTs). However, one of the challenges of reproducing claims, particularly in biomedical informatics, is the lack of information about experimental protocols. Ioannidis looked at a sample of 441 biomedical articles, finding only one made a full protocol available and none shared their raw data. Raw data often cannot be shared due to privacy and ethics reasons, though some benchmark datasets in related areas such as pharmacovigilance have been shared.

Reproducibility in biomedical informatics has primarily been studied in terms of how portable algorithms for identifying phenotypes are between institutions. However, few studies have been done to evaluate the reproducibility of machine learning results across settings. The difficulty in reproducing studies is further compounded when we aim to infer causal relationships and not simply correlations. Here we must be sure that any effects we observe are not the result of hidden common causes, such as a latent variable causing both a treatment to be selected and outcome to be observed.

One work attempted to replicate a data-driven study of risk factors for congestive heart failure in two EHR systems. However, when using existing, observational, data, there are often many differences between two settings – data formats, population characteristics, medical practice – and it can be impossible to disentangle which of these are responsible for differences in results. As a result, it was both logistically difficult to reproduce the main approach for identifying cases and controls (as different data were collected) and difficult to evaluate whether results were reproduced. Many of the same problems plague multi-site randomized controlled trials (MRCTs), where standardization across sites is critical to finding the true impact of an intervention. Chesworth et al. assessed treatment fidelity for a specific trial, finding that in many cases actual procedures differed substantially from the protocol. Spirito et al. examined the role of differences in sample population and study protocol in a 6-site MRCT, and found that among other factors attrition varied by site and accounted for some outcome differences.

Medical simulations

The studies described in the previous section have shown difficulties in reproducing results between settings, and have retrospectively analyzed reasons for lack of reproducibility for individual experiments. However, the same incorrect finding can be made in two places, and when we are testing a new method, a failure to reproduce does not mean the method is incorrect (as the difference may be due to differences in data or the population). To systematically test how factors such as error in documentation or variation in protocol affect inference algorithms, we need 1) ground truth (so we know what should be found) and 2) variation (systematically changing features of the problem). Simulations allow us to replicate real-world scenarios such as a hospital stay, and enable one to learn about how outcomes would differ under various parameters (e.g. how mortality rate would differ if doctors had less variation in their processes). Importantly, all variables are observed and we have perfect ground truth in the simulation, and can test what happens in other cases (e.g. latent treatment) by removing some variables from the output analyzed.

Simulations have primarily focused on modeling spread of infectious diseases such as influenza, with less work on simulating medical data itself. The Observational Medical Dataset Simulator created simulated longitudinal medical data, using real data as input to determine realistic population characteristics. The approach generates populations where individuals each have a set of diseases and treatment assignments, then simulates the effect of treatment on outcomes. This approach is similar to the one we take, using probabilistic modeling of treatments...
Figure 1: Overview of system. A patient has an underlying physiological state, measured with some error. A provider makes qualitative observations, observes the noisy measurements, and chooses interventions based on these. Interventions affect both underlying physiology and measurements. Finally, documentation is a noisy and incomplete recording of a patient’s status, and affects intervention choice.

Figure 1: Overview of system. A patient has an underlying physiological state, measured with some error. A provider makes qualitative observations, observes the noisy measurements, and chooses interventions based on these. Interventions affect both underlying physiology and measurements. Finally, documentation is a noisy and incomplete recording of a patient’s status, and affects intervention choice.

and outcomes and aiming to capture the confounding that makes inference so difficult. However, OSIM2 models only patients and treatments, and not the bias and latent variables that make causal inference challenging. On the other hand, we aim to capture the heterogeneity and error introduced in the medical process through providers and documentation, and directly model unobserved factors that may affect outcomes.

Methods

In this section we describe the architecture of our simulation, data generation approach, and analysis methodology.

Simulation

We propose an agent-based approach to simulating medical interventions, which can capture the complex interactions between a patient’s state, a provider’s translation of their observations into interventions, and the documentation of these processes (that become input to other cognitive processes). One of the advantages of an agent-based approach is being able to simulate individual characteristics of providers, versus having the same parameters for all. This approach will ultimately allow us to model the interaction between providers (nurses, doctors) over time. An overview of the proposed approach is shown in figure 1. The idea is that we can clearly separate the different sources of error and bias so they can be systematically varied in combination and alone. A patient (purple segment at top) has a true underlying physiological state, which is distinct from measurements of this state (e.g., laboratory tests), which may be error-prone. In the clinician layer (green, middle), a clinician’s assessment of a patient is dependent on their skill and experience, and these plus noisy measurements and documentation guide intervention choices. Thus we can simulate how an error in a note could lead to errors in intervention (e.g., incorrect medication dosage). Finally, EHRs and other documentation are not simply a faithful recording of all events, but depend on skill and experience, and this documentation (orange, bottom layer) feeds back into intervention choice.

In this work we focus on the middle layer in the diagram: modeling provider features. We are interested primarily in features of the medical process that can lead to erroneous inferences, rather than the specifics of any particular illness. Thus we develop an agent-based simulation to model interventions at a high-level, using Repast Simphony, an open-source toolkit for agent-based simulations. To simplify the problem, we focus on the case where each patient has a single medical encounter with a single provider, and can receive (or not) an observable treatment and can also receive (or not) a latent treatment. A latent treatment is one that is not documented (unobserved). The effect of both the latent

1https://repast.github.io/index.html
Figure 2: Detail of simulation process. Individual patients and providers are drawn randomly from the relevant defined distributions. For patients, these are overall risk of death and for providers they are efficacy of interventions. Then, at each time step instantiations of treatment are drawn from the distributions. Patient, provider, and treatment characteristics all modify overall risk rate.

and observed treatments can vary in a provider or site dependent way, enabling simulation of some of the challenges of multi-site RCTs. For example, there may be systematic differences in standard of care or adherence to protocols, which can confound results, such as finding no difference between intervention and control if the intervention protocol has significant variation. While at a large scale such differences are assumed to average out, cluster randomized trials for example have lower effective sample size, as conditions within a site are not independent.

The flow of the simulation is shown in figure 2. There is a set of patient and provider agents, each of whom has their own features drawn from a distribution of distributions. Instead of describing a treatment in terms of only its mean effect and standard deviation (s.d.), we draw the mean and s.d. from distributions. For each encounter between a patient and provider, the intervention effects for latent and observed interventions are chosen from the intervention distributions. Finally, each patient’s outcome is simulated by combining the factors that modify their relative risk (personal risk rate, latent treatment, observed treatment). In this work, the outcome for each patient at the end of the simulation is survival, so each factor modifies risk of mortality.

The key parameter distributions in the simulation are as follows:

- Risk of death (mean and standard deviation)
- Treatment effect mean (mean and standard deviation)
- Treatment effect standard deviation (mean and standard deviation)
- Latent effect mean (mean and standard deviation)
- Latent effect standard deviation (mean and standard deviation)

Again, rather than a single distribution for each treatment parameter, the key parameters themselves vary according to user-defined distributions. This allows groups of patients (risk of death) and groups of providers (treatment and latent effects) to be modeled automatically. For example, if there is one group of providers being studied, such as in a single center study, the treatment effect would draw upon a single mean and a single standard deviation. If there are several groups of providers being studied, such as a multi-center study, then each center would have a treatment mean with an associated standard deviation. We can choose the four variables that affect treatment mean and treatment standard deviation to describe the overall distributions that inform each center’s treatment effect parameters.

We can thus simulate effects which are uniform or highly variable (normally centered around a single mean average effect) and which are evenly or unevenly applied (also normally centered around a single mean standard deviation).
Table 1: Parameters across experiments. The two risk of death mean values shown as high mortality (low mortality in parentheses) are constant across experiments. Brackets indicate iteration with a given step size.

For example, we can simulate an intervention that has minimal variation in its standard deviation at each site, but large variations in its mean effect. The treatment effects and risk of death are expressed as relative risk (RR), which is the probability of death under exposure divided by the probability in a non-exposed group. An RR of 1 leaves risk unchanged, while effects < 1 reduce risk and those > 1 increase it.

The latent treatment effect can be used to express a number of unrecorded or unobserved qualities, such as actual unobserved treatments or factors affecting outcome such as provider skill. For example, a latent effect mean of 1 and standard deviation of 0 mean the provider outcome is exactly the same as that of the treatment. However, one can also imagine cases with mean < 1 but wide standard deviation, meaning that on average the provider’s outcomes improve upon the treatment effect, but that there is high variance.

In reality, many important factors appear as latent for varying reasons. In some cases data may not be recorded or available, such as when using only claims data rather than the full EHR. In other cases, data on interventions may be recorded with a delay, so we do not know when a treatment happened relative to a change in a patient’s condition and cannot use such data to identify a causal relationship. With this simulation we aim to be able to systematically vary such factors, to test how well algorithms can handle these cases and develop new approaches that are more robust.

Data simulated

To demonstrate our approach, we create three types of datasets that illustrate features of our simulation and the difficulties posed for even simple comparisons. In each experiment we simulate 1000 patients, varying the risk of death from the illness itself (high vs. low mortality rate) as well as the efficacy of both the latent and observed treatments. Due to the randomness inherent in the simulation, we run 10 simulations for each parameter setting and average the results. Parameters for the three datasets are shown in table 1. In all cases, risk of death is given as a relative risk. Risk of death is that at each time step, so that for a simulation with $t$ time steps, the actual risk is $(1 - \text{risk})^t$. In this work we use $t = 10$, so the high mortality settings have an overall mortality rate of 40%, across the 10 time steps. The primary outcome of each simulation is the mortality rate, which we compare across simulations, aiming to replicate what happens in a multisite trial. We aim to determine under what conditions we can find statistically significant differences between groups, and how much unmeasured latent effect is required to draw erroneous conclusions.

Varying latent treatment effect: We begin with the common case of determining whether there is a difference in mortality rate between two conditions. In this example we fix the treatment as having no effect on risk of death, and compare two population risk of death means (0.05 for high mortality, 0.005 for low mortality) while varying how effective the latent treatment is (iterating from 0.1 to 1.0 by 0.1). This case can occur when there are unknown risk factors for a disease, such as environmental exposure, that differ between sites in a multi-site trial.

</table>
Mixed latent and observed treatment effects: Once again we use a sample size of 1000 patients, but now include an observed treatment effect. All settings are the same as for the previous set-up, except now there are high (RR=0.3), medium (RR=0.5), and low (RR=0.9) observed treatment effects simulated in each of the high and low mortality conditions. As before, we iterate over latent treatment effects from 0.1 to 1.0 by increments of 0.1 and average the results of 10 runs with each setting.

Constant mean effect, varying standard deviation: Finally, we examine the effect of variance in latent treatment effects. Here we fix mortality as high (0.05) and treatment as moderately effective (RR=0.5), and use a latent effect of 0.7, based on results of the first two simulations. These parameters are now fixed as we iterate over latent effect standard deviation mean from 0.5 to 2.5 by increments of 0.5. Once again we use 1000 patients in each run and 10 runs for each parameter setting.

Analysis

The primary outcome from each dataset generated is the mortality rate. We first aim to compare groups to determine if we can distinguish between more and less effective treatments. We test statistical significance using a Fisher exact test and threshold of $p < 0.05$ for statistical significance. We also assess observed study power (using actual mortality rate of the simulations and other simulation parameters), as it can differ from expected power.

Results

We now examine results for each of the three simulated scenarios, where the primary outcome is mortality and we aim to determine whether there is a statistically significant difference in mortality rate between treatment groups.

Effect of latent treatment

In the first case, we simulated a totally ineffective treatment, but varied the latent treatment and base risk of mortality. In this case we ask, at what point will there be a statistically significant difference between groups? Figure 3 shows the total number of survivors (out of 1000 patients) as we vary how effective the latent treatment is, holding constant an ineffective observed treatment under the two mortality conditions (high and low). When base mortality rate is high, the latent treatment has a substantial impact on total number of deaths, and a statistically significant effect on mortality once RR=0.8. This is because with a higher mortality rate, there is more opportunity to show a difference. On the other hand when mortality rate is low, it takes a much stronger latent treatment effect to show a difference in mortality (compared to a treatment effect of 1, meaning no impact). It is only once the relative risk reaches 0.7, that the difference between that and the condition where the latent treatment has no effect (RR=1) reaches statistical significance using a Fisher exact test, though the effect size remains small. This means that if we are comparing two groups with a high mortality condition (e.g. such as stroke), even if the treatment we are interested in has no effect on outcome, a relatively modest latent effect may confound our results.
Mixed latent and observed treatment effects

Now we combine observed and latent treatments, studying the impact of latent treatment effects with varying efficacy of observed treatments. Results are shown in figure 4. Different y-axis scales are used to better highlight subtle differences within the low mortality condition. First, within the high mortality condition, when the latent treatment effect is at least 0.6, the high and medium treatment conditions are no longer statistically distinguishable ($P > 0.14$). That is, even though there is an actual difference between these two treatments, if these were two groups in an RCT, we would no longer be able to find a difference between them because of the impact of the unobserved latent treatment. Further, in the low treatment effect condition, the latent effect makes the intervention seem to have a bigger effect on mortality than it actually does, which could lead to erroneous conclusions about the efficacy of an intervention.

In the low mortality condition (note that the range for the Y-axis is 970-1000), none of the differences between high and medium treatment effect are significant (P-values $> 0.6$), as the number of deaths ranges from 0 to 4. Thus, even though the observed treatments have a different effect on mortality in the ground truth of the simulation, we are unable to distinguish between them. Further, once the latent effect reaches 0.6, the medium and low treatment effects are no longer distinguishable (P-value $> 0.2$). The fact that the effects are indistinguishable does not represent the fact that the effects are somehow the same (the ground truth is that they are different). It simply means that the experiments are underpowered to detect a difference among them. If we were to increase the total number of patients in the experiment we would eventually reach a number where we could detect these differences.

Using a standard power calculation, the power for a study with 1000 patients in each group (high and medium efficacy treatment) using the actual true effect sizes, is 97.6% with an alpha of 0.05. Thus power calculations that ignore latent effects may lead to significantly underpowered studies. The actual observed power for detecting a change between these treatment groups, as a function of the strength of the latent effect is shown in figure 5. Once the latent effect reaches 0.7, power drops significantly, and critically is below the commonly used 0.80 threshold. Comparing the low and moderate treatments, power drops into an unacceptable range when the latent treatment effect reaches 0.4. We propose that power calculations may be augmented with simulations such as ours to explore how various unmeasured factors can affect effective power, and provide a more realistic estimate of the necessary sample size.

Effect of variance

Finally, we fix both treatment (RR=0.5) and latent effects (RR=0.7) along with mortality rate and now vary the standard deviation for the latent effect. This captures the scenario when the latent effect is incorporated in power calculations, but its variation is not properly accounted for. In most cases, we assume the treatment will have the same effect in different settings, but provider characteristics may vary in important ways between sites such as degree of adherence.
Figure 5: Actual power using $\alpha = 0.05$, when comparing two treatments, as a function of latent treatment effect’s impact on relative risk.

Figure 6: Result of variation in latent effect on mortality rate.

to protocol, level of experience, or workload. Figure 6 shows the result, where increased variation in treatment effect leads to significant differences in mortality rates within and across experiments. With zero standard deviation (so treatment effect is always mean of 0.5 and latent effect is mean of 0.7), mortality averages less than 3%, but this increases to 10% with s.d. 1.5, and 19% with s.d. 2.5. If these were multiple sites in an RCT, then significant differences may seemingly be observed even though the treatments have exactly the same mean effect in every experiment.

Discussion

Our simulations suggest that traditional sample size calculations may lead to underpowered studies in cases where there are latent effects or multiple sites. Further, due to the potentially complex interaction of multiple latent effects, some of which may be positive (high adherence to protocol) and some negative (high variance in clinician skill level), sample size calculations that account for these interactions may be prohibitively complex. Even when actual characteristics of an observed intervention are completely known (versus hypothesized, as in actual practice), we showed that when latent factors are not considered, studies become underpowered as latent effect size grows. Yet, these factors are rarely considered. One review found that only 41% of a set of pediatric ICU RCTs considered these nuisance parameters, leading to reduced estimates of variance and lower sample sizes than would actually be needed\(^{21}\). Another review found that many studies were either underpowered or overpowered (which can waste resources and time, and expose more patients to risks) due to incorrect assumptions about nuisance parameters\(^{22}\), which usually are not precisely known. While computational work on causal inference has aimed to identify latent confounders, the effects observed
here are not of the usual form considered (where a latent common cause may lead to inferring spurious relationships between its effects). This is exactly the type of variation that the randomization in RCTs aims to remove the effect of, but in research (1) from EHRs or (2) multi-site trials where effective sample size is much smaller due to site-related dependence, we cannot easily remove such effects through experiment design.

**Recommendations**

We propose that there are some key benefits for the simulation of medical processes and make suggestions for future work. First, while we focus here on a single latent treatment, the simulation introduced allows any number of such factors, enabling exploration of the impact of multiple latent effects which may have nonlinear interactions. This can enable better understanding of the effect different variances, treatment effects, and interactions have on sample size determinations. We propose that this can be used to complement standard power analysis and explore how effective sample size may differ under various conditions. Further this approach may be useful for analyzing RCT results (both the trial data and associated EHR data) to distinguish between intervention effects and other effects. As the simulation is extended to include other factors in EHR recording, latent factors like physician variation may have an identifiable signature. Second, it is customary to account for the effect of known co-interventions in any study. However normally only aggregate measures are available and used for analysis. With the advent of EHR documentation, one can envision a study where all of the co-interventions, known or unknown, are documented. Unfortunately, our ability to use this data is limited. The correctness of time varying analyses that aim to account for variations in co-interventions will need to be tested. Only with data for which ground truth is known can the validity of these algorithms be truly tested. By extending our simulation to include intermittent documentation of latent treatments, one can validate these time varying algorithms against with ground truth. Finally, simulation can be used to estimate the distribution of these latent effects to create data patterns that are similar to real world EHR data patterns and thus provide possible hypotheses of the underlying data generation processes that then can be tested. Ultimately, this approach will separate the underlying truth of a patient’s state from our sporadic and noisy measurement and documentation of this state, allowing better use of EHRs for research.

**Limits of Simulation**

The key limitation of our simulation approach is that it is meant to test the behavior of algorithms and contain similar structure to real scenarios, but it cannot be used to answer counterfactual queries about specific treatments. That is, we aim to capture the structure of the system (e.g., features leading to error) rather than to create an exact model of a specific disease process. Thus it cannot be used for developing intervention strategies. Further, some confounding factors may not be removable in practice. However, if they can be explicitly documented, it may be possible to account for their effects using EHR data and computational algorithms. In addition, we have chosen to use normally distributed parameters to model risk of disk and effects, for the sake of simplicity and because RCT power calculations are often based on such distributions. It is possible that the actual structure of the effects have bimodal or multimodal effects, which should be studied in future extensions to this work.

Thinking Together: Modeling Clinical Decision-Support as a Sociotechnical System

Mustafa I. Hussain, MS¹, Tera L. Reynolds, MPH, MA¹, Fatemeh E. Mousavi, MS¹, Yunan Chen, PhD¹, Kai Zheng, PhD¹

¹University of California, Irvine, Irvine, CA, USA

Abstract

Computerized clinical decision-support systems are members of larger sociotechnical systems, composed of human and automated actors, who send, receive, and manipulate artifacts. Sociotechnical consideration is rare in the literature. This makes it difficult to comparatively evaluate the success of CDS implementations, and it may also indicate that sociotechnical context receives inadequate consideration in practice. To facilitate sociotechnical consideration, we developed the Thinking Together model, a flexible diagrammatical means of representing CDS systems as sociotechnical systems. To develop this model, we examined the literature with the lens of Distributed Cognition (DCog) theory. We then present two case studies of vastly different CDSSs, one almost fully automated and the other with minimal automation, to illustrate the flexibility of the Thinking Together model. We show that this model, informed by DCog and the CDS literature, are capable of supporting both research, by enabling comparative evaluation, and practice, by facilitating explicit sociotechnical planning and communication.

Introduction

Computerized clinical decision support systems (CDSSs) are designed to improve patient safety, but may cause harm if implemented improperly.¹ The determinants of CDSS effectiveness are poorly understood, and the problem space is complicated by heterogeneity in CDSS system design.² Although CDSS taxonomies exist that acknowledge the importance of sociotechnical context,³,⁴ which we use here to refer to the collection of relationships between actors and artifacts, we have found in this work that this context is often missing in peer-reviewed CDSS research. Specifically, we found that 1 out of 7 articles did not define or describe how suggestions were delivered to the user (e.g., “a pop-up alert,” “a phone call,” “a fax”). Additionally, although we identified 9 articles documenting a system in which a pharmacist filtered automated suggestions for presentation to a physician, none of these provided enough information to model the sociotechnical system in which the computerized subsystem was situated, missing key sociotechnical information, such as how advisories were presented (individual pop-up alerts or a list), and what other advisory systems were already in place. This makes comparative evaluation difficult. Additionally, while it is possible that sociotechnical design is considered in practice and simply not reported, it is also possible that this reflects a scarcity of sociotechnical consideration in practice.

In this theoretical development paper, we aim to expand the understanding of CDSSs as sociotechnical systems, where humans and computers think together to steer the course of clinical care. Explicit sociotechnical consideration may also improve adoption and clinician responses to computerized decision-support advisories, which may, in turn improve workflow, care coordination, and ultimately quality of care and patient safety.⁵ Inadequate sociotechnical consideration can disrupt work and even lead to patient mortality.¹

To this end, we present the main contribution of this paper, the Thinking Together model, a diagrammatical representation for communicating the sociotechnicalities of CDSSs. It provides a common diagrammatical language for guiding the sociotechnical design of CDS systems, conducting research studies of these systems, and reporting research results. Widespread usage would provide researchers with a uniform body of comparable literature. This would ultimately benefit practice indirectly, by providing evidence upon which to guide the design of sociotechnical systems. The Thinking Together model also provides a more direct benefit to practitioners: Monk and Howard similarly created the Rich Picture as a tool for designers of business information technology to think, talk, and negotiate sociotechnical design by making it explicit.⁶ We have developed the Thinking Together model specifically for the sociotechnical context surrounding CDSSs, to benefit both research and practice.

We developed the Thinking Together model using a systematic approach, by conducting a comprehensive review of articles documenting CDSSs published in the past decade. We used the theoretical lens of Distributed Cognition (DCog)⁷ to interpret descriptions of CDSSs, because DCog is well-suited to studying the complex, collaborative, and dynamic nature of clinical work,⁸,⁹ and it has been widely used to study health informatics applications, such as interruption management in the intensive care unit¹⁰ and whiteboard use in a trauma center and an operating room.⁹
Rather than focusing on the individual actors (e.g., an internist, a pharmacist), DCog emphasizes the sociotechnical system, which includes actors, roles, and artifacts. In this study context, actors perform roles. Human actors include physicians, nurses, and pharmacists. We also speak of computer systems as actors—such as a computer program that fires alerts. These actors think together by representing and conveying information through artifacts, such as pop-up alerts, faxes, and spoken words. Artifacts have intrinsic properties with implications for design; an utterance is immediate, intangible, and ephemeral, while a fax alert must be discovered, can be annotated, and persists until destroyed. By applying DCog to understand CDSSs, we are able to more clearly depict important sociotechnical features, and how they work together to achieve a common goal: delivering high-quality patient care.

In the next section, we briefly present the history of CDSSs which led up to this work. Then, we describe the methods that we used to develop and validate the Thinking Together model instances. In the section titled Two Case Studies, we present two resultant Thinking Together model instances, based on CDSSs selected from the literature, to illustrate how the Thinking Together model can be used to represent CDSSs as sociotechnical systems. We follow these with a discussion of uses, benefits, and limitations of these model instances, and some concluding remarks.

**Background**

Long before the computer became widely available, a clinician’s decision making was supported by artifacts such as reference manuals and dose charts, and by talking to other clinicians. The advent of the computer presented the possibility of using computing methods to automatically generate decision-support advisories. There was a significant effort to develop expert systems, usually based on artificial intelligence methods, to automate the diagnosing process. This attempt fell short, partially because these AI-based applications were unable to reason anatomically or temporally, and because they were unable to explain their reasoning. These shortcomings persist today in machine learning applications, and much computerized clinical decision support instead tends to use explicitly defined, step-by-step rules, usually from evidence-based clinical guidelines. Today’s applications of CDSSs include antibiotic stewardship, opioid management, and adjusting doses for renal insufficiency. The suboptimal usage of these CDSSs, however, has been an enduring issue. The lack of usability is well documented, where low rule specificity and a lack of accurate patient data result in too many irrelevant alerts. When alerts are no longer perceived to be valid problem-indicating cues, they become habitually ignored.

Today’s CDSSs are highly heterogeneous, with different capabilities for patient information access, rule programming, advisory display, and shortcuts for immediate action. Various taxonomies have been developed to organize this heterogeneity. For example, Wright et al. developed a taxonomy to classify the problems that computerized CDSSs address, and some user interface characteristics. Berlin et al. presented a taxonomy with 26 axes and 108 descriptors to classify clinical context, information sources, the underlying recommendation-producing mechanism, information delivery, and how it relates to clinical workflow, noting that one should be cautious when generalizing results of randomized controlled trials of a CDSS intervention across different clinical or workflow settings. Over a decade later, we find that generalization remains difficult, because although these taxonomies exist, many research papers do not use them to report CDSS characteristics. While the question of why these taxonomies are underused remains open, we speculate that this may be because taxonomies do not depict systemic configuration, and so may be less than useful in CDSS design. Rather than provide another taxonomy, our goal in this work is to provide a means of depicting systemic configuration that practitioners find useful, and can be just as easily repurposed to provide context when submitting manuscripts for publication. The Rich Picture, a similar approach, has seen success in business-oriented software design.

**Methods**

In order to develop a flexible representation system—the Thinking Together model—for characterizing CDSSs that depict their systemic configurations, we first needed to arrive at a reasonably inclusive set of features that differentiate CDSS systems. We used a systematic review approach, illustrated in Figure 1. In the first stage, we developed search queries for PubMed/MEDLINE, EMBASE, CINAHL, and Cochrane literature databases. The queries included keywords such as “decision support,” “alert,” and “error.” Since this is intended to model contemporary systems, we restricted the queries to literature published in the last 10 years. The final queries returned a total of 2,760 results, of which 996 were duplicates. We reviewed the remaining 1,764 unique papers for relevance. Of these, 255 met our criteria for inclusion, which were that a paper must be (1) peer reviewed, (2) about a CDSS that targeted clinicians, and (3) written in English. When the same research team reported multiple times on the same system, we kept only the most thorough report.
Figure 1. Literature examination process.

We attempted to identify descriptions of the CDSS in all of these papers, in particular what clinical role was targeted (e.g., physician or pharmacist), how alerts were generated and filtered (e.g., automatically or by a pharmacist), how the advisory was presented (e.g., pop-up dialog or human phone call), and what action shortcuts it provided (e.g., cancel or substitute medication), if any. Notably, approximately 1 in 7 did not define or describe any of this key information. This eliminated 38 articles. For the 217 papers that remained, we inductively identified categories that characterize the sociotechnical aspects of CDS systems, using the constant comparative method. More specifically, we started with an empty list of categories, and for each paper, we compared the described CDSS to the current list of categories, such as “interruptive pop-up alert” and “tab highlights yellow to draw attention, user clicks tab and views list of alerts”. If the system did not fit in any of the existing categories, we extracted or generated a brief description to add to the list. Otherwise, we categorized the system accordingly. This analysis was independently performed by two of the authors, Hussain and Reynolds.

In the second stage, we iteratively developed the properties of the Think Together model by generalizing phrases from the categories into properties, such as by generalizing the phrases “interruptive,” “non-interruptive,” “searched database” (among others) into a broader means of discovery and retrieval. Some of these properties formed groups; for example, means of discovery and retrieval and means of destruction (again, among others) into a broader means of interaction. Properties that characterized content mapped to Grice’s maxims of communication, so we formed these into a group as well. We then organized these properties into theoretical elements by mapping them to DCog theoretical elements. The DCog concepts of systems, roles, and artifacts became prominent. Any ambiguities were resolved through discussion among the two coders. Finally, we selected two sample CDSS systems to validate the model. We purposefully selected one system that is almost fully automated, and another that is almost entirely manual, in order to “stress test” the model using extreme cases to ensure its robustness and representativeness.

Results

Before describing the theoretical elements and their properties, we will provide a general overview of the Thinking Together model. Roles are played by actors; these actors manipulate artifacts. Together, they compose a sociotechnical system. These concepts are holdovers from DCog, where a sociotechnical system performs cognition by transiting information between specialized roles, which process information, collectively determining the course of action. Information is not only distributed among the heads of actors, but also on external artifacts, enabling problem-solving and team coordination. In this work, we differentiate between human and automated actors.

Theoretical elements and properties

As previously mentioned, we identified theoretical elements and properties relevant to CDSS sociotechnical consideration, based on the systematic review and the DCog theory. The results are presented in Table 1, and discussed in this section. Key concepts are italicized in this section. These concepts are important to understand before interpreting instances of the Thinking Together model, which we present in the case studies that follow this section. Below, we explain these theoretical elements and their properties.

Sociotechnical Systems

The Systems element addresses the fundamental premise underlying a CDSS: What is the purpose for this system’s existence? Is it there to support clinical care, or to avoid legal consequences? If the latter, then it is worth considering whether other, more clinically valid CDS alerts are more likely to be ignored in the same sociotechnical system due to a perception of pop-up alerts as an irrelevant nuisance, contributing to alert fatigue.

**Means of interaction**

- Discovery and retrieval
- Generation and processing
- Storage and sending
- Destruction

**Content (Grice’s maxims)**

- Quantity
- Quality
- Relation
- Manner

Also, what is the story of this system’s *inception*? Was it by administrative mandate, or regulatory requirements? Did clinicians push for it? Whether manually-programmed or machine learning algorithms are used, were they calibrated to the locality? Finally, how is the system *maintained*? Is it updated to reflect emerging, improved understandings of medical practices and/or the particular sociotechnical environment? Is there a regular, ongoing review of consequences that results in safety-improving updates to the sociotechnical system?

**Roles**

There are many roles in healthcare, including physicians, nurses, clerical staff, administrators, software developers, and patients. In this work, we draw a distinction between *human* actors and *automated* actors. Human information processing may be characterized as ranging from fast and subconscious to slow and conscious. Automated actors (in the form of computer programs) can apply rule-based or statistical methods quickly, but their results can be lacking due to an absence of context-dependent understanding, and machine learning applications tend to suffer from “black boxing,” wherein a human-understandable rationale may not be readily available. Also, whereas humans tend to be better conversationalists than chat-bots, computers excel at creating precise drawings and producing formatted information quickly.

While examining the literature, it became apparent that, whether it is an experienced brain surgeon, or an advanced analytic application that monitors patients for signs of sepsis based on algorithms trained with historical data, a role has a *level of expertise* and an area of *specialization*.

**Artifacts**

Artifacts include physical objects such as phones, dose calculators and conversion charts, checkbox forms, injection site maps, exam room flags, and patient schedules, as well as virtual objects, such as pop-up alerts, lists of suggested doses presented during order entry, and online reference entries. The artifact’s properties are largely reflected in Berlin’s taxonomy; here we focus on contextualizing it as a core element of a sociotechnical system.

Physical artifacts are designable and configurable by nearly any user. With a paper chart, one can fold a corner, jot a note, stick a colored dot. This flexibility allows for spontaneous creation and modification of external representations, which, in turn, allows for problem reframing, an essential step in problem solving.

Virtual artifacts, on the other hand, are interesting because they are not bound to the same laws as physical artifacts. For example, a modal dialog or modal window is a pop-up message that is not escapable, and which usually locks down several on-screen background artifacts until an action is taken. The modal dialog does not accommodate situations in which information must be retrieved from these frozen background windows, but the needed information is scrolled out of sight. Further, once these dialogs disappear, they are usually gone forever, and cannot be retrieved again at will for reference, that is, they are transient, not permanent. This type of brittle interactivity violates Nielsen’s heuristic of *user control and freedom*. Careful design can resolve many usability issues.

972
Artifacts are manipulated by actors. In the literature, we found that an actor may discover an existing artifact in different ways (perhaps the “new email” notification sound plays), or they might retrieve it from a storage system. They may process an existing artifact, or generate a new one. Finally, they may store, send, or destroy it. Many virtual artifacts found in health IT systems, such as physician notes, cannot be modified or destroyed, for legal reasons rather than those relating to clinical care.29 Modal dialogs, eager to self-destruct, are a curious exception. It may be wise to approach object permanence, and destructibility on a case-by-case basis.

An artifact’s medium of conveyance determines much of what can be done with the information it represents. A pharmacist’s phone call about a medication error may be easy to discover because the phone is ringing, but the content may need to be transcribed for future reference, perhaps on a pad of sticky notes. It may take some time for this phone call to arrive, because the pharmacist is human, and so their information processing tends to be slow.

Though delayed, the content of a human-generated phone call may conform better to Grice’s maxims of communication30 than a computer-generated phone call. Grice’s maxims of communication were reflected in the literature we examined, underscoring the relevance of broader social sciences research to the design of health IT systems. Grice’s maxim of quantity states that one should be no more and no less verbose than is required to convey the information. When an action is suggested, is a rationale provided? If not, the content may be too sparse. Is the entire text of a literature review displayed to explain a particular computer-generated decision-support advisory? This may be too much. Grice’s maxim of quality refers to the accuracy of the information presented. Is a suggestion based on a study in rodents? Were there conflicts of interest that may diminish the legitimacy of the results, and therefore the recommendation? Grice’s maxim of relation refers to the relevance of the content to the task and context at hand. Is an alert for drug-allergy interaction presented because the patient is known to have an allergy, or is it presented for all patients “just in case?” If a phone call about a prescribing error interrupts note-taking, is it important enough in relation to note-taking to justify the potential loss in productivity and accuracy in note-taking?29 Grice’s maxim of manner states that communication should be clear, brief, orderly, and specific. Tabular formats may be more appropriate than prose in certain CDS pop-up alerts,32 possibly because the spatial order and the discrete nature of the information displayed can be more easily retrieved.

If a document is represented in an electronic health record (EHR), one may need to access a computer to interact with it; its physical location is constrained, and this limits the contexts in which suggestions may be displayed. The dimensions and resolution of the display also constrain the design of virtual artifacts. On the other hand, virtual artifacts can also provide convenient shortcuts for common actions that one may need to take, such as ordering appropriate consultations or medications upon receipt of an abnormal test result. Smith et al presented shortcuts for such actions within pop-up alerts, rather than simply demanding clinician acknowledgement.5

Some artifacts in the literature were intended to follow up on a previous communication. This sometimes comes in the form of personalized phone calls conducted by humans, and sometimes as pop-up reminders that are displayed at regular intervals until a task is accomplished. When deciding between these options, one might consider that nuisance alerts contribute to alert fatigue.19

The Thinking Together Model

The configuration of information flow is modeled in numbered stages. During each stage, an artifact may be retrieved from storage or generated anew, processed by an actor, and then sent or stored to another actor or a storage system. When using Thinking Together to model a sociotechnical system, we recommend first drawing and labelling all of the roles and storage systems involved, in the order in which they come into play, working clockwise. Next, connect the roles and storage volumes with arrows, showing the flow of information. Finally, label these roles and arrows, one stage at a time, starting with the number one, and labelling each step in each stage as r, p, g, and s, for retrieval, processing, generation, and storing or sending (See Figure 3 and Figure 4). Even if the present study focuses on one prong of a multi-prong intervention, be sure to include other forms of decision support that clinicians receive addressing the same topic. For example, if physicians already receive antibiotic management alerts, and the study at hand addresses the additional intervention of pharmacist review and counseling, document both of these interventions in the diagram, since the interaction between these two interventions may need to be later teased out in an aggregated literature review.

![Figure 2: Recommended cyclical modeling process.](image-url)
Next, interrogate the diagram, considering the theoretical elements and properties in Table 1. For example:

- How is this rule-based advisory system maintained as new clinical evidence emerges?
- How do users point out problematic alerts, so that rules can be changed?
- While making this phone call, does the pharmacist adjust dose on behalf of the physician, for later signing?

If the answer to a question is unknown, it may be worthwhile to find out, such as by interviewing physicians to find out what they do, as one does when generating a Rich Picture. Next, update the design, and continue to ask questions. Continue this cycle, as shown in Figure 2, until no new questions emerge.

Because Thinking Together is a descriptive, rather than prescriptive, modelling system, we do not prescribe rules for evaluating or suggesting changes. Rather, Thinking Together is intended to facilitate interrogative reflection.

**Two Case Studies**

We selected 2 CDSSs described in the literature to illustrate how the Think Together model can be applied. As mentioned earlier, we purposefully chose two systems at the extremes of the automation spectrum to validate the robustness and representativeness of the model. The first system is primarily automated, requiring little to no human involvement, while the second is operated almost entirely by human actors.

**Case 1. Pre-Surgery Lab Alerts**

In Figure 3, we show a rule-based alert system documented by Freundlich et al. It was put into place following an adverse event in which a patient’s partial thromboplastin time (PTT), a lab value that indicates blood coagulation, became abnormal without the awareness of the surgical team. The surgery was performed without additional precautions that may have prevented the patient’s death. To address this, a system was instated that retrieved patients scheduled for surgery, along with their lab values (1r), and compared their lab values with predefined thresholds (1p). It then generated (1g) and sent (1s) alphanumeric pages to the surgical staff concerning patients with abnormal lab values. This alerting process was performed every afternoon for most surgical units, and also in the morning before surgeries in the neurosurgery unit.

The authors reported that feedback was largely positive, and that suggested improvements to the rules encoded in the system had been received and were implemented. However, since we do not know how this feedback was collected, we are unable to draw this portion of the diagram. It is imaginable that this may impact how the rules were updated. This has practical, real-world implications. To name an example, two-way pagers might elicit more contextual feedback than a one-way pager, since email, phone call, or face-to-face conversation require more steps to providing feedback than replying to a page. On the other hand, individual pages might provide less information.

The authors also stated that some clinicians may have perceived the alerts as a redundant nuisance. It is possible that this refers to the less-frequent manual laboratory review prior to scheduling the surgery, which also cannot be diagrammed because it is similarly left unspecified.
A Systematic Oversight

We would like to make it clear that we hold the work of Freundlich et al. in high regard. Their paper was well-written, the methods were reasonable, the alerting system appeared thoughtful, and the technology staff appeared responsive to clinician feedback.

It is easy to overlook the provision of additional context when focusing on a specific problem, and their paper is certainly not alone. We also wished to show a diagram displaying a system in which an automated system generated many alerts that were then whittled down by a pharmacist, who then contacted physicians personally, by phone or email. Hybrid systems like this would serve as an illustrative contrast between a fully automated system, like the one we presented in the preceding case study, and a fully manual system, like the one we will present in the following case study. However, although we identified nine articles that documented such a system, none provided the reader with the full sociotechnical system, missing key information, such as whether suggestions were presented to the pharmacist as pop-up alerts or as a list, whether the physician received other alerts (and in what form), and how follow-ups were conducted, such as via email, face-to-face conversation, or phone call. This suggests that some sociotechnical aspects of these CDSS designs went without consideration. This illustrates a systematic oversight that we have observed in the clinical decision support literature: Although sociotechnical context is widely recognized as an important factor to consider in the implementation and alteration of CDS systems,1,32,33 this information is under-reported to the extent that it is currently difficult to systematically analyze the effectiveness of real-world interventions.

This has importance to practitioners for two main reasons. The first is less direct; comparative evaluation research will benefit practice by providing reliable, useful guidance. The second is more direct; explicitly diagramming sociotechnicalities may help the practitioner reason about, communicate, and negotiate sociotechnical design.6

Case 2. A Human-Operated CDSS

![Diagram](Figure 4. A Thinking Together model of a multidisciplinary CDSS with minimal automation.24)

We selected the CDS presented by Sullivan et al.24 for modeling as well; it is presented in Figure 4. In Stage 1, prescribers write prescriptions, which are stored electronically. In Stage 2, pharmacists retrieve (2r) and review (1p) these prescriptions daily. When they see an error, they take two send/store actions: they call the prescriber (2s1) and log the error (2s2).
In Stage 3, the multidisciplinary team meets every other week, retrieving all error reports (3r), aggregating them (3p), writing feedback emails (3g), and sending them (3s). In this same meeting, the team also retrieves prescribers' emails about systemic concerns (4r), plans corrective action (4p), and contacts the appropriate party (4s). We considered these to be two separate stages because they appeared to be two separate tasks. In Stage 5, prescribers receive (5r) and read (5p) these emails, and write (5g) and send (5s) responses about systemic concerns that may underlie the errors if appropriate. These emails are read during the next biweekly meeting.

We found this case interesting because it is run manually; though information was relayed and stored with computers, it is hard to argue that automated actors were really supporting decision-making by filing data and shuttling emails. It is also difficult to argue that clinical decision-making is not supported in this sociotechnical system. The choice to shun computerization was conscious; the authors cited unintended consequences, alert fatigue, and low effectiveness at preventing medical errors as rationale. Their system serves as a counter-example to CDS definitions that assume computer dependence: one could imaginably replace the databases and email server with file cabinets and couriers, while maintaining similar functionality. Also noteworthy is that feedback from prescribers could be flexibly handled by the multidisciplinary team precisely because they are human; they were able to translate explanations for errors into plans for corrective action (4p), and relay those plans to the appropriate recipients (4s). For example, they had rotavirus vaccine intramuscular removed from the available CPOE options because, after it caused a medical error, a prescriber pointed out in a systemic concern email (5s) that it was not an appropriate option in any case. Also noteworthy is the care with which the multidisciplinary team composed the feedback emails (3g); they were careful not to place blame, in order to maintain workplace safety culture, and they provided details on specific errors and advice for avoidance. Courteous prose and real-world reasoning are hardly a computer’s forte.

Discussion

In this work, we developed the Thinking Together model, a descriptive and flexible means of representing CDSS sociotechnicalities. We are confident in its flexibility due to the contrast between the two case studies presented, as well as its grounding in DCog, which has remained largely the same for over two decades. Usage in future research is likely to provide a basis upon which to compare the effectiveness of CDSS implementations, since sociotechnical context is critical to a CDS implementation’s success. The ability to comparatively analyze the body of work on CDSS in aggregate will allow researchers to make meaningful recommendations to improve CDS systems. It will be difficult to perform such comparative analyses without clear information about the sociotechnicalities of the CDS systems from which individual results originated. The Thinking Together model is also intended to support the examination of the sociotechnical context when implementing and altering CDS systems in practice. The potential of this model to improve both research and practice can only be realized through cooperation among researchers, clinical practitioners, and technologists.

System representation is powerful insofar as it shows only key details, allowing an overview. Many low-level details that may affect system efficacy cannot be shown. For example, a neural network trained on too many dimensions may learn a practically useless identity function, and may be outperformed by one trained on only the most relevant dimensions (as determined by a principal components analysis, for example), which would arrive at an equation that is valid for previously unseen cases. This distinction will not be apparent in a Thinking Together diagram. However, the burgeoning work in automated information processing complements the sociotechnical viewpoint. Likewise, interpersonal relationships can affect healthcare safety; this is also hidden from view by necessity, but is complemented by work in Crew Resource Management.

The Thinking Together model should be thought of as a tool in a toolbox of complementary approaches, from algorithm design to workplace culture. It provides an intuitive means of representing and communicating sociotechnical clinical decision support, to support comparative evaluation in research and design in practice.

We invite practitioners to use the Thinking Together model for integrating CDSSs in sociotechnical design, to reflect on their experiences, and to publish their results. We believe they will be useful in practice, and we hope that this will transform reporting sociotechnical context from a tangential burden into a simple matter of cleaning up and attaching an existing drawing that was used during design. We plan to conduct and publish comparative analyses of CDS system effectiveness as articles documenting both results and sociotechnical design become available.

Conclusion

In this paper, we described the Thinking Together model, which was based on a systematic review of the literature and the theory of Distributed Cognition. Through two case studies, we demonstrated the flexibility of the Thinking
Together model. We believe that practitioners will find this model useful when considering sociotechnical context in computerized decision support system design, and it will support systematic sociotechnical reporting in the literature, enabling comparative evaluation of CDSS efficacy.

Differential Data Augmentation Techniques for Medical Imaging Classification Tasks

Zeshan Hussain\textsuperscript{1}, Francisco Gimenez\textsuperscript{2}, PhD, Darvin Yi\textsuperscript{2}, Daniel Rubin\textsuperscript{2}, MD, MS
\textsuperscript{1}Stanford University, Department of Computer Science, Stanford, CA; \textsuperscript{2}Stanford University, Department of Radiology, Stanford, CA

Abstract

Data augmentation is an essential part of training discriminative Convolutional Neural Networks (CNNs). A variety of augmentation strategies, including horizontal flips, random crops, and principal component analysis (PCA), have been proposed and shown to capture important characteristics of natural images. However, while data augmentation has been commonly used for deep learning in medical imaging, little work has been done to determine which augmentation strategies best capture medical image statistics, leading to more discriminative models. This work compares augmentation strategies and shows that the extent to which an augmented training set retains properties of the original medical images determines model performance. Specifically, augmentation strategies such as flips and gaussian filters lead to validation accuracies of 84\% and 88\%, respectively. On the other hand, a less effective strategy such as adding noise leads to a significantly worse validation accuracy of 66\%. Finally, we show that the augmentation affects mass generation.

Introduction

Tremendous progress has been made in using deep learning models for image classification and segmentation. In particular, these methods have been adapted in medical diagnostic tasks, such as the prediction and segmentation of cancerous masses, across different modalities, including lung, liver, and breast scans\textsuperscript{123}.

One important preprocessing method that has been shown to be effective in training highly discriminative deep learning models is data augmentation. Data augmentation was initially popularized by Tanner and Wong in order to make simulation more feasible and simple\textsuperscript{4}. In computer vision, because there are generally millions or even billions of parameters in CNNs, data augmentation is critical to accumulate enough data to attain satisfactory performance. Multiple data augmentation strategies have been proposed to improve vision tasks for natural images. Conventional strategies including horizontally flipping images, random crops, and color jittering\textsuperscript{5}. Krizhevsky et al. employ a technique called fancy PCA, which alters the intensities of the RGB channels in training images\textsuperscript{6}.

While different augmentation strategies and their combinations have been researched heavily for natural image tasks, there has been little work on finding optimal augmentation strategies for medical imaging tasks. Unlike in the natural image domain, where ImageNet and similar datasets provide millions of images, there are far fewer training images available in medical imaging\textsuperscript{7}. This dearth of training data makes it critical to explore methods such as data augmentation, which serves as a regularizer and addresses the data-scarcity problem. In this work, we study different strategies for binary image classification of mass and non-mass mammogram images. We show that some augmentation methods capture medical image statistics more effectively than others, leading to higher training and validation accuracy. Finally, we demonstrate that smarter augmentation may result in fewer artifacts in CNN visualizations.

Methods

We attempt to gain insight into the effect that various augmentation methods have on classification accuracy and visualizations of trained CNNs. Our workflow consists of four main steps, the details of which are given in the following sections. First, for each image $I$ in the entire dataset, we perform initial preprocessing, which includes cropping the full size image and splitting into training and validation sets. Second, for each image $I_t$ in the training set, we perform one of eight augmentations. Third, after performing additional cropping of the augmented images, we train eight VGG-16 nets independently on the eight uniquely augmented sets. Finally, we evaluate performance of the trained CNN by measuring training and validation accuracy of mass/non-mass mammogram classification as well as qualitatively assessing visualizations generated from the CNN.
Dataset & Preprocessing

A set of 1650 mass cases and 1651 non-mass (normal) cases were obtained from the Digital Database for Screening Mammography (DDSM)\textsuperscript{8}. The full sized images were initially cropped to 1000 by 1000 images to improve augmentation speed. Each mass image was cropped around the mass lesion, while a random 1000 by 1000 crop of the breast tissue was taken in normal images. Finally, we split the full dataset into a training set and validation set, where approximately 80\% of the images are in the training set and 20\% are in the validation set.

![Example Mass Case + Augmentations](image)

**Figure 1:** Example Mass Case + Augmentations

Augmentations

Before training the models, we utilize eight augmentation strategies to generate eight new training sets. Each new training set is simply the original training images in addition to the training images augmented by one of the techniques below. Each augmentation is as follows:

- **Flips:** We perform a horizontal and vertical flip for each image $I$ in the training set. Even though only horizontal flips are used in natural images, we believe that vertical flips capture a unique property of medical images, namely, invariance to vertical reflection. Conventionally, for natural images, only horizontal flips of the original images are used, since vertical flips often do not reflect natural images (i.e. an upside-down cat would not generally make a model more discriminative during training). However, a vertical flip of a mass would still result in a realistic mass.

- **Gaussian Noise:** We generate an array, $N$, where each element in the array is a sample from a gaussian distribution with $\mu = 0$ and with $\sigma^2$ in the range of $[0.1, 0.9]$. Then, for each image $I$, we obtain a noisy image, $I' = I + N$.

- **Jittering:** For each $I$, we add a small amount of contrast (+/- 1-4 intensity values).

- **Scaling:** We scale each $I$ in either the $x$ or $y$ direction; specifically, we apply an affine transformation, $A = \begin{pmatrix} s_x & 0 \\ 0 & s_y \end{pmatrix}$ on $I$.

- **Powers:** We take each $I$ to a power. To calculate the power, $p$, we use the following equation, $p = n \cdot r + 1$, where $n$ is a random float taken from a Gaussian distribution with mean 0 and variance 1 while $r$ is a number less than 1. Then, to generated the augmented image, $I_a$, we have, $I_a = \text{sign}(I) \cdot (|I|^p)$. The sign and power are both taken elementwise.

- **Gaussian Blur:** We blur each image $I$ by a gaussian function defined by a variance between 0.1 and 0.9. The filter size is then generated internally by scikit-image\textsuperscript{9}, where the radius of the kernel is, $r = 4 \cdot \sigma$.

- **Rotations:** The following affine transformation, $A = \begin{pmatrix} \cos \theta & -\sin \theta \\ \sin \theta & \cos \theta \end{pmatrix}$, where $\theta$ is between 10 and 175 degrees, is applied.

- **Shears:** Finally, each image $I$ is sheared, represented by the following affine transformation, $A = \begin{pmatrix} 1 & s \\ 0 & 1 \end{pmatrix}$. $s$ defines the amount that $I$ is sheared, and it is in the range of $[0.1, 0.35]$. 

980
For each augmentation, we vary the augmentation hyperparameters across their specified ranges and generate a final augmented training set of 15673 images. These ranges were chosen such that a single transformation in the range preserves the class while a transformation outside of the range is not guaranteed to be class-preserving. Note that no augmentations were done on the validation set.

**Training & Evaluation**

Before we begin the training, we further crop each image in both the training and validation set to 500 by 500 pixels. We do so to retain as much information as possible before down sampling to 224 by 224 pixels, which is the input image size expected by the VGG-16 CNN. Then, we train eight VGG-16 CNNs on the eight augmented training sets. The specific experimental parameters are described in the next section.

Before evaluating model performance, we first quantify the augmentation by comparing the similarity between the mean image of the augmented training set, \( M' \), and the mean image of the pre-augmented training set, \( M \). The mean image is an intuitive representation of the training set because it captures the basic regularities across all the training images (e.g. general mass shape, location, etc.). Specifically, we compute the mutual information between \( M \) and \( M' \). Mutual information has emerged as an effective similarity metric between two images; it captures the reduction in uncertainty of one variable given that we know the other. We evaluate each model by observing the variation in training and validation accuracy across augmentations.

Additionally, we qualitatively assess visualizations generated by the CNNs. The visualizations for each CNN are generated according to the class visualization method detailed by Simonyan et al. Specifically, we numerically generate an image that represents the class of interest, which in this case is "mass", from an input image of normal breast tissue. We do this generation by performing gradient ascent on the target class.

Formally, let \( I \) be the the input image and let \( y \) be the target class. \( s_y(I) \) is the score that a CNN assigns to image \( I \) for class \( y \). The image, \( I^* \), that maximizes the score for class \( y \) is generated by solving the following optimization problem,

\[
I^* = \arg \max_I s_y(I) + \lambda \|I\|_2^2.
\] (1)

Note that \( \lambda \) is a regularization parameter. We solve this optimization using backpropagation, where we initialize the scores to be a one-hot vector, with the target class set to 1 and the other class set to 0. Letting \( dI \) be the gradients derived from backpropagating from the score layer, the final gradients are defined by the following equation,

\[
dI = dI - 2\lambda \cdot I,
\] (2)

where the second term, \( 2\lambda I \), comes from the derivative of the second term in the objective function.

**Experiments**

We perform eight training experiments, where one experiment consists of training a VGG-16 net on one of the eight augmented sets. For each experiment, the learning rate is set to \( 1e^{-3} \), L2 regularization is set to \( 1e^{-7} \), and the dropout parameter \( p \) is 0.5. The network is then trained over its corresponding augmented training set for 2500 iterations. We train each network for approximately 1.5 epochs, since the classification accuracy generally plateaus around this point.

For the visualization experiments, we find the gradients that need to be applied to image \( X \) at each iteration via backpropagation (derivation not shown). If we let \( dX \) be the gradients derived from the backpropagation at iteration \( i \), then the update step at \( i \) will be \( X = X + \alpha \cdot dX \), where \( \alpha \) is the learning rate. For each of the eight visualizations, the learning rate is set to \( 1e^{-1} \), the regularization parameter applied to \( dX \) is \( 1e^{-7} \), and the number of iterations where we update \( X \) is 350.
Results

To visualize the effect of each augmentation on the training set, in Figure 2, we present the mean image of the training set before augmentation as well as the mean images of each augmented training set. The mutual information between the mean images of each augmented training set and the mean image of the original data set are given in Table 1. These values enable us to explore the relationship between the mutual information of a mean image generated from an augmented training set and the training and validation accuracy of the CNN trained on that augmented set. In other words, we attempt to determine if the extent to which an augmentation captures information about the original training set affects the training and validation accuracies. Because the original training set is representative of the validation set, this effect gives us some intuition on how the model might generalize given some augmentation on the training set. Figure 3 shows how classification accuracies vary with the mutual information of the augmented training set’s mean image.

Table 1: Mutual Information between Mean Images + Average Accuracies

Figure 3: Accuracy vs. Mutual Information of Mean Images

Generally, we wish to see how each model performs by observing its classification accuracy over some number of epochs. The training/validation accuracy is computed simply by finding the number of samples classified correctly as mass or non-mass out of the total number of samples in the training/validation set. These accuracies are tracked over 2500 iterations (approximately 1.5 epochs), and the mean accuracies are shown in Table 1. Finally, we also assess the
performance of each model by qualitatively analyzing the image generated from the CNN using the class visualization method described previously, where we iteratively alter an input image to make it look more like a "mass". These images are shown in Figure 4.

![Figure 4](image_url)

**Figure 4**: Visualizations; augmentation used has significant effect on the generated mass image. Artifacts that appear are correlated to the type of augmentation used.

**Discussion**

Looking at the results from Table 1 and Figure 3, we notice that aside from the accuracies for the shear and rotate augmentation sets (the cluster on the top left), a higher mutual information correlates to a higher classification accuracy. Specifically, the augmentations that resulted in mean images that had mutual informations of approximately 2.6-2.7 (flips, scale, jitter, gaussian filter) had accuracies of around 0.85 while those that resulted in mean images with mutual informations of around 2.3 (noise, powers) had much lower accuracies of around 0.65-0.70. Also, in general, the noise and powers augmentations, resulting in mutual information 2.27 and 2.33, respectively, have more variance in their validation accuracies over time compared to augmentations resulting in higher mutual information (plots not shown).

With regard to the shear and rotation augmentations, which result in mean images with relatively low mutual information but high classification accuracies, there is an intuitive explanation as to why this is the case. Namely, rotations and shears do retain many of the image statistics in the original training set, leading to a high classification accuracy, but artifacts in the augmented images may affect the mean image and lead to a lower mutual information. For example, if a mass appears on the edge of a breast, then the 500 by 500 crop of the original image will retain the 0 pixels that appear when rotating the 1000 by 1000 image. Generally, if the mass is near the center of the crop, as is the case for the majority of the training images, then the 0 pixels will be cropped away. These slight artifacts may decrease the overall mutual information, even though the high classification accuracies suggest that rotations and shears preserve mammography image statistics. To solidify the correlation between mutual information and classification accuracy, future work includes investigating other augmentation strategies and deriving a better representation to capture image statistics than the mean image.

Furthermore, we see that the augmentation strategy used has a significant effect on the type of mass that is generated, as shown by the images in Figure 4. In general, we see that the augmentation determines the type of artifact that predominates the mass generation. For example, the artifacts that appear in the generated image from the CNN trained on the rotations set has circular patterns. We see a similar phenomenon for the 'flips' generated image, where we see several masses that look they have been flipped. These results suggest that using a combination of augmentations
that have high mutual information might lead to an ensemble effect where the medical image statistics are holistically captured, leading to generated images with fewer artifacts. We hope to use these findings when applying generative deep learning techniques in our future work.

Conclusion

We show that the mutual information captures the basic image statistics of an augmented dataset and roughly correlates with the performance of a CNN trained on that augmented set. Overall, our work shows that augmentation strategy greatly affects discriminative performance but also drastically affects generative performance, suggesting a strong link between discriminative and generative learning.

Measuring Workload Demand of Informatics Systems with the Clinical Case Demand Index

M. Sriram Iyengar, PhD¹, Deevakar Rogith, MBBS, PhD², Jose F Florez-Arango, MD, PhD¹,³

¹Center for Biomedical Informatics, College of Medicine, Texas A&M Health Science Center, Houston, TX, USA; ²The University of Texas Health Science Center at Houston (UTHealth) School of Biomedical Informatics, Houston, TX, USA; ³Escuela de Ciencias de la Salud, Universidad Pontificia Bolivariana, Medellin, Colombia

Abstract:

Introduction: The increasing use of Health Information Technology (HIT) can add substantially to workload on clinical providers. Current methods for assessing workload do not take into account the nature of clinical cases and the use of HIT tools while solving them. Methods: The Clinical Case Demand Index (CCDI), consisting of a summary score and visual representation, was developed to meet this need. Consistency with current perceived workload measures was evaluated in a Randomized Control Trial of a mobile health system. Results: CCDI is significantly correlated with existing workload measures and inversely related to provider performance. Discussion: CCDI combines subjective and objective characteristics of clinical cases along with cognitive and clinical dimensions. Applications include evaluation of HIT tools, clinician scheduling, medical education. Conclusion: CCDI supports comparative effectiveness research of HIT tools. In addition, CCDI could have numerous applications including training, clinical trials, design of clinical workflows, and others.

Introduction

In recent years, there has been increasing interest in assessing and quantifying healthcare provider workload¹-³. A major motivation is that excessive workload has a substantial negative effect on quality of care provided and patient safety⁴-⁶. The introduction of Informatics tools such as Electronic Health Records EHRs, Computerized Prescription Order Entry, CPOE systems, mobile health decision support tools, is known to contribute to workload⁷,⁸ for example by increasing cognitive and physical demands on the provider⁹-¹¹. Therefore, there is a need for methods to quantify the impact of Health Information Technology (HIT) on provider workload and, especially, to perform comparative effectiveness research of informatics tools with respect to workload.

While objective measures, such as time performances, and subjective measures like the National Aeronautics and Space Administration -Task Load Index (NASA-TLX)¹², and the Subjective Workload Assessment Technique (SWAT)¹³ have productive uses in healthcare, they do not explicitly consider an important factor: the nature of the clinical case¹⁴. For example, it seems intuitively clear that 8 hours spent in handling routine and simple outpatient cases impose less clinical demands and workload on healthcare providers than 8 hours in an intense trauma and critical care setting. This aspect of clinical tasks is not captured explicitly or adequately in current workload analysis. This means that evaluation of HIT tools is limited to task efficiency or subjective factors while ignoring the influence of the nature of the clinical problem on effectiveness of HIT tools. Quantifying workload characteristics at the clinical case level enables detailed analysis, modeling, and simulation of clinical cases. For example, when performing comparative effectiveness research of informatics tools using clinical trials it can become necessary to provide patient cases that make comparable clinical demands across study design groups.

In this paper, we present the Clinical Case Demand Index (CCDI), a tool that succinctly combines objective and subjective characteristics of clinical cases with respect to the multifactorial demands they place on clinicians. The CCDI focuses on evaluating clinical cases while the NASA-TLX and SWAT are primarily focused on evaluating subjects¹⁵,¹⁶. A major application of CCDI is to compare two or more cases and determine how similar or different they are in terms of the demands these cases make on providers.

BROADLY SPEAKING,
metric to identify such comparable clinical cases. In the following we describe such a comparative effectiveness study in some detail.

**Related Work: Workload factors in Clinical Care**

Provider workload can be measured objectively by metrics such as physical hours spent in patient consulting, number of patients seen, type of patients / diseases seen. For example, in a study, primary care physicians worked about 50-60 hours per week, with about 18 patient visits per day per physician. These sorts of measures are aggregates focused on quantity of provider services and do not account for the multifactorial demands made on clinicians by specific clinical cases and types of cases.

In addition to the purely objective measures, subjective measures of workload, developed initially for engineering and manufacturing contexts have also been applied in the clinical domain. Notable among these are The National Aeronautics and Space Administration -Task Load Index (NASA-TLX) and the Subjective Workload Assessment Technique (SWAT). The NASA-TLX incorporates mental, physical, and temporal demands as well as the operator’s assessment of his/her performance into its model of workload. The SWAT considers the operator’s time pressures, mental effort, and psychological stress. When assessing the workload, the scenario is distilled into its tasks. In this context, we note that physical workload can be defined as physical strength and resources required for completing a task. Mental (Cognitive) workload is defined as effort required for thought processes, reasoning, calculating, decision-making, memory, learning, and other cognitive activities.

NASA-TLX and SWAT are aggregates of purely subjective perceptions that do not consider the multiple characteristics of the clinical case. Some of these case characteristics are objective, such as the number of clinical tasks needed, whether the case is routine, is an emergency, and so on. Others are subjective such as perceived cognitive and physical demands.

Workload and performance in clinical cases have also been quantified using case complexity measures. Such case complexity measures consider intrinsic factors including clinical, social, and epidemiological factors. These complexity measures are used in training and research. However, these measures do not consider extrinsic factors such as provider skill and available resources, including HIT tools, for solving clinical cases. So far, workload assessment of HIT tools supporting clinical practice has been done using total time spent and conventional human factors assessment of task performance, ignoring the nature and complexity level of clinical cases. It is useful to combine both intrinsic and extrinsic factors since irrespective of its intrinsic complexity, provider factors such as decision-making skills and executing needed tasks are crucial to outcomes.

In addition, the comprehensive relationship between sources of workload and human performance evaluation does not seem to have been investigated in detail for this purpose. Florez-Arango, Iyengar, and Smith (2016) developed an ontological approach to model properties of actions performed by clinicians and related human factors. This ontological approach combines previous work describing task as goals or processes, and human factors derived from NASA TLX.

**Methods:**

**Clinical Case Demand Index**

Clinical cases are a fundamental unit in healthcare, comprising of a complex micro-environment of physical and mental processes. While solving a clinical case a healthcare provider typically performs several actions such as taking blood pressure, performing auscultation, arriving at a diagnosis, providing a treatment plan, and so on. We denote these actions as Tasks. Each task contributes to the overall demand and workload on the provider. With this nomenclature, solving a clinical case is equivalent to performing a sequence of one or more tasks by the provider or team. For example, most clinical practice guidelines (CPGs) are structured as a series of tasks to be performed considering clinical signs and symptoms. In this paper, we are concerned with the use of HIT tools while performing one or more of these tasks.

The CCDI is based on five dimensions derived from a formalism to represent tasks that are widely regarded among researchers and practitioners as contributing significantly to case demand. It includes clinical and cognitive dimensions that are related to use of HIT tools. Physical Demand (PD) and Cognitive Load (CL) are ubiquitous when assessing provide workload. The Time Pressure (TP) dimension is related to urgency as a factor for decision making.
The \textit{Expertise (EX)} dimension is a combination of importance/criticality\textsuperscript{34, 35} and familiarity/uniqueness\textsuperscript{36} as a factor for decision making. The \textit{Task Complexity (TC)} dimension counts the number of tasks required to solve the clinical case, noting that the ability to make clinically meaningful clinical decisions decreases as the number of tasks in a case increases\textsuperscript{37}. An issue here is that even for the same clinical case, the sequence of tasks that is performed can vary widely depending on the institution, the qualifications of the healthcare provider, national and local standards. To account for these variations in clinical practice the Task complexity is normalized over a given cohort of clinical cases. This means that CCDI is most meaningful over that cohort, such as within a specific care context or research setting.

CCDI consists of both a numerical summary, CCDI-S and a visual depiction, CCDI-V, of these 5 dimensions. CCDI-S provides an overall idea of the case demand and lends itself to statistical analysis, while CCDI-V enables rapid comprehension of the differential roles of the five dimensions listed above. We suggest that maximum benefit of the CCDI will be obtained by utilization of both the summary value and the visual component.

Developing the Clinical Case Demand Index

The CCDI is computed as follows based on five dimensions.

1. \textbf{Time Pressure (TP)}: This dimension of CCDI describes the temporal constraints on tasks in case. If a single task in a case must be executed immediately, for example, because the patient is in imminent risk of death, it is an \textit{emergent} case. When a single task is required to be executed to avoid death or permanent sequels it is an \textit{urgent} case. Cases with lack of emergent or urgent task are \textit{non-urgent}.

2. \textbf{Expertise (EX)}: This dimension relates to the level of knowledge or skills required to complete the case. It is rated \textit{Low} if the provider can complete the task by himself or herself without needing additional resources. If any task in the case requires the provider to call on another individual of same knowledge and skills, the task is rated \textit{Medium}. Finally, if specialized expertise, knowledge, or skills is needed, the expertise level is rated \textit{High}.

3. \textbf{Cognitive Load (CL)}: In the context of HIT tool use, this dimension is rated \textit{High} when majority of tasks in the case require recall from long-term memory. A \textit{medium} cognitive load occurs when tasks only require use of working memory such as calculations. Any other kind of cognitive processing, such as mechanical click-through and simple note-taking, is scored as \textit{low}.

4. \textbf{Physical Demand (PD)}: When a task in a case requires heavy manual labor, muscular strength, the whole body, or constantly switching positions PD is scored as high. If a task requires use of both hands to manipulate and solve the problem it is graded as \textit{medium}. When there is little or no physical effort is \textit{low}.

5. \textbf{Task Complexity (TC)}: This component is a function of the cases in the cohort under consideration, as explained above. It is a continuous variable in range 0-3.

\[
TC = \frac{n_t \cdot 3}{\max(n)}.
\]

\(n_t = \) number of tasks in the case \(i\), obtained by heuristic task analysis\textsuperscript{38} \(\max(n)\) is the number of task in the largest case.

Each factor is scored between 0 and 3 as shown in Table 1.

\]
Clinical Case Demand Index – Summary (CCDI-S):

Summarizing the 5 axes, a composite numerical measure is calculated as shown below:

\[ CCDI - S = \frac{TP^{EX} + CL + PD + TC}{15} \]

Interpretation: The values range from 0-1. Lower numbers represent lower case demand.

Clinical Case Demand Index – Visual (CCDI-V):

The graphical component of the CCDI is a 5-axis radar plot corresponding to each of the five dimensions, TP, EX, TC, CL, and PD. In the rest of this paper we shall refer to each of this interchangeably as a dimension or an axis. Radar Plots (Figure 1) are a graphical method of displaying multivariate data with axes radiating from a central point. The plot consists of spokes radiating from a central point separated by equal angles. The spokes correspond to the axes. The axis values determine the length of a spoke. The number of axes determines the shape of the plot - from a triangle, pentagon, to full circle. Radial lines connecting the major and minor ticks in the axis can be drawn to help in both plotting and reading the graph. The values of the variables are encoded into the lengths of the axes and normalized to fit in the overall area.

Figure 1 - CCDI-Visual (CCDI-V) component of CCDI

In each of the five axes the value of that axis increases from the origin to the perimeter. A case in which all 5 dimensions have a value of 1 (typically interested as defining low demand in that dimension) would appear as a filled in symmetric pentagon with internal radii equal to 1. Asymmetric radar plots indicate that at least one dimension makes greater demands than others. For example, in the 6 radar plots shown in Figure 2 below, the top left plot shows high demand (need) for expertise and low demand for physical effort.

Evaluating CCDI for grouping cases in a clinical trial for a mobile health tool

An example application of CCDI is a mobile Health study at the simulation lab of Universidad de Antioquia (UdeA), Medellin, Colombia. The purpose of this study was to determine the benefits of presenting clinical practice guidelines in a media-rich step-by-step algorithm presented on smart phones vs the same content on paper. The study design was a randomized cross-over in which each subject managed 15 cases using the mobile health tool and another 15 using paper-based guidelines. To make the comparison meaningful the two sets of cases needed to be “equivalent” and yet different, to prevent learning effects. The CCDI was used to quantify clinical demands on 30 clinical cases and determine 15 comparison of cases per subject between treatments. The cases were selected from an existing case bank at Simulation Center and Clinical Skills lab (CS) in UdeA. Physician experts from UdeA reviewed the cases and trained Community Health Worker (CHW) performed the clinical tasks. The CHWs who performed the task were predominately male (58%), and were qualified as CHW by training or experience, comparable by their training. Mean years of training was 3.24 years.

Three physicians, as a group, conducted ontological informed task analysis over the 30 cases (10 pediatric, 10 trauma, and 10 non-trauma) and came to a consensus on the values of the five factors (axes) for all 30 cases. The CCDI was computed for all 30 cases based on the consensus values developed by the 3-physician group for each of TP, EX, TC, CL, and PD. CCDI-S and CCDI-V were calculated for the 30 cases using a Microsoft Excel spreadsheet. Based on the CCDI, cases were indexed from 1-5 and grouped under 6 categories (A & D – Pediatrics, B& E- Trauma, C&F – non-trauma). They are grouped in such a way that cases A1-D1 are equivalent, A2-D2 are equivalent and so on.
Figure 2 - CCDI-V plots of 6 cases.

Case ID - Row 1: A1, B2, C4; Row 2: D1, E2, F4

Figure 2 shows radar plots of six cases from the sample. The cases illustrated in Figure 2 are A1-Mastoiditis, B2 Burns, C4-Hypertension, D1-Severe Malnutrition, E2-Below-Knee Amputation, F4-Headache. Visual analysis, based on area and length of axes in the CCDI-V enabled grouping of the pairs of cases with respect to case demand. It is seen that A1 and D1, B2 and E2, C4 and F4 are equivalent. Using a combination of CCDI-V and CCDI-S allowed to avoid pairing cases like B2 and A1 with similar CCDI-S values but clearly different CCDI-V.

A total of 50 CHWs were recruited. We selected 5 of these CHWs to pilot the CCDI on 30 cases. Three independent physician observers noted that no additional tasks needed to be added to any cases, and that the evaluation of other axes were appropriate. Based on this review no changes to the scale or study design were made, and the data from the 5 pilot study CHWs were included in the final analysis of 50 CHWs. They were divided into two groups and each group performed 15 cases out of total 30. In Group 1, Cases A-C were included and in Group 2, Cases D-F were included. In Group 1, 21 CHWs, and in Group 2, 23 CHWs completed all the 15 cases allotted. Only these completed cases were included in the final analysis. The groups were exclusive and independent samples with no overlap of cases.

To understand whether CCDI provides meaningful values consistent with workload analyses we compared the case groupings described above with the NASA-TLX values assigned by care providers to the 30 cases as follows. One Laerdal Simman® and one Laerdal Simbaby® human patient simulators at the CS were programmed with the selected cases. The simulated cases were presented to CHW subjects. Cases were completed by CHWs in each treatment (mobile vs paper guidelines) group. At the end of each case, the subjects completed NASA-TLX questionnaire in Spanish. For each case the NASA-TLX was computed as average of all subjects’ score in the group. Consistency of grouping by CCDI with NASA TLX grouping is important to validate CCDI as a predictive measure of case demand. NASA TLX has been validated in health-care contexts as a measure of perceived workload.

We compared the CCDI to NASA-TLX using Pearson correlation, regression analysis and paired t-test. Our null hypothesis is that CCDI and NASA-TLX are not comparable with a 0.05 level of significance. We used R software package for statistical analysis.

Results:

CCDI is a valid, strong predictor of NASA-TLX with R-squared of 0.33, and Pearson correlation is 0.58. The difference between the means of CCDI and NASA-TLX would be between 0.11 and 0.01 with 95% confidence interval. The accuracy of CCDI is 0.06 - i.e. 68% of values predicated from CCDI would lie within 0.06 of the NASA-TLX value in the population. Table 2 shows that the grouping of cases by CCDI, which is a prospective, pre-task scale is consistent with NASA-TLX which is a subjective post-task measure off perceived workload.

Discussion:
The Clinical Case Demand Index is a measure of the multifactorial subjective and objective demands required to handle clinical cases in healthcare. In Human Factor research, workload is defined as “that portion of the operator’s limited capacity actually required to perform a particular task” 40. Measuring workload helps in assessing the capacity required for optimal performance. Workload assessment is typically performed to improve productivity, reduce adverse events, plan resource allocation, training, and for quality management. CCDI serves as a tool to assess workload in healthcare. The CCDI includes both a summary numerical value (CCDI-Summary) and a succinct visual in the form of a pentagonal radar plot (CCDI-Visual). The radar plot generated helps to visualize the workload, while maintaining the weights of the dimensions. Radar plots have been used in healthcare to display multivariate data 41, 42. They show the areas of strength and weakness, as well as a general overall summary. The CCDI-V, among other benefits, provides a rapid way to differentiate cases with respect to the specific factors, TP, EX, TC, CL, and PD. CCDI can be applied in selection of clinical cases for training, evaluation, resource management and research purposes.

The CCDI-V is designed to support visual analytics, a technique that’s growing rapidly in popularity in biomedical informatics. They can be inspected rapidly both in regards to the relative sizes of the axes and the size and shape of the shaded area. For example, the relative roles of each of the five axes, representing the impact of each of the five factors making up the overall CCDI, can be assessed at a glance. If multiple cases are being considered, a side-by-side visual inspection can simply assess their similarity. For example, cases that have high cognitive load (CL) can be
grouped together if the corresponding axes on their CCDI-V plots are similar in length. The size and shape of the shaded area also rapidly yields useful case demand information. If the shape of the shaded areas of the CCDI-V plots for several cases are similar, but the sizes are different it is immediately apparent that these cases make similar demands in terms of the 5 factors, TP, EX, TC, CL, and PD, but the overall demand varies.

One of the applications of CCDI is in comparative effective research of HIT. As described above, we used CCDI to allocate cases with equivalent workload in two treatment groups. CCDI enabled presentation of cases matched with respect to difficulty level from simple to more difficult in each group. This enabled meaningful comparisons of clinician performance, learning and burnout. Thus, CCDI can be applied to create standardized cases, normalized with respect to clinical demand, for clinical student evaluation and training purposes.

Applications of the CCDI include training, evaluation, planning healthcare provider schedules, and quality management. The combined CCDI can be used in training contexts such as evaluation of resident’s skills, allotment of cases for examinations. Comparing cases based on CCDI can be useful in quality assessments, planning clinical workflow, and for insurance purposes.

Limitations:
Formal reliability and validity analyses of CCDI need to be performed. The scale was developed as part of study to train community health workers; thus, it may not represent the workload of another clinical environment. The cases used for testing the scale were subjectively chosen and may be subject to selection bias. The task complexity component involves summary of count of number of tasks, irrespective of inherent complexity of the task itself. The CCDI is designed to be applied only when at least two fully specified cases (using an ontology for example) are being considered.

Future Work:
Immediate future tasks include reproducing the evaluation in a variety of clinical settings with various types of providers including nurses, physicians, and specialists with larger sample sizes. These studies will facilitate factor analysis studies. Also, we are currently designing software tools to generate CCDI from case repositories.

Conclusion
The Clinical Case Demand Index measures the combined effects of five dimension typically contributing to provider workload in solving clinical cases especially when using HIT tools. Unlike currently used measures of workload CCDI takes into account intrinsic and extrinsic factors related to solving clinical cases. In this paper, its utility in comparative effectiveness research of a mobile health tool was demonstrated. In addition, CCDI could have numerous applications including training, clinical trials, design of clinical workflows, and others.

Real-time mortality prediction in the Intensive Care Unit

Alistair E. W. Johnson, DPhil1, Roger G. Mark, MD PhD1
1Massachussetts Institute of Technology, Cambridge, MA, USA

Abstract

Real-time prediction of mortality for intensive care unit patients has the potential to provide physicians with a simple and easily interpretable synthesis of patient acuity. Here we extract data from a random time during each patient’s ICU stay. We believe this sampling scheme allows for the application of the model(s) across a future patient’s entire ICU stay. The AUROC of a Gradient Boosting model was high (AUROC=0.920), even though no information about diagnosis or comorbid burden was utilized. We also compare models using data from the first 24 hours of a patient’s stay against published severity of illness scores, and find the Gradient Boosting model greatly outperformed the frequently used Simplified Acute Physiology Score II (AUROC = 0.927 vs. 0.809). We nuance this performance with comparison to the literature, provide our interpretation, and discuss potential avenues for improvement.

Introduction

The intensive care unit (ICU) admits severely ill patients in order to provide radical life saving treatment, such as mechanical ventilation. ICUs frequently have a very high staff to patient ratio in order to facilitate for continuous monitoring of all patients and ensure any deterioration in patient condition is detected and corrected for before it becomes fatal; an approach which has been demonstrated to improve outcomes1. As a result, the ICU is a data rich environment. A major effort was placed in utilizing this data to both quantify patient health and predict future outcomes, and one of the most immediately relevant outcomes to the ICU is patient mortality. The APACHE system was first published in2, and provided predictions for patient mortality based upon data collected in the ICU. While the initial system was based off expert rules, later updates used data driven methods3. Other prediction systems have also been developed, including the Acute Physiology Score (APS) III4, Simplified Acute Physiology Score (SAPS)5, SAPS II6, the Sequential Organ Failure Assessment (SOFA) score7, the Logistic Organ Dysfunction Score (LODS)8, and the Oxford Acute Severity of Illness Score (OASIS)9. For a review of severity illness scores in the ICU, see10, 11. Note that these models were universally agreed to lack sufficient calibration to be used on the individual level12, and research goals were shifted to quantify the performance of ICUs and hospitals in aggregate.

With the recent advances in both machine learning and hardware for data archiving, research has begun to return to building better prediction models using more detailed granular data. Past models have been limited by technical and practical considerations, often using summary data from an entire day of a patient’s ICU stay which was manually documented by trained personnel. Given many hospitals now have electronic data collection as a part of routine clinical practice, a wealth of data is becoming available for use in predictive modeling. The Medical Information Mart for Intensive Care (MIMIC-III) database by13 is an example of such an archive. MIMIC-III is a large collection of de-identified electronic medical records for over 40,000 patients admitted to the Beth Israel Deaconess Medical Center in Boston, MA, USA between 2001 and 2012.

Hug et al.14 investigated the use of real-time prediction models on MIMIC-II, an early version of MIMIC containing patient data up to 2008. They extracted observations for 10,066 patients and used a logistic regression model on all observations, achieving a held-out performance Area Under the Receiver Operator Characteristic curve (AUROC) of 0.885. Mortality prediction was the topic of a PhysioNet Computing in Cardiology Challenge in 2012, specifically the prediction of in-hospital mortality for patients who stayed in the ICU for at least 48 hours15. The winning entry utilized a tree based ensemble in a Bayesian framework, with components of the trees being updated using Markov chain Monte Carlo, and achieved an AUROC of 0.86016. The runner up included an ensemble of six support vector machine models built on balanced subsets of data each using the same set of all positive outcomes17.

Lehman et al.18 applied hierarchical Dirichlet Processes to clinical notes during the first 24 hours and found that the addition of extracted topics to a classifier using only severity of illness improved performance (AUROC = 0.82 versus 0.78 with only SAPS I). Ghassemi et al. extracted topics from the notes and combined these topics with static features from MIMIC in a support vector machine to classify in-hospital mortality (AUROC = 0.840)19. The authors
furthered this approach by extracting dynamics associated with topics using a multi-task Gaussian process, improving upon the AUROC of SAPS (AUROC = 0.812 vs 0.702)\textsuperscript{20}. Caballero et al.\textsuperscript{21} created a latent state model incorporating numeric features, text, and modelled topics achieving an AUROC of 0.866 during the first 24 hours on patients in the MIMIC-II database. Finally, Luo et al.\textsuperscript{22} proposed an unsupervised feature extraction model using non-negative matrix factorization, focusing on creating an interpretable model (AUROC=0.848).

The use of mortality prediction models to evaluate ICUs as a whole has found great success, both for identifying useful policies and comparing patient populations. Furthermore, as mentioned, much research has advanced the current state of the art in mortality prediction. In this paper, we propose to address the task of predicting individual patient mortality using a distinct sampling scheme. The aim is building a model which could be applied continuously for a patient, which departs from the common analysis framework of the first 24 hours or distinct daily models. This paper will proceed as follows: first, the patient population is defined and data extraction steps are outlined. Common mortality prediction systems in the literature (commonly called severity of illness scores) are then compared to machine learning approaches using data extracted from the first 24 hours of a patient’s stay. The framework for evaluating a real-time mortality prediction system is then established and we evaluate various machine learning models in this context, concluding with a discussion on their efficacy and avenues for improvement.

Data

We initially extracted data for 61,533 distinct ICU stays (all stays available in MIMIC-III v1.4). We subsequently excluded patients who met the following criteria: age less than 16 (MIMIC contains neonatal admissions), an ICU stay shorter than four hours, no data present in the patient flowsheet (likely an administrative error resulting in an incorrect ICU admission), and organ donor accounts. We also excluded patients who had an order for limitation of treatment (not full code) on or before ICU admission. Note that we otherwise retained all ICU stays, including readmissions for patients with multiple visits. The final cohort had 50,488 ICU stays. This cohort was used for both experiments (described later). These stays correspond to adult ICU admissions for surgical, medical, neurological, or coronary critical illness. Table 1 provides a description of the study population.

Feature Extraction

For each patient’s ICU stay, we extracted data from a fixed window of length $W$ (hours) ending at time $t_{i,w}$ (hours) for each patient $i$. $t_{i,w}$ was set to some value during a patient’s ICU stay, i.e. if $t_{i,adm}$ was the time of the patient’s ICU admission and $t_{i,dis}$ was the time of the patient’s ICU discharge, then $t_{i,w} \in [t_{i,adm}, t_{i,dis}]$. For the initial evaluation of models against severity scores, $t_{i,w} := 24$ hours and $W := 24$ hours, resulting in data being collected from the first day of a patient’s ICU stay. For the second evaluation setting, $t_{i,w}$ was set to a random time during the patient’s ICU stay, and $W$ was varied from 4 to 24 hours.

Features extracted from the window of fixed size $W$ are detailed in Table 2. Features were extracted from a number of physiologic and laboratory measurements. Notably, no explicit data regarding treatment was extracted (e.g. use
of vasopressors, mechanical ventilation, dialysis, etc). Features extracted used consistent functional forms: the first, last, minimum, maximum, or sum (in the case of urine output) was extracted from all measurements of the variable made within the window $W$. As laboratory values are less frequently sampled, this window was extended 24 hours backward for these measurements. Table 2 lists the window sizes used for each of the features extracted. In addition to those listed in Table 2, a set of static features which do not change during an ICU stay were extracted. These included gender, age, ICU service, and whether the hospital admission was an emergency (binary covariate). Service was coded using one-hot encoding for the following services: coronary medicine, coronary surgery, surgery, neuro-surgery, other surgery, trauma, neuro-medicine, other medicine, orthopedic, gastro-utinery, gynecology, and ear/nose/throat. A total of 148 features were extracted.

**Methods**

We evaluated multiple machine learning models both to quantify the improvement possible from more flexible approaches and to ensure robustness of our findings across multiple settings. The models used were: logistic regression (LR), logistic regression with an L1 regularization penalty using the Least Absolute Shrinkage and Selection Operator (LASSO), logistic regression with an L2 regularization penalty (L2), and Gradient Boosting Decision Trees (GB).

In addition to the above models a set of five severity of illness scores were calculated on the data. Severity of illness scores are a form of mortality prediction model where the result is an integer score correlated with mortality. Severity of illness scores evaluated here are the APS III\(^4\), SAPS\(^5\), SAPS II\(^6\), SOFA\(^7\), LODS\(^8\), and OASIS\(^9\).

For all models, the outcome evaluated was in-hospital mortality. The area under the receiver operator characteristic curve (AUROC) was used to evaluate the models. The AUROC is the probability of ranking a patient who dies higher than a patient who lives: higher values of the AUROC indicate better model discrimination, and a value of 0.5 is equivalent to random chance. We also evaluated the models using the area under the precision recall curve (AUPRC), which provides a measure of performance which is agnostic to the number of true negatives and can be useful for problems with class imbalance. Hyperparameters were set using an internal three-fold cross-validation within the external five-fold cross-validation. Once hyperparameters were selected using the internal three-fold cross-validation, the model was retrained using the entire training set and subsequently evaluated on the external validation.
fold. This process was repeated five times for each external validation fold. Hyperparameters searched were as follows: regularization penalty (LASSO/L2), the number of trees in the ensemble (GB), the learning rate (GB), and the maximum depth of each tree (GB). The other parameters were set to their default values. We used scikit learn v0.18.1 and XGBoost v0.6 with Python 2.7. Model performance is reported as the average across five held out folds in an outer cross-validation, with the minimum and maximum performance across all folds.

Experiments

Two experiments were conducted which essentially involve defining the window to be used for data extraction for each patient. In the first experiment, the window size was set to 24 hours ($W := 24$), and $t_{i,w}$ was fixed to 24 hours after ICU admission (i.e. $t_{i,w} := t_{i,adm} + W$). This emulates the most common framework for evaluating mortality prediction models used for risk adjustment. As these models aim to capture patient health on admission to the ICU (to reduce the impact of ICU care and acquire an estimate of how severely ill a patient was on admission), the data analyzed is from the first 24 hours (except labs, which are again allowed an additional 24 hours as in Table 2). We refer to this experiment as the "benchmarking experiment".

In the second experiment, $t_{i,w}$ is defined as a random time between ICU admission and ICU discharge or the first instance of a treatment limitation order, whichever is earlier, i.e. $t_{i,w} \sim \mathcal{U}[t_{i,adm}, \min(t_{i,dis}, t_{i,dnr})]$. This experiment is designed to create a model which is applicable at all possible times during a patients ICU stay, rather than traditional models which are only applicable using data from the first 24 hours. Furthermore, in order to avoid the model learning from data corresponding to the withdrawal of treatment rather than severe illness, no data is extracted after a patient’s code status is changed. For example, a do-not-resuscitate (DNR) order indicates that a patient does not desire to be resuscitated in the case of cardiac arrest. While some treatments are still given for patients who have a DNR, we took the conservative approach of excluding this data. Note that if a patient has a code status change, the data before this code status change would still be eligible for data extraction. Patients who had a code status other than full code on admission to the ICU were previously removed from this cohort as detailed earlier. We refer to experiment as the "real-time experiment". We utilized a window size $W := 4$ hours. We experimented with longer windows of 8 and 24 hours, though these did not impact model performance significantly (results not shown).

The models developed in the real-time experiment were also evaluated using windows ending at a fixed time to death. This experiment aims to evaluate the construct validity of the algorithms: as the window approaches patient mortality, we assume that the data will reflect worsening physiology. If the classifier has captured this information then the classifier’s performance should increase. To this end, the models were trained as detailed above using a random time window during the patient’s ICU stay. When evaluating the model, patients who died in the ICU had the end of the window set to 0, 4, 8, 16, and 24 hours before mortality. If the patient did not expire in the ICU, then a random time window during their ICU stay was used as was done during normal model development, and their outcome was set to zero (that is, a low prediction for a patient who dies more than 24 hours after ICU discharge is no longer penalized by the evaluation).

All code for this paper is open source and available online.

Results

Two exemplar patients are shown in Figure 1 with the two types of data extraction used for the benchmarking experiment and for the real-time experiment. The patient in the top plot survived to ICU discharge, while the patient in the bottom plot had a code status change and subsequently died in ICU. The gray background indicates the window used for data extraction, representing the benchmarking experiment in the top plot (first 24 hours of ICU admission) and the real-time experiment in the bottom plot (a random time during the ICU stay which cannot occur after a code status change).

Benchmarking experiment

The LR, LASSO, L2, and GB models were trained using features extracted as detailed for the benchmarking experiment. A total of 50,488 patients were included (the full cohort). Five fold cross-validation was used to obtain held
Figure 1: Two exemplar patients shown with vital sign data with measurement values along the y-axis. The shaded gray region corresponds to the window used for data extraction. In the top plot, the dark rectangular patch represents the window used in the benchmarking experiment (24 hours long), and the end of the window set to 24 hours after ICU admission. The lighter rectangular patch represents the additional window used for extracting laboratory measurements, which can be present before ICU admission. The patient in the top plot survived to ICU discharge.

The bottom plot represents a distinct patient with the patches representing an example window (4 hours) used in the real-time experiment hours and the end of the window set to a random time during the patient’s ICU stay before any code status changed. This patient was made do-not-resuscitate (DNR) and subsequently died in ICU.
out estimates of model performance. These models were compared to severity of illness scores: SAPS II, APS III, LODS, SOFA, and OASIS. AUROCs for severity of illness scores were calculated for each fold, and the minimum, maximum, and average AUROCs are reported, along with AUROCs for models trained in this work and models from the literature (Table 3).

Table 3: Comparison of models trained here and in the literature with severity of illness scores. Models utilize data from the first 24 hours of a patient’s ICU stay for predicting in-hospital mortality unless otherwise stated. For models trained in this work the average, minimum, and maximum performance across five folds of cross-validation is reported. *These models used all adult ICU admissions greater than 4 hours (N=50,488) split in 5-folds of cross-validation.

**Real-time experiment**

The real-time experiment assessed the performance of models both trained and evaluated using a random time point during the patient’s ICU stay.

The performance of the LR, LASSO, RF, and GB models are shown in Table 4. These models were trained using data extracted from a window of length $W = 4$ hours located at a random time point during a patient’s ICU stay, at least $W$ hours before ICU discharge.

Table 4: AUROC and AUPRC of models trained and evaluated on distinct patients using a single window of data occurring at a random time during a patient’s ICU stay (N=50,488). The average AUROC/AUPRC across 5-folds of cross-validation is reported, with the minimum and maximum value in brackets.

The models trained above were evaluated at fixed time points from patient mortality. Figure 2 shows the AUROC at different lead times from ICU discharge.

Figure 3 shows an example of applying the model to every hour of ICU stays for four patients; two of whom survived to hospital discharge and two of whom died in ICU.
Figure 2: AUROC of models when $t_{i,w}$ is fixed at a certain distance from death for those patients who died in the ICU. If the patient survived past 24 hours from their ICU discharge, $t_{i,w}$ was set to random time during their ICU stay, and their outcome was set to 0 (i.e. they were treated as a survivor).

Discussion and Related Work

The benchmarking experiment demonstrates that the use of GB had a substantial improvement over previous methods. GB achieved an AUROC of 0.920, which is substantially higher than severity of illness scores evaluated on the same data (e.g. SAPS II with AUROC of 0.809). The improvement is likely attributable to a combination of more data and a more flexible modelling approach. The progression of the APACHE models for predicting mortality reflect this as well: later installments of the models had higher dimensionality and incorporated both cubic splines and interactions in order to better predict outcome\textsuperscript{3}. The ability of GB to assign non-linear risk across values of a single feature could also contribute to its higher performance (e.g., low and high blood pressures could be assigned distinct risk estimates).

Interestingly, the LR model was extremely competitive, achieving an AUROC of 0.892. The LASSO model was slightly worse than LR (AUROC=0.888). In medicine, a key component of any decision support tool is interpretability, and many practitioners will not trust a tool if they do not understand how it produces predictions. While higher performance is certainly a desirable aspect of the model, the use of a simpler regression model which can be interpreted still remains a promising avenue of future research.

Comparing this performance to the literature, we see that the GB had a slightly higher AUROC than published for the APACHE IV model (AUROC of 0.89)\textsuperscript{3}. It is worth noting that the models here used purely physiology, laboratory measurements, and minimal demographic variables available on admission, whereas the APACHE system utilized over 100 diagnostic categories, comorbid burden, and treatment. These additional features can often require manual collection which can complicate automatic application of the model. In a comparison of APACHE IV versus SAPS II, data abstraction per patient took much longer for APACHE IV (37.3 minutes) versus SAPS II (19.6 minutes)\textsuperscript{26}, and the difficulty in acquiring features was certainly a large factor there. The use of automatically or routinely collected features has many advantages in the potential practical application of models such as the one presented here. Further, the capability of the models to predict well given only physiology may indicate that with enough measurements regarding the patient manually laborious and potentially ambiguous tasks such as classifying patients into a single diagnosis could be circumvented.

The models developed here resulted in higher AUROCs than those reported in the literature. While it could be claimed that the results here represent the “state of the art” in mortality prediction for ICU patients, there are too many caveats to make this statement. First, we cannot claim to have exhaustively located all mortality prediction models built using the MIMIC database or otherwise. However, more importantly, we cannot even claim that the GB model is the best
of those reported in Table 3, even though all utilized some version of the MIMIC database. This is due to a number of reasons. First, there is a lack of consistency in the dataset definition and extraction, and in particular in the timing of data extraction. While most studies utilize the first 24 hours, some required the patients to stay at least 24 hours, while others utilized 48 hours and required patients to stay 48 hours. These decisions substantially impact the patient case-mix and consequently the difficulty of the problem. This is even highlighted by Luo et al.\(^\text{22}\), who utilize the first 12 hours of mortality as it is a more challenging prediction task. In addition to timing, studies frequently disregard samples due to missing data\(^\text{18, 19}\), inappropriate patients (this study removed organ donor accounts), and in order to reduce heterogeneity in the cohort (Hug et al.\(^\text{14, 22}\) removed neuro-surgical and trauma patients).

As MIMIC is a completely open database, and as tools to facilitate sharing of data analysis have matured, there is a unique opportunity for research in this area to be fully reproducible. We hope that future work will aim to alleviate this issue by releasing source code associated with their analysis. In this spirit, we have made all code for this study public and hope that this facilitates future research to improve upon the benchmark we have established\(^\text{25}\).

The real-time experiment was consistent with the benchmarking experiment in that the best performing model was GB (AUROC = 0.920), with the LR model having competitive performance (AUROC = 0.892). The AUROC of the LR model was slightly lower than the model using data from the first 24 hours (0.896), though not greatly. The L2 model had approximately equivalent performance to the LR model in all experiments.

Figure 3 demonstrates that as the models approach the time of mortality their ability to discriminate mortality increases. This is intuitively sensible and acts as a sanity check that the models are capturing abnormal physiology which relates to mortality, though it is not clear why the GB model had a much lower improvement as opposed to other models.

In the medical domain it is important to consider the interpretability of the final model developed. In Figure 3 we see an example of how the predictions of the model would result in a trend, as if used at the bedside continuously, and there appear a few spikes in the predictions. The use of a LR model would allow easy explanation of why the risk profile changed: the following covariates changed which consequently increased or decreased the final prediction. However, a similar interpretation cannot easily be produced using GB, as multiple features will have changed and translating the impact of these changes within the model is non-trivial. The interpretation of tree based models continues to be an active area of research. The trends shown in Figure 3 also show that there is a great deal of information in the trend which could be used to further improve the model performance.

There are limitations to our study. First, as all data in MIMIC is acquired from a single hospital, these models may not be applicable for outside datasets. However, the applied methodology is relatively simple, and we plan to evaluate a

---

**Figure 3:** Example trends for four patients in the ICU. Two of the patients survived to ICU discharge, while two of them died in the ICU.
similar framework in a large multi-center database. Second, the exact mechanism for utilizing such a model is unclear. While synthesizing patient health as presented could have applications for resource utilization and decision support, integrating such a model into clinical practice is a difficult process which must be made with careful consideration. Finally, the data used was a small subset of what is available in MIMIC. Specifically, we did not utilize any data regarding patient treatment, high resolution waveforms, or notes written during routine patient care. The incorporation of information from these sources may improve model performance.

Conclusion

We have shown that classic mortality prediction models can be improved by the use of flexible machine learning approaches combined with more granular data. A GB model had the highest performance here and than models reported in the literature, but we argue that the field must adopt benchmark datasets and a dedication to making code openly available code in order to both validate this claim and to allow research to progress in this field. Finally, we demonstrated a feasible architecture for developing a real-time mortality prediction system for evaluating patient health. The predictions made may provide clinicians with an accurate and rapid summary of patient health, though further research is necessary in order to ensure models are both interpretable and usable at the bedside.

Abstract
Cancer is a major public health challenge in developing countries but the healthcare systems are not well prepared to deal with the epidemic. Health information technologies such as electronic medical records (EMRs) have the potential to improve cancer care yet their adoption remains low, in part due to EMR systems not meeting user requirements. This study aimed at analyzing the user requirements for an EMR for a cancer hospital in Uganda. A user-centered approach was taken, through focus group discussion and interviews with target end users to analyze workflow, challenges and wishes. Findings highlight the uniqueness of oncology in low-resource settings and the requirements including support for oncology-specific documentation, reuse of data for research and reporting, assistance with care coordination, computerized clinical decision support, and the need to meet the constraints in terms of technological infrastructure, stretched healthcare workforce and flexibility to allow variations and exceptions.

Keywords: Medical Oncology, Developing countries, Electronic Health Records, User requirements, Requirements engineering, User-Centered Design Methods.

Introduction
Cancer is one of the leading causes of morbidity and mortality worldwide. According to the World Health Organization (WHO), there were an estimated 17.5 million cancer cases and 8.7 million deaths globally in 2015.1 Probably more striking is that developing countries bear the largest burden of cancer, a disease which was associated with affluence. Currently over 60% of cancer cases and over 70% of cancer deaths occur in these resource-poor settings and the numbers are projected to increase. Cancer is responsible for more deaths than HIV/AIDS, Tuberculosis and Malaria combined.2
Several reasons can be given to explain the cancer epidemic in developing countries including: 1) improved life expectancy, 2) infectious diseases such as HIV/AIDS, Hepatitis B and C, Epstein Barr Virus (EBV), Human papilloma virus (HPV) which are common in developing countries and are involved in pathogenesis of many cancers including Kaposi sarcoma, Non-Hodgkin lymphomas, Cervical cancer, liver cancers, 3) lifestyles that increase risk to cancer such as smoking, being sedentary, unhealthy diets, and 4) industrialization and pollution increasing exposure to carcinogens1-3.4
In addition, the healthcare systems in developing countries are ill-equipped and ill-prepared to deal with the cancer burden. Healthcare budgets are small and most of the spending is allocated to infectious diseases (cancer is not seen as a priority intervention area). There is also lack of critical cancer care infrastructure and services such as functional pathology and radiotherapy services as well as inadequately trained and insufficient staffing. Low health literacy within the population in developing countries leads to delayed presentation and treatment abandonment, and limited research on cancers (basic science, translational and clinical trials) also negatively affects cancer care.2,5 Health information technologies (HIT) such as electronic medical records (EMR) have been postulated to improve healthcare quality, safety, effectiveness, efficiency and to reduce healthcare cost. EMRs are more accessible and can easily be shared between healthcare providers to the benefit of the patient (timeliness, better care coordination, easy consultations, reduction of unnecessary repetition of tests, etc) and electronic data can be reused for research to improve medical knowledge, and for reporting for better healthcare planning/management. Features and functionalities such as computerized order entry and clinical decision support also improve time efficiency, enhance adherence to guidelines and improve safety, and enhance translation of research knowledge into clinical practice, among other benefits6,7.

Several projects and studies have demonstrated the above benefits in a variety of contexts. In developed countries EMRs have been used in different clinical contexts including primary care, ambulatory care, oncology and for care of other non-communicable diseases; where EMRs have shown to reduce patient waiting times and improve time efficiency8,9 save costs,10,11 improve communication12 etc. In developing countries, most of the experience is in
HIV/AIDS care and EMR have also been shown to improve time efficiency\textsuperscript{13-15} increase adherence to guidelines\textsuperscript{16} improve care coordination and reduction in loss to follow-up\textsuperscript{17,18} among other benefits. These benefits if harnessed could potentially contribute to improved cancer care and reduction of the cancer burden in developing countries. However, the adoption of EMRs in oncology remains poor, especially in developing countries.

One reason for low adoption and/or failure of EMRs in general is that many EMRs do not meet the requirements of the users. Requirements of a system are the attributes, capabilities, characteristics or qualities that a system must have for it to be of value to the user - the services that a system is expected to offer and the constraints under which it must operate\textsuperscript{19-21}. Requirements depend on the context of use i.e. the users (their experiences/skills, attitudes, prejudices, etc), tasks and equipment (hardware, software and materials), and the physical and social environments in which the system is used\textsuperscript{22}.

Oncology is a complex medical specialty with unique workflows, information management needs and challenges (chronic, multidisciplinary and multi-modality care, expensive and toxic treatments such as radiotherapy and chemotherapy, complex schedules and combinations, etc) thus it poses unique requirements on an oncology EMR. In developed countries such as the United States and the United Kingdom, there have been efforts to define the unique requirements for oncology EMRs so as to guide vendors to develop usable EMRs and users to select those that are likely to meet their need.\textsuperscript{23-28} But due to differences in socio-economic status and healthcare system organization/workflows (available technological infrastructure, policies, human resource, standard operating procedures, etc) the requirements for an oncology EMR for developing countries are likely to be different compared to developed settings. Yet there have been no studies on requirements for an EMR for use in cancer care in low-resource settings.

**Purpose:** To elicit and analyze the requirements for an EMR suitable for use in oncology in developing countries. The study was party of the Master's thesis of the first author (JK), and contributes to the ongoing EMR implementation process of a national cancer hospital in Uganda, the Uganda Cancer Institute (UCI).

**Methods**

A qualitative study was carried out, consisting of a focus group discussion (FGD) and follow-up one-on-one interviews. These were held in English. This approach was chosen because of the explorative nature of the study. Requirements engineering (RE) as a key component of the user-centered design (UCD) process\textsuperscript{27} requires understanding the perspectives (views, opinions, attitudes, limitations, etc) of the users and the context of use of the system\textsuperscript{22} and FGDs and interviews allow for this\textsuperscript{28,29}. Since requirements are for the same system, some form of consensus is needed which can be got during FGD in addition to allowing a comprehensive exploration of views from different people, as opposed to interviews with one person. However, in-depth interviews allow for detailed discussion which is important in RE to understand the users' challenges and wishes so as to come up with a usable solution, since often the users don't know exactly what the solution or requirement is or there are misunderstandings and miscommunications.\textsuperscript{30}

The FGD followed a semi-structured format where probes were used that sought to understand the different tasks that the target EMR users routinely do, the information they collect and how it is exchanged/reused, as well as challenges faced in cancer care and how these could be alleviated by the EMR. These probes (available as supplement up on request) were developed prior to the study by JK basing on literature review, and they were discussed and agreed up on with MH and SK who are senior researchers in health informatics. The follow-up interviews were unstructured but followed up on issues that had been raised during the FGD.

Considering that the study site is at an early phase of EMR implementation and the participants have limited experience with EMRs, it was suspected that they might have had limited opinions on requirements. To give the participants more insight about EMR and RE, a two hour workshop was set up prior to the FGD where JK presented about these concepts. In addition, a mockup of RE was done for a chemotherapy management system, and a representative of the EMR vendor Clinic Master International\textsuperscript{†} (an EMR used by several hospitals in Uganda) was invited to give a demonstration of the EMR during this workshop.

**Study site:** The study was conducted at the Uganda Cancer Institute (UCI) in Kampala, Uganda. The UCI is a 100-bed public cancer hospital established in 1967 by the Uganda Ministry of Health and Makerere University in collaboration with the US National Cancer Institute (NCI). It was an important center for research and advancement of cancer treatment especially for combination chemotherapy and description and treatment of Burkitt's lymphoma, Kaposi's sarcoma and other cancers common in this area. The UCI has grown to become the main cancer hospital in

---

\textsuperscript{†} http://clinicmaster.net/
Uganda and in the East African region, with over 240 staff, about half of whom are clinicians (29 doctors, 58 nurses, 7 lab staff and 5 pharmacy staff, among others). Currently the UCI is in the process of implementing an EMR.

**Participants:** Participants were selected strategically and purposively to represent the main target end user of the EMR at the UCI i.e. doctors, nurses, pharmacists, medical records officers, lab technicians, etc. These user groups interact directly with patients hence they understand the work processes and dynamics of patient care at the institute including its challenges. They will also be the ones most likely to directly interface with the EMR once it is implemented.

Nine of the 12 participants approached agreed to take part, with 4 males and 5 females and age range between 27 and 51 years. All had worked at the UCI for at least 2 years each and were familiar with the work processes. All the participants had computer literacy at least to the level of comfortable day-to-day use such as internet and email, Office suite and have had exposure to tasks such as data entry for clinical research. Some had also used the Clinic Master EMR system in the past, but not in the setting of the UCI, rather in other private hospitals.

The table below shows the professions/job of the participants and whether they had used an EMR software before.

One FGD lasting two hours was conducted, followed by five follow-up interviews with participants 01, 02, 05, 06, and 08 in the subsequent week after the FGD. The interviews lasted average 25 minutes each.

**Data collection:** Data was collected as audio recordings of the FGD and follow-up interviews that were later transcribed verbatim. The FGD was moderated by an independent moderator who is experienced in qualitative research (a nurse). This moderator was first trained by the author in advance to make sure the moderator fully understands the probes to be followed in the FGD. The moderator also attended the workshop prior to the FGD. The author was present in the FGD as a note taker, and he also conducted the follow-up interviews which followed the notes taken during the FGD - to clarify on issues that were not fully explored in the FGD.

**Data analysis:** The audio recordings were transcribed verbatim by the first author and printed out for manual content analysis. Throughout the process of transcription and from the FGD/interviews, the author gained insight into the contents of the transcripts by the time they were printed. The author then read all the transcripts carefully and thoroughly to identify meaningful units and assigned codes/themes following a deductive approach\(^{1, 2}\). Statements that mentioned tasks, challenges or wishes that could translate into EMR functionality or constraint were identified and a mind map made (available as a supplement). A logical workflow model was also made to summarize the key tasks (see figure 1). The figure summarizes a typical flow but variations and exceptions are common among individual patients e.g. some new patients who aren't very ill can do their staging workup as outpatient and some patients continuing with treatment occasionally get admitted if they become ill due toxicity of chemo or radiotherapy or when they are to undergo surgery.

Requirements were derived\(^ {3, 4}\) following categories of EMR functionalities/features in literature especially in\(^{27}\). Throughout this process, JK had several meetings with MH and SK who were his academic supervisors, to discuss the findings and translate requirements from the transcripts.

**Study period:** Data collection was done in February and March 2016 and analysis was done in April and May 2016.

**Ethics:** The study was approved by the Uganda Cancer Institute Research and Ethics Committee (#UCI REC REF 01-2015). All participants gave written informed consent and their privacy and confidentiality was ensured during the study.
Results
The user requirements were derived from understanding the target users' workflow and tasks they need to accomplish as they described them in the sessions, from the challenges and constraints as well as their wishes and what they envisioned if an EMR had would make their work easier or the adoption and usage of the EMR easier. Detailed descriptions of the requirements with explanation or motivation and illustrative quotes from the participants are available as a supplement up on request. The requirements can be categorized as follows: Documentation, Communication and care coordination, Computerized order entry and results management, Computerized clinical decision support, Inventory/Stock management, as well as "Meeting the constraints (Fit into context)".

1. Documentation.
1.1 Routine documentation: When discussing the workflow and tasks, documentation was repeatedly mentioned as crucial routine. The system should support clinical documentation including identification and demographics, clinical history and findings, treatment details, etc, as these are routinely recorded in any clinical setting. The added benefit expected from the EMR however is alleviation of the challenges that come with paper documentation such as paper getting lost or torn or being bulky to store and being inaccessible especially in the complex setting of multidisciplinary and multi-service cancer care. Another challenge that was pointed out is that the current paper files are not structured and documentation not standardized with resulting inconsistence and incompleteness, making the data hard to compute and reuse downstream e.g. in CDSS or for research and automatic report compilation. The EMR should thus address this challenge.

"...we have no unified documentation system. Every oncologist reviews the patient the way he wants. You can write 2 lines, I can write 4 lines, another can write 8 lines. 4, no standardized [documentation]... I feel that if you have a standard template of what we want, every clinician to ask a patient of a class of disease, then such issues of omissions will be minimized... you'll have a consistent standard information... the computer... should be able to give us all the detailed headlines of what we are supposed to do... such that we have consistence of information. If am reviewing the patient, I must enter something in all these areas, otherwise it will not go to the next page." -- Participant 07, Pediatrician
"We write on papers... that you just punch and fix in the files, so many times they can pluck out... So many times you find that you look for a chemotherapy recording paper, you cannot find it. this patient has been on treatment for like 3 months so that means there should be some recording and you can't find it." -- Participant 06, Nurse

"... right now we don't have enough space in Records [storage room]..." -- Participant 08, Medical records officer

"...we have a challenge of files getting lost... and that usually comes for example a file will go to OPD and then somebody picks it for example for research -- Participant 08, Medical records officer

1.2 The EMR should support oncology specific documentation: Oncology as a medical specialty has differences from other specialties and these also show in the documentation. There are oncology specific data such as cancer diagnosis, tumor descriptions (size, location, metastasis, etc), cancer stage, cancer risk factors, special investigations (e.g. biopsy/histology results and metastatic workup), treatment (chemotherapy, radiotherapy), in addition to emphasis put on "routine" data such as patient height and weight which are important for calculating body surface are onto which chemotherapy prescriptions are tightly based, vital signs which often change frequently in cancer patients due to the severity e.g. neutropenic sepsis, drug dose to track ceiling/life time doses, etc.

"... the UCI is a specialized center, .. it's not... where a malaria will walk in... It's a specialized center. So, the system should be tailored to an oncology center... frequency of investigations that are done at the UCI. It's much more...and the importance. Down there [referring to an non-cancer referral hospital] sometimes people request. RFTS, LFTS, just for just. But here, we request things which we actually want to use...the system should incorporate something that can help us to analyze our investigations. Like, you know, CBC and chemistries, ok? And also a way to sort them out... which one is acceptable, which one is not acceptable, which one needs attention..." - Participant 01, Junior doctor

"...a provision where we can fix our observations as a nurse... the chemotherapy sheets or checklist or whichever or road map as per patient treatment schedule.. and also this other supporting treatment cause, well most of them are admitted not for chemo but for other reasons for example neutropenic sepsis..." - Participant 06, Nurse

The quote above also points out an important aspect about cancer care in that patients commonly have multiple medical conditions and co-morbidities besides the malignancy making documentation complex. In addition, care is chronic and information intensive so the participants mentioned a wish for the EMR to offer efficient ways of documentation e.g. by having pre-populated menus which they just check off.

"...if there was a check-check-check...that would be very easy." -- Participant 02, Doctor (Internist)

2. Communication and care coordination
2.1 The system should enable/facilitate communication between the different care teams including the clinical service points (Outpatient department and wards), laboratory, imaging/radiology, radiotherapy, surgery, etc which are not co-located. The EMR should connect and transmit messages between all these service points, so that each knows what the other is doing for the patient for better coordination, to avoid delays, conflicts and medical errors (such as doing surgery in a patient who has just received chemotherapy or radiotherapy, or giving chemotherapy to a neutropenic patient), and to ensure continuity of care.

"...the time spent during movement, usually we have very ill patients and as a clinician you're moved to walk to the lab to get the report ... there's a lot of time lost that could be reduced." - Participant 02, Doctor (Internist)

"... many patients are sometimes lost up within the system because as you know this place UCI has more than three campuses ... and some patients tend to cut across all these areas. For instance a patient is seen by a surgeon, the surgeon does mastectomy ... sends the patient for radiation at the lower campus... the radiation oncologist .. attends to the radiation part of it and if the patient is not well informed that you need further chemotherapy, that patient may be lost to follow-up" -- Participant 02, Doctor (Internist)

"...I would have loved having a prescription coming to me electronically with lab results ... that is very important because before I go ahead to prepare chemo I must know that the patient is suitable for chemo..." -- Participant 05, Pharmacist
2.2 Scheduling: Participants highlighted challenges with scheduling of patients, with "patients tend to walk in sometimes on days that are not theirs" and thought that "the computer system would be important in helping with patients' scheduling dates.. when they're supposed to come back". The EMR should therefore have functionalities to assist/coordinate scheduling of patients for the different appointments and care activities during active treatment and follow-up, according their care roadmap, which is fairly standard.

2.3 Communication with patients: Also due to the complexity of the treatment roadmaps and chronic nature of cancer care, loss to follow-up are common at the UCI and participants need a system that can assist in tracking patients and communicating with them e.g. through calls or SMS reminders. This also enables collecting survivorship data in addition to allowing better preparation and coordination of clinic visits.

"...but we have people who got lost to follow up... people who died at home... we have to be able to track patients... a way of contacting patients.. maybe somewhere where we can incorporate a patient's contact.. maybe phone numbers.. to be able to call them.. also because our patients come periodically we have to be able to incorporate into the system a scheduling system for instance, if someone is on a 3 weekly schedule of chemotherapy, the system should be able to .. I don't know how it works but it should be able to say patient A, patient B, patient C, patient.. D are the ones who are supposed to come tomorrow or the other day, so that it helps one, the records people to prepare the files, 2, the nurses to know how many patients are coming, 3, to deal with people who.. unscheduled visits" - Participant 01, Junior doctor

3. Order entry and result management
The system should assist in making orders for investigations and in managing the results - quickly selecting the orders (e.g from a predefined list) or automatically generating orders basing on previous information on a patient such as their histological diagnosis; communicating the order to appropriate target (e.g. lab or imaging) and communicating back the results to the sender in time. This is key because there is a myriad of tests done along the roadmap of care for the cancer patient, some at particular times and others routinely and more efficient ways of ordering them and transferring of results is needed to avoid wastage (e.g. in repetition of tests) and delays.

"... communication between department, If I order for hemogram or chemistry, how quickly do I get results?...you need the renal function but you find it was ordered yesterday you don't have it yet you order it again, it is lost somewhere either is in the machine not printed yet because no paper or it is printed and kept in the file or printed and lost on the ward or printed and somebody's pocketed it. So some information that has been ordered for doesn't affectively get to the patient chart, which delays care and leads to misuse of resources..." --Participant 02, Doctor (Internist)

Other orders such as instruction sets for a particular task or patient were also pointed out as sources of inefficiency that the EMR could alleviate by automating or reusing existing data or order sets, as exemplified by this quote:

"There is a lot of repetition of things for example commonly we do feeding gastrostomies and there's a feeding protocol after, which is actually similar in all the patients, at least most of them. So you write for this patient Day 1 you give this and this and this day 2... then you if you've done 3 patients, maybe 5 patients on that day, you do that for each of the patients that you've done" - Participant 03, Surgeon

4. Computerized clinical decision support (CDSS) and safety checks
4.1 Adherence to protocols/guidelines and filling in knowledge gaps (expert system): Participants gave several examples of scenarios in which they would need assistance from the EMR in form of CDSS. The want the EMR to assist clinicians in making a cancer diagnosis and stage (according to clinical and investigations), and in making treatment decision (according to stage, co-morbidities, drug availability, drug interactions and contra-indications, etc). The CDSS is needed because some clinicians "lack specialized knowledge" or "oncology specific training", in addition to the complexity and large amount of information that has to be synthesized and acted up.

"... a patient comes with breast cancer and you order for chest x-ray of abdominal scan, hemogram, liver function, renal function,. the essence of all those tests is to map out that the disease stage. So if this program is able to get all this information that we feed it in at the end of the day it prescribes a specific stage, this would help us to treat a patient better. To follow up with that, once a stage of the cancer is prescribed then we need more guidance with the specific treatment." - Participant 02, Doctor (Internist)
"...once a nurse or somebody makes an observation and they are entered patient's e-file then probably they can give a siren or can give a warning that you know this temperature you need to act this BP you need to act." - Participant 02, Doctor (Internist)

Because many protocols and guidelines used at the UCI are adopted from developed countries where clinical trials and research are performed, the logic for the CDSS should be according to accepted modifications of such or local consensus because there are observed differences in patients in the two contexts as this participant explains:

"Nutritional issues may vary, immune status may vary, especially when I deal with children. So, if I get the protocol developed in the UK or the US to be used here,... we must modify them based on some small criteria like nutrition status of the patient." -- Participant 07, Pediatrician

4.2. Chemotherapy safety checks: Participants reiterated the complexity and difficulty of chemotherapy management including correct dose calculation, monitoring of ceiling doses, side effects and contra indications such as allergies, co-morbidities that might require modification of doses e.g. HIV/AIDS, malnutrition or organ dysfunction (e.g. renal failure) or cytopenias. One requirement they had of the EMR therefore is for it to assist in checking these to ensure safe chemotherapy use because errors can be detrimental.

"It's really very easy for someone to write chemotherapy twice... but if we had a system that has everyone's name once, ok? and you know these are the people for chemotherapy... a centralized system that has all the patients.. But we have a very erratic recording system that allows for a lot of mistakes." - Participant 01, Junior doctor

"If the patient was treated with doxorubicin the program gives an alert: echo at six months, echo at 1 year, echo every year after treatment..." - Participant 02, Doctor (Internist)

5. Inventory/stock management

The system should keep track of stock of medications and supplies, and update the different users (prescribers, pharmacists, etc). Participants need this functionality because stock management is hard in the current paper-based system, yet it greatly affects patient care. Prescriptions and protocols for treatment are chosen in part basing on available drugs, and stock records are needed to make orders for drugs and other supplies in time to avoid stock-outs.

"...to manage stock and supplies.. monitor drugs in my store rather than going there in the last minute and am putting in a request in the store and they tell me it's out of stock, it got finished, I gave you the last stock last week... then you can be able to prioritize...in terms of ordering... Then the other thing would be the cost attached to that because in most cases we don't know these costs. It may not be that patients are going to pay but it is important to know how much the government is spending on the patients..." -- Participant 05, Pharmacist

6. Meeting the constraints (Fit into context)

Participants mentioned several conditions and pre-requisites that an EMR suitable for their context should meet. These stem mainly from the fact that the UCI is in a low-resource setting, while others are due to the unique workflow of cancer care at the UCI. The following are the key constraints: i) The system should allow for mobility or "computer on wheels" because users need to access the system at the bedside during ward rounds. ii) The system should fit into the technological infrastructure e.g. working with unreliable internet connection and electricity supply (or backups should be in place. As one participant noted, "In 24 hours, there are 10 blackouts in Uganda... Even when you talk about a backup generator, with fuel, this fuel must come from ministry of energy". iii) The system should allow flexibility to accommodate variations and exceptions that are common in healthcare, and to accommodate new requirements that may arise (such incorporation of new medical knowledge). iv) In addition, functionalities such as CDSS should not take over control from the clinician. Authorized users should be able to make modifications to the rules/functionalities.

"...there should be room for clinicians to have control over system... and I think that also still need to be restricted, not every clinician should have... because if that is the case, a nurse can sit somewhere and modify a protocol, a pharmacist can sit somewhere and single handedly modify a protocol. I think the lead clinicians who are authorized by the Institute to actually prescribe should be given the administrator access administrator password to modify some protocols." -- Participant 07, Pediatrician
Discussion

This study aimed at eliciting and analyzing the user requirements for an EMR for the UCI as a cancer hospital in a low-resource setting. A user centered approach was taken where target end users were involved in a FGD and interviews to analyze the workflow, their challenges and wishes and to derive the requirements. The key findings were that cancer care is complex - chronic, multidisciplinary with many care points, and it is faced with many challenges that a usable EMR could help in solving. The target end users thus require an EMR that supports structured and standardized clinical documentation, and in particular, oncology specific documentation such as cancer diagnosis, stage, tumor descriptions and treatment details (such as chemotherapy roadmaps) among other things. Consistent and complete structured data can also be reused for reporting and research which are key tasks/processes for the UCI. Participants also require functionalities to assist/support tasks such as scheduling and coordination of the complex, multi-disciplinary care for cancer patients, CDSS to compliment the limited expertise in oncology and offer automated safety checks as well as taking stock for better planning. The system should however fit into the context and function despite such limitations as unreliable internet and electricity supply, it should be flexible to allow exceptions/variations (such as authorized modifications of the guidelines/protocols on which CDSS is based) and shouldn't take over control or decision making from the clinicians.

On a high level, these requirements are similar to those described for oncology EMR in resource-rich countries possibly because cancer care is quite similar in terms of care coordination, scheduling, documentation needs, etc. However, due to differences in the context, extra constraints and often context specific requirements are posed to the EMR on a detailed level. For instance, technological infrastructure such as internet and electricity supply is not usually considered a key issue in HIT in developed countries yet is it a major constraint in developing settings. Policy and organization of healthcare e.g. reporting requirements to ministry of health or other stakeholders or the procurement process for drugs and supplies (drugs are procured by a central national body on behalf of the hospitals so timely orders from this national medical store are required) also call for EMR features and functionalities at the UCI to serve these needs hence requirements like stock management which might not be emphasized in oncology EMR specifications for other contexts. Moreover, there is more emphasis on CDSS because of the overstretched healthcare workforce and limited number of cancer care experts making automation very crucial if cancer care in this setting is to be improved. Users' experience e.g. prior use of EMR or computer skills which are generally less compared to developed settings might lead to usability challenges when a system is developed, in addition to limiting the opinions of the participants during requirements elicitation. Demographics and identification data can also be different e.g. use of social security numbers or RFID in which was never suggested or not feasible in the context of UCI because such systems aren't in place. Other key requirements specified for oncology EMRs in developed countries that were not mentioned or emphasized included billing features (possibly because the UCI is generally a public facility and healthcare is free), clinical trials support (because the UCI is not involved in many complex clinical trials), and provisions for a patient portal or mechanisms for patients to access their records and contribute to them e.g. through patient reported outcomes (because health and computer literacy levels are relatively low in developing countries and patients probably wouldn't use this feature even if it was available. Besides, there were no patient representatives among the participants).

It is worthwhile noting that some of the challenges and wishes by the participants in this study do not necessarily need a technological solution and are rather organizational. For instance, proper documentation (consistence and completeness) should be organizational culture with or without an EMR. Implementing an EMR before such issues are streamlined might actually lead to failure of the EMR even when it is in fact a good system. Nevertheless, the RE process allows organizations to review their workflows and identify inefficiencies. As an example, a key organizational challenge that came out during the data collection in this study was the fact that there was no triage area and patients would first meet with the records personnel on arrival at the UCI. Because the records personnel aren't clinical, there would be challenges of dealing with patients who came in critical conditions and needed urgent evaluation. This challenge has since been addressed by setting up a triage area at the UCI where new patients report first and a doctor is present to do a quick assessment. It is also common, especially in the initial phases of implementation, that EMR implementation leads to reduced productivity and inefficiency and this might further negatively affect care in the setting of an overstretched healthcare workforce. An analysis of such potential impact on productivity or workflow changes was beyond the scope of this study but needs critical thought during EMR implementation process.

Strengths of the study: Target end users who understand the workflow and intended context of use of the EMR were involved as participants (UCD). In addition, two qualitative methods, FGD and interviews were used, and
participants were from different medical backgrounds representing different perspectives. Moreover, involvement of the target end users also has an advantage of giving them ownership which enhances buy-in.

**Weakness of the study:** Only opinions can be obtained from FGDs or interviews and before these are implemented and tested, one can never be sure of how users will perceive and if they will accept it. More pragmatic and interactive RE techniques such as prototyping need to be applied, and more importantly the process needs to be iterative until usability is achieved.

**Future steps**
This study elicited a comprehensive list of user requirements from the perspective of different stakeholders involved in documentation and care of patients at the UCI without any form of prioritization. Since all the requirements might not be delivered at once, a next step of prioritization is needed e.g. in terms of which requirements, if delivered, provide maximum benefit. The resulting prioritized requirements should then be availed to EMR developers/vendors such as Clinic Master Inf1 to guide customization of their product to fit the UCI's needs. In addition, an analysis is needed of other organizational and human issues such as training, availability of human resource, funding and other support from management, workflow changes, etc which influence (or might be influenced by) implementation of an EMR, as well as engaging potential users beyond the UCI to ensure generalizability.

**Conclusion**
Oncology is a unique medical specialty and cancer care is complex with many challenges in terms of documentation, care coordination and need for support from "expert systems" to ensure patient safety and standardized care based on guidelines, among others. If an EMR is to be used in the context of low resource settings, extra constraints are imposed to it resulting from the resource limitation (limited funding, lack of human resource, technical infrastructure and skills) and differences in organization of healthcare (reimbursement/billing, procurement process for medication, etc). These context-specific constraints and requirements have to be met to ensure usability and acceptability of the EMR, and might require customization of existing EMRs or specifically developing one targeted for this context.

Mechanism-based Pharmacovigilance over the Life Sciences Linked Open Data Cloud

Maulik R. Kamdar, M.Tech., Mark A. Musen, M.D., Ph.D.
Center for Biomedical Informatics Research, Stanford University, CA, USA

Abstract

Adverse drug reactions (ADR) result in significant morbidity and mortality in patients, and a substantial proportion of these ADRs are caused by drug–drug interactions (DDIs). Pharmacovigilance methods are used to detect unanticipated DDIs and ADRs by mining Spontaneous Reporting Systems, such as the US FDA Adverse Event Reporting System (FAERS). However, these methods do not provide mechanistic explanations for the discovered drug–ADR associations in a systematic manner. In this paper, we present a systems pharmacology-based approach to perform mechanism-based pharmacovigilance. We integrate data and knowledge from four different sources using Semantic Web Technologies and Linked Data principles to generate a systems network. We present a network-based Apriori algorithm for association mining in FAERS reports. We evaluate our method against existing pharmacovigilance methods for three different validation sets. Our method has AUROC statistics of 0.7–0.8, similar to current methods, and event-specific thresholds generate AUROC statistics greater than 0.75 for certain ADRs. Finally, we discuss the benefits of using Semantic Web technologies to attain the objectives for mechanism-based pharmacovigilance.

1 Introduction

Pharmacovigilance methods are used to detect unanticipated adverse drug reactions (ADR) that manifest due to the intake of drugs by patients. These ADRs are often not detected during the clinical trials of the corresponding drugs. A majority of these ADRs are caused by polypharmacy, a situation where multiple concomitant drugs are administered to one patient in a short span of time to treat multiple medical conditions.1 These drugs may interact with each other through several different underlying biological mechanisms.2 Drug–drug interactions (DDI) due to polypharmacy are potentially avoidable, if detected early.3 ADRs are the 4th leading cause of death ahead of diabetes, AIDS, and pneumonia.4 ADRs often result in the hospitalization or serious injury of more than 2 million individuals in the United States, with more than 100,000 deaths annually.5 The costs of drug-related morbidity and mortality in the United States alone were estimated to be US$177.4 billion in 2000, and have been rising ever since.6

Pharmacovigilance methods often use data from Spontaneous Reporting Systems, such as the US Food and Drug Administration (FDA) Adverse Event Reporting System (FAERS),7 or electronic medical records.8 These methods have inferred new DDIs and the ADRs that manifest on the account of those interactions (e.g., Vioxx → Heart Attack and Aspirin + Warfarin → Bleeding). However, these studies do not systematically demonstrate how the drugs interact within the biological system of the patient, leading to a particular adverse reaction. Mechanism-based pharmacovigilance can lead to the inference of newer DDIs and ADRs, and can also provide a better understanding of the underlying biological mechanisms behind the DDIs.9 Moreover, this understanding can lead clinicians to prescribe drugs that can treat the same medical conditions in a patient while minimizing the risk of DDIs due to different mechanisms of those drugs. The objectives of mechanism-based pharmacovigilance can be attained through the development of network-based approaches of integrative pharmacology, often termed systems pharmacology.9 These approaches rely on an exhaustive systems network, that possesses knowledge of the drug-induced perturbations of the physiological functions in a biological system as well as knowledge of the underlying biological interactions.

However, the data and knowledge to generate such a network exists in several databases and knowledge bases that may be fragmented across the Web. These sources, if available for download, may: i) use varying schemas to structure the data, ii) use different entity notations (e.g., proteins referenced using HGNC10 or KEGG11 identifiers), and iii) use different formats for storage (e.g., XML, CSV, etc.). An ad hoc integration approach involving downloading and integrating each source independently, and reconciling similar entities, is non-trivial, non-scalable and is often redundant for different tasks. Hence, the objectives of mechanism-based pharmacovigilance are yet to be realized.
1.1 Semantic Web Technologies and Linked Data

The Semantic Web was conceived with the vision that a decentralized, distributed and heterogeneous data space, extending over the traditional Web, can reveal hidden associations that are not directly observable. Semantic Web technologies and linked data principles enable the representation, linking and querying of data and knowledge on the Web. Semantic Web technologies include the W3C standards Resource Description Framework (RDF) and the SPARQL graph query language. Due to the challenges of integrative bioinformatics, biomedical researchers have been the earliest adopters of Semantic Web technologies and linked data principles to create the Life Sciences Linked Open Data (LSLOD) cloud. Biomedical data and knowledge sources are converted to graphs using the RDF model. SPARQL can use specific graph patterns to query these RDF graphs. Several different efforts publish and link biomedical data and knowledge in the LSLOD cloud (e.g., Bio2RDF). Several sources that may be relevant to systems pharmacology, such as PharmGKB and DrugBank, are made available through the LSLOD cloud.

An example of an RDF graph that represents the following information — “Gleevec (Mol. Wt.: 589.25, Half-Life: 18 hours) inhibits PDGFR (platelet-derived growth factor receptor), involved in signal transduction” — is shown in Figure 1a. Here, similar entities (e.g. Gleevec) in two different sources, DrugBank and the Kyoto Encyclopedia of Genes and Genomes (KEGG), are linked together using explicit x-ref (cross-reference) attributes. Attributes and relations stored in these data sources are represented as nodes and edges in the RDF graph. Moreover, as shown in Figure 1b, the following query — “List drugs that have Mol. Wt < 1000 and inhibit proteins involved in signal transduction. Mention their half-life.” — can be executed using SPARQL. The graph expression patterns are derived from the RDF schema that is used to structure the graphs, as well as the x-ref attributes.

It should be noted that these biomedical RDF graphs may be exposed through isolated SPARQL endpoints on the web. Querying multiple isolated SPARQL endpoints simultaneously over the web requires a scalable SPARQL query federation method. Different graph patterns may be used to represent the same relation type. In Figure 1c, the relation Drug hasTarget Protein is represented using different labels (drug-target and target) and different graph patterns in DrugBank and KEGG respectively. In the latter case, as KEGG is a pathway data source, the RDF graph also captures the type and provenance of the interaction between the Drug and Protein. Query Federation methods can transform a given query to source-specific queries and retrieve information from two or more sources simultaneously.
In our previous research, we had developed such a query federation architecture, termed PhLeGrA – Linked Graph Analytics in Pharmacology, over the LSLOD cloud. PhLeGrA uses prior knowledge on such graph patterns to generate a systems pharmacology network by retrieving data from four different biomedical sources. As there is minimal overlap between different sources for drugs and drug–protein relations, we had also demonstrated how query federation over the LSLOD cloud can help systems pharmacology approaches.

In this research, we extend the PhLeGrA architecture, with an improved inference module to detect drug–drug interactions and adverse drug reactions. The module will also assign confidence scores to all possible underlying biological mechanisms for the DDIs. The key contributions of this research can be outlined as follows:

1. We propose and implement a graph analytics method, inspired from the Apriori algorithm for association rule mining, to identify frequent substructures in our systems network, as derived from mining FAERS reports.
2. We compare our method with two baseline methods in pharmacovigilance – the Gamma Poisson Shrinker (GPS) method and the Bayesian Confidence Propagation Neural Network (BCPNN) over three different validation sets.
3. We discuss briefly, the insights obtained from our method on few drug–ADR associations as well as discuss the advantages of using Semantic Web Technologies for mechanism-based pharmacovigilance.

All the results described in this paper, as well as prior research on the PhLeGrA platform, are available online at http://onto-apps.stanford.edu/phlegra/.

2 Related Work

Several methods have been developed to predict DDIs, or predict ADRs that manifest due to concomitant intake of multiple drugs, by mining spontaneous reporting systems such as FAERS or electronic medical records. Harpaz et al.7,22 used the Apriori algorithm to mine the FAERS reports and generate statistically significant association rules between multiple drugs and ADRs (e.g. Aspirin + Warfarin → Bleeding). Iyer et al.8 used electronic health records and generated patient timelines of drug and ADR mentions in the records. Using adjusted disproportionality ratios to identify significant drug–drug–event associations, and a manually-curated gold standard of such associations from Drugs.com and MediSpan, they demonstrated that their approach can be used to complement FAERS mining for pharmacovigilance. Bayesian approaches such as the Multi-Item Gamma Poisson Shrinkage (MGPS) algorithm and the Bayesian Confidence Propagation Neural Network (BCPNN)24, as well as approaches using existing knowledge on drug and ADR similarities, have recently been proposed to deal with reporting bias and confounding factors, observed in Spontaneous Reporting Systems. The performance of these methods are compared by Harpaz, et al.26 However, these methods fail to demonstrate the possible underlying molecular mechanisms behind these associations.

Systems pharmacology methods9,27 have also been explored in the context of drug–ADR association discovery or drug repurposing (use of existing drugs to treat new conditions). These methods generally combine databases and knowledge bases, to generate a systems network, manually without the use of Semantic Web technologies. CauseNet28 combines four biomedical sources into a k-partite network for generating new drug repurposing hypotheses. Berger, et al.29 integrated diseases with the human protein–protein interaction network to understand the systems pharmacology underlying specific forms of drug-induced arrhythmias. While these approaches are similar to our research, our method retrieves data and knowledge from the LSLOD cloud and can generate such systems networks more easily21.

The LSLOD cloud has been utilized to predict new DDIs recently. Tiresias processes drug-related data and knowledge and predicts new DDIs using large-scale similarity matching. Most approaches consider binary drug pairs and not multiple drug interactions, they ignore the underlying molecular mechanisms, and they may not associate the adverse drug reactions with the DDIs. Noor et al.33 constructed a mechanism-based DDI knowledge warehouse by integrating knowledge from multiple sources in the LSLOD cloud at the pharmacokinetic, pharmacodynamic, and pathway interaction level, and developed an inference engine to generate mechanistic explanations for DDIs. However, this method does not rank the mechanistic explanations, is not implemented for pharmacovigilance, and due to the knowledge warehouse, updates in the underlying sources are not captured instantaneously.
3 Materials and Methods

3.1 PhLeGrA network generation

In this section, we summarize the query federation method to extract a \( k \)-partite network from multiple, heterogeneous biomedical data sources available through the Life Sciences Linked Open Data Cloud (LSLOD). The method is described in more detail in Kamdar, et al.\(^{21}\). We integrate four different data sources that are published as SPARQL endpoints by the Bio2RDF project\(^{17}\) (Version 4) in the LSLOD cloud – DrugBank\(^{19}\), PharmGKB\(^{18}\), Kyoto Encyclopedia for Genes and Genomes (KEGG)\(^{11}\) and Comparative Toxicogenomics Database (CTD)\(^{34}\). These four sources contain data and knowledge on drugs, proteins, pathways, phenotypes and their inter-connections (e.g. drug–protein target relations) and have been used in several pharmacological methods previously.

We use a pattern-based query federation method\(^{20,21}\) to query the SPARQL endpoints of these sources simultaneously to generate the \( k \)-partite systems pharmacology network. Specifically, we retrieve four different types of entities — (E1) Drug, (E2) Protein, (E3) Pathway, and (E4) Phenotype (adverse drug reaction). We also retrieve five different types of biological relations — (R1) Drug hasTarget Protein, (R2) Drug hasEnzyme Protein, (R3) Drug hasTransporter Protein, (R4) Protein isPresentIn Pathway, and (R5) Pathway isImplicatedIn Phenotype. The SPARQL graph patterns used to retrieve the entities and relations from the sources are listed at http://onto-apps.stanford.edu/phlegra/about.

The entities and relations, retrieved from the LSLOD cloud, form a \( k \)-partite network — a network whose nodes can be partitioned into \( k \) different independent sets (\( k = 4 \)). We decided on these types of entities and relations to capture the following underlying mechanisms behind drug–drug interactions: a) one drug may inhibit the enzymes that metabolize a second drug to its inactive or active state, c) one drug may inhibit the transporters that decrease the absorption or elimination of a second drug, c) two drugs may target the same protein, leading to varying effects of both drugs, or d) two drugs may target proteins in the same pathway leading to varying effects of both drugs. Hence, here we consider transporters and enzymes to be considered as specialized proteins.

Figure 2: PhLeGrA network generation. a) PhLeGrA query federation method uses the type of entities and relations, as well as prior knowledge on SPARQL graph patterns to query four sources (DrugBank, KEGG, PharmGKB and CTD) in the LSLOD cloud to create a \( k \)-partite network composed of drugs, proteins, pathways and phenotypes. The phenotypes are further arranged using the MESH hierarchy tree. b) A visualization of a small portion of the network, with the Drugs Invega and Viagra, Enzyme CYP3A4 and Phenotype Hypertriglyceridemia highlighted.

To reconcile similar entities in different sources (e.g. drugs present in KEGG and DrugBank referenced using different identifiers), we use the \( x \)-\( ref \) attributes provided by the Bio2RDF project. We reconcile entities to a uniform identifier.
nomenclature scheme using existing terminologies – ATC (Anatomical Therapeutic Chemical Classification) for Drug, HGNC (Hugo Gene Nomenclature Committee) for Protein, KEGG for Pathway, and MESH (Medical Subject Headings) for Phenotype. We further organize the Phenotype MESH identifiers into a hierarchy, using the MESH hierarchy. As Spontaneous Reporting Systems (e.g., FAERS) collect patient reports in which the adverse reactions may be specified at different levels of abstraction, this step helps in aggregation of reports on higher abstract terms. For example, there may be patient reports on both Anaphylaxis and Hypersensitivity, Immediate, where the former Phenotype term is a subclass of the latter term. Hence the k-partite network is coupled with the MESH Phenotype hierarchy. A visualization of such a network is shown in Figure 2b.

3.2 FDA Adverse Event Reporting System

Spontaneous reporting systems are the primary means to conduct post-marketing surveillance of drug products to detect ADRs that were not determined during clinical trials. The US Food and Drug Administration (FDA) collects reports on the adverse drug reactions observed in patients subjected to multiple drugs. The FDA Adverse Event Reporting System (FAERS), a public data portal, publishes these reports after the anonymization of the patient data. We downloaded the FAERS datasets for three years from January 2013 to December 2015. Each dataset is composed of several safety reports. Among many features, each safety report indicates the set of ADRs observed in a patient (e.g., heart attack), and the set of drugs administered to the patient (e.g., Sildenafil). The steps taken to process and align the FAERS records with the Drug and Phenotype nodes in our k-partite network are described previously.

3.3 Frequent Substructure Mining

We extend the method proposed by Harpaz, et al. for statistical mining in FAERS datasets. This method is inspired from the Apriori algorithm to mine association rules (e.g., \{Drug\}_n \rightarrow ADR) in large databases, in an unsupervised, computationally tractable way. The Apriori algorithm prunes the search space of associations, such that if a certain combination of drugs and ADRs is infrequent, then any larger combination that builds upon the smaller infrequent one, will also be infrequent. Certain thresholds can be decided for ignoring these combinations. The Apriori algorithm has also been modified to mine frequent substructures in graphs. We have used this implementation of the Apriori algorithm to work on k-partite networks. Specifically, we can determine the set of FAERS reports that contain any specific (drug, ADR) pair. As shown in Figure 3a, we propagate the set of reports along all the possible shortest, directed, paths that connect the corresponding Drug node to the Phenotype node in the k-partite network. We decided to use only the shortest paths to make the method computationally tractable. Hence, each node in the k-partite network is annotated with the set of reports it may be associated with. We are unaware of the underlying biological mechanisms at this point, so all implicit associations are equally probable.

Generally, Apriori-based methods compute the Support and Confidence statistics for an association rule. Suppose,
\(S(A)\) indicates the number of reports that describe the items in itemset \(A\) (e.g. set of drugs). Then the support for an association rule is simply \(S(A \rightarrow B) = S(A \cup B)\) (i.e. number of reports where the items in itemsets \(A\) and \(B\) cooccur). The confidence of an association rule can be described as \(C(A \rightarrow B) = S(A \cup B)/S(A)\) (i.e. the conditional probability for observing items in itemset \(B\), given items in itemset \(A\)). The space of all possible association rules is pruned by selecting only those itemsets that exhibit a minimum value for the support statistic. In our method, as we have four different types of nodes, the association rules are generated by observing a minimum support at each step, where the direction of adding new itemsets is strictly Drug \(\rightarrow\) Protein \(\rightarrow\) Pathway \(\rightarrow\) Phenotype. Nodes and edges that do not exhibit a support statistic that exceeds a given threshold are automatically pruned from the \(k\)-partite network. To further reduce the number of computations, we only consider Drug \(\rightarrow\) ADR associations such that they have some direct path in the \(k\)-partite network, and we only consider \(\{\text{Drug}\}_2 \rightarrow \text{ADR}\) associations such that the paths that link the two drugs to the ADR have a common intersection point, either at the Protein or the Pathway node in the network. This method and our optimizations are visually explained in Figure 3b. It should be noted that this method can be extended to include multi-drug interactions (\(\{\text{Drug}\}_n \rightarrow \text{ADR}\)).

The confidence statistic is computed as \(C(\text{Drug} \cup \text{Protein} \cup \text{Pathway} \rightarrow \text{Phenotype})\), and is used to rank the different substructures (i.e. different underlying mechanisms), that lead to the manifestation of the ADR given the set of drugs. However, due to the reporting bias in FAERS, this statistic in itself is not sufficient to actually determine if there is any association between the drugs and the ADR, as indicated by Harpaz, et al.\(^7\) Hence, we also compute a Network-based Relative Reporting Ratio (RRR) statistic, that considers the Actual/Expected ratio at each path in the \(k\)-partite network. Hence, each possible substructure has an RRR statistic. RRR is defined as the ratio between an association rule’s observed frequency to a baseline expected frequency under the assumption of independence.

\[
\text{RRR} = \frac{N \times S(A \cup B)}{S(A) \times S(B)}
\]

Here \(A = \text{Drug} \cup \text{Protein} \cup \text{Pathway}\), \(N\) is the total number of FAERS records, and \(B = \text{Phenotype}\). The median value of the RRR, computed for relevant substructures, is used as the statistic to compare our method against other baseline methods. To summarize, Support statistic is used to prune the \(k\)-partite network, Network-based Relative Reporting Ratio is used to determine whether an association between a set of drugs and an ADR exists, and Confidence statistic is used to rank the different underlying mechanisms behind \(\{\text{Drug}\}_n \rightarrow \text{ADR}\) association.

### 3.4 Method Evaluation

We collected three different datasets that consist of manually-curated positive and negative drug–adverse reaction associations. These datasets have been used to validate DDI prediction methods previously. The Observational Medical Outcomes Partnership (OMOP\(^3\)) dataset and the European “Exploring and Understanding Adverse Drug Reactions” project (EU-ADR\(^4\)) dataset consists of single drug–ADR associations. The dataset described in Iyer, et al.\(^8\) consists of drug–drug–ADR associations retrieved from Drugs.com and MediSpan.

**Table 1:** The coverage of different validation datasets used in this study.

<table>
<thead>

</tbody>
</table>

Some statistics for these datasets, in terms of positive and negative associations, as well as coverage of drugs and ADRs are shown in Table 1. All the three validation sets were transformed, such that the drugs were referenced using ATC identifiers and ADRs were referenced using MESH identifiers. Some common ADRs across the three datasets include – Gastrointestinal Hemorrhage, Hyperkalemia, Acute Kidney Injury and Drug-induced Liver Injury. Using these validation sets, we compare our method with two baseline methods — the Gamma Poisson Shrinkage (GPS) method and the Bayesian Confidence Propagation Neural Network (BCPNN) method. We used the R package for PharmacoVigilance Signal Detection (PhViD\(^1\)) for the baseline methods.

\(^1\)https://cran.r-project.org/web/packages/PhViD/PhViD.pdf
4 Results

The $k$-partite network that was generated from the PhLeGrA query federation method, consisted of 2,759 drugs (E1), 3,890 phenotypes (E4) organized using the MESH hierarchy, 19,903 genes (E2) and 301 pathways (E3). The network also consisted of 249,001 drug–target relations (R1), 2,062 drug–enzyme relations (R2), 919 drug–transporter relations (R3), 25,480 protein–pathway relations (R4) and 46,300 pathway–phenotype relations (R3). Individual statistics for the different entities and relations extracted from each source were presented previously by Kamdar, et al.21. We used ≈ 3 million FAERS reports for the frequent substructure mining method demonstrated in this research.

The FAERS reports were propagated along our $k$-partite network, with each node in the network annotated with the set of nodes that it may be associated with. We use a Support threshold of 200 to filter out nodes and edges in the $k$-partite network. After applying the support threshold, we were able to decrease our $k$-partite network to include only 7,217 nodes and 89,451 edges. Moreover, as seen from the Figure 4, the number of entities and relations of a specific type (e.g. Drug hasTarget Protein) is reduced drastically for a particular source (e.g. CTD). It can be argued that our method can remove spurious relations in the $k$-partite network that may not be relevant, or may be incorrect.

We compute the Network-based RRR statistic for a given association between a set of drugs and an ADR, given all possible substructures. We compare this statistic with the GPS and BCPNN statistic over the three validation datasets. The Receiver-Operator Characteristic curve for each validation dataset is shown in Figure 5. It can be seen that the area under the curve (AUROC) statistic for each of the three validation sets is almost similar to the baseline methods, and the value is around 0.7–0.8. The AUROC statistic actually exceeds by 0.01–0.02 over the baseline methods for the OMOP and the EU-ADR validation sets. Moreover, as observed by Iyer et al.8, using event-specific thresholds on the statistic can actually generate higher AUROCs for certain ADRs. This is observed in Figure 5d where we obtain an AUROC of almost 0.94 for rhabdomyolysis. Finally, we would like to note that for higher values of Specificity, our sensitivity is considerably less than existing baseline methods. This may be due to the reporting bias in FAERS, which is not tackled in this research. However, using GPS-adjusted Expected values in the Network-based RRR statistic actually alleviated this issue (plot not shown). On a closer inspection of the false positive associations, we observed that these associations have more connecting paths in the $k$-partite network when compared to the true negative associations. Similarly, the false negative associations have fewer connecting paths in the $k$-partite network when compared to the true positive associations. Using a $t$-test, we found that these comparison findings were statistically significant ($p < 0.05$). Hence, the topology of the network has an impact on the association discovery method.
Figure 5: The first three plots include the ROC (Receiver-Operator Characteristic) curves for the three validation datasets used in our study – a) OMOP, b) EU-ADR and c) Drugs.com-MediSpan corpus curated by Iyer, et al. The predictive power of our Network-based RRR method is represented using the solid yellow line, whereas the dotted magenta and the dotted blue line indicate the predictive power of the GPS and BCPNN methods respectively. In d), we demonstrate ADR-specific predictions using the Network-based RRR method.

5 Discussion

Using the confidence statistic that is also computed by our method, we were able to observe some interesting and some known substructures. For example, while it is known that simvastatin may interact with the CYP3A4 inhibitor itraconazole to cause rhabdomyolysis, the corresponding substructure was observed to have a high confidence value in our analysis. Moreover, we found that the drug paliperidone, which is another CYP3A4 inhibitor and is used as a treatment in bipolar disorder, may interact with several other drugs to cause hypertriglyceridemia, hyperprolactinemia and gynecomastia. However, these findings need to be validated by a domain expert in the future. We plan to incorporate this method in the PhLeGrA visualization browser², such that different substructures can be highlighted and ranked with the support and confidence statistics and can provide a better understanding to the domain user.

Currently, our method is limited to substructure discovery from only those parts in the networks where there exist some edges that connect the different entity types (e.g. two drugs may interact with the same proteins, but this knowledge is derived from an existing source). This assumption was used to allow our Apriori algorithm to terminate under a reasonable runtime. However, there may exist drug–protein relations that are not known currently, or may not be stored.

²http://onto-apps.stanford.edu/phlegra/
in the biomedical sources that were integrated to generate the $k$-partite network. We will argue that the benefits of the Semantic Web technologies and Linked Data principles allows us to incorporate multiple data sources in the $k$-partite network, whereas the initial thresholding using the Support statistic can allow us to filter irrelevant edges and nodes in the network. This was observed for the Comparative Toxicogenomics Database that incorporated a huge proportion of noisy edges between drugs and protein targets that were not actual relations.\textsuperscript{21}

As presented here, pattern-based query federation\textsuperscript{21} can bring together pharmacological knowledge existing in isolated, heterogeneous sources without being concerned about the underlying semantics and schema differences. This advantage, when coupled with the network-based Apriori method for association rule mining, can facilitate domain users to obtain mechanistic explanations behind detected DDIs and ADRs, as well as generate new knowledge on underlying biological mechanisms (frequently observed substructures). Such systems pharmacology networks, as previously described\textsuperscript{21} are easier to generate using Semantic Web technologies and query federation methods.

6 Conclusion

In this research, we have demonstrated a method for mechanism-based pharmacovigilance from Spontaneous Reporting Systems, such as the FAERS datasets. While our method has equivalent, if not better, performance compared to existing state-of-the-art methods in pharmacovigilance, it can also be used to provide a mechanistic understanding behind the drug–drug interactions and the adverse reactions that manifest on the account of those DDIs. Moreover, it can enable biomedical researchers to obtain newer knowledge on molecular mechanisms that may be relevant in pharmacovigilance, or may be spurious in a particular database. We use Semantic Web technologies to easily generate a systems pharmacology network, and to the best of our knowledge this is the first approach to provide explanations of underlying biological mechanisms using a ranking scheme.

Initializing and Growing a Database of Health Information Technology (HIT) Events by Using TF-IDF and Biterm Topic Modeling

Hong Kang, Zhiguo Yu, Yang Gong
School of Biomedical Informatics, the University of Texas Health Science Center at Houston, Houston, TX, USA

Abstract

Health information technology (HIT) events were listed in the top 10 technology-related hazards since one in six patient safety events (PSE) is related to HIT. Although it becomes a common sense that event reporting is an effective way to accumulate typical cases for learning, the lack of HIT event databases remains a challenge. Aiming to retrieve HIT events from millions of event reports related to medical devices in FDA Manufacturer and User Facility Device Experience (MAUDE) database, we proposed a novel identification strategy composed of a structured data-based filter and an unstructured data-based classifier using both TF-IDF and biterm topic. A dataset with 97% HIT events was retrieved from the raw database of 2015 FDA MAUDE, which contains approximately 0.4~0.9% HIT events. This strategy holds promise of initializing and growing an HIT database to meet the challenges of collecting, analyzing, sharing, and learning from HIT events at an aggregated level.

Introduction

Patient safety event (PSE), defined as any process, act of omission, or commission that results in hazardous healthcare conditions and/or unintended harm to the patient 1, is the third leading cause of death in the United States2-4. PSEs are complex and difficult to control because they are related to healthcare systems, operations, drug administration, or any clinical aspect of patient care 5. Due to the wide application of health information technology (HIT) in clinical settings, HIT events become a key component of PSEs. HIT includes hardware or software that is used to electronically create, maintain, analyze, store, receive (information), or otherwise aid in the diagnosis, cure, mitigation, treatment, or prevention of disease, and that is not an integral part of an implantable device or medical equipment 6. The positive impacts of HIT 7, 8 include cost savings and improved patient outcomes 9, 10, decreased occurrence of medication errors 11, and improved healthcare process measures across diverse settings 12. However, if HIT is poorly designed or implemented, it poses a risk to patient safety 13-15. For instance, an anesthesiologist did not know his patient had taken oxycodone because of the lack of interoperability between the office-based medical record platform and the inpatient system; the patient became somnolent upon receiving morphine after the oxycodone 16. HIT events were listed in the top 10 technology-related hazards identified by the Emergency Care Research Institute among a range of common problems in 2015 17. One in six PSEs is related to HIT, such as medical devices, EHRs, and CPOE 18. Therefore, HIT related events pose a major threat and barrier toward a safer healthcare system, and the large number of HIT related events must be addressed to reduce patient harm.

Safety event reporting has been proven effective in many high-risk industries 19-21, for improving safety and enhancing organizational learning from errors. Healthcare systems have adopted event reporting since the 1999 Institute of Medicine (IOM) report 22 that greatly raised the public awareness of patient safety issues. Through collecting reports of adverse events and near misses in healthcare, reporting systems would enable safety specialists to analyze events, identify underlying factors, and generate actionable knowledge to mitigate risks 23. In the U.S., the IOM recommended using patient safety reporting systems 24, 25 to determine why patients are sometimes harmed during medical care. The Agency for Healthcare Research and Quality (AHRQ) created the Common Formats (CF), common definitions and reporting formats 21 to help healthcare providers uniformly report PSEs.

However, collecting data on HIT-related PSEs for learning purposes is challenging owing to the lack of HIT reporting forms or platforms. Although CF forms are commonly used in Patient Safety Organizations (PSO), the CF form containing HIT event categories is defined at a very high level and embedded with the category of device or medical/surgical supply. This makes it difficult for reporters to recognize the proper categories when reporting, and as a result, reporters often leave fields blank rather than responding to the prepopulated questions. In the 2015 annual report of a PSO institute, the Missouri Center for Patient Safety, only one PSE was identified in the original report as an HIT event. Therefore, the scarcity of HIT event-exclusive databases and event reporting systems indicates the challenge of identifying the HIT events from existing resources.
EHR seems to be a potential resource to extract HIT events because EHRs are real-time, patient-centered records that make information available instantly and securely to authorized users. While an EHR does contain the medical and treatment histories of patients, an EHR system is built to go beyond standard clinical data collected in a provider’s office and can be inclusive of a broader view of a patient’s care26. However, EHR itself belongs to HIT, which may hide a large amount of EHR related events that happened during data entry and data transfer. In addition, there is no structured field that could help extract HIT events in an EHR that is not designed for such a purpose.

The U.S. FDA Manufacturer and User Facility Device Experience (MAUDE) database27 is a rich and publicly accessible resource with the potential of extracting HIT events. Different from EHRs, the FDA MAUDE database focuses on the reports of events involving medical devices, voluntary reports of medical device malfunction, and reports of problems leading to serious injury and death since June 199328. The database houses medical device reporting submitted to the FDA by mandatory reporters (manufacturers, importers and device user facilities) and voluntary reporters (healthcare professionals, patients and consumers). The FDA MAUDE is updated weekly and searchable online. As of February 2017, MAUDE had more than 6 million reports. The challenge of identifying HIT events from the FDA MAUDE is that only 0.1% of reports are related to HIT, and are mixed with other reports regarding equipment failures and hazards29. Due to the enormous size of the FDA MAUDE and the small percentage of HIT events, directly identifying and extracting all HIT events from the FDA MAUDE is almost impossible using a straightforward strategy. The classification of data with imbalanced class distribution has encountered a significant drawback of the performance attainable by most standard classifier learning algorithms30. In addition, the rapid evolvement of topics and free text regarding HIT events presents another challenge for distinguishing these events from others. The initialization of HIT event database based on the FDA MAUDE database requires an up-to-date, efficient, and effective strategy.

A MAUDE report is composed of structured fields (device and patient information) and unstructured fields (textual information). In the preliminary study, we developed an HIT filter based on the generic name and manufacturer name, two structured fields of the 2015 MAUDE database, enabling us to screen the FDA MAUDE and consequently create a report subset with more than 50% HIT events31. We sampled and reviewed the filtered reports which resulted in an estimate that 0.4~0.9% FDA MAUDE reports were HIT events. Although this ratio has been significantly enhanced, it is still far away from establishing an HIT dataset. Fortunately, a classifier based on unstructured field may be feasible to further identify HIT events, since the information from unstructured data provides an integrated and comprehensive view. In addition, the ratio of the HIT events in filtered data is perfect for classifier training and evaluation.

In this study, six popular classification algorithms were compared on 2015 MAUDE database by using term frequency-inverse document frequency (TF-IDF)32 as the feature of each single word in the unstructured fields. Then bitem model (BTM)33, a word co-occurrence based topic model that learns information from word combinations, was applied to further improve the best classifier of the six. After discussing the balance of precision and recall, according to the learning requirement, a final model that can provide a dataset with more than 97% HIT events was proposed. This model offers the probability of initializing and growing an HIT database from the FDA MAUDE and other potential resources. The outcome will be a timely reflection of the evolvement of HIT events and will be helpful for enriching HIT knowledge and better using the historic reports toward an overall understanding and analysis of the characteristics, occurrence, observation, and description of HIT events. In addition, this project provides an intelligent strategy to connect structured data with unstructured data and holds promise in triggering a revolution of data management and analysis in healthcare and other industries.

**Methods**

**Improve the filter for the structured fields of FDA MAUDE**

Most of the 45 structured fields of the FDA MAUDE database are either left blank by reporters or are of little use for the purpose of identifying HIT related events. The only two fields have the greatest potential in identifying HIT related events are **generic name** and **manufacturer name**. Therefore, a filter based on these two fields was established in our preliminary study31.

We started with a set of common computer hardware and software related keywords that had been previously identified34. The starting keyword list was expanded by the addition of several generic terms such as “software,” “program,” and “hardware” and several more modern terms such as “electronic medical record” and “portal technology.” Then all of the generic names from the FDA MAUDE database starting from Jan 2010 to Dec 2015 were extracted, yielding a total of 60,000 unique generic names. Next, through partial keyword matching of the generic names to the keywords list, a subset of generic names appearing HIT-related was extracted. The subset was further
analyzed by domain experts to determine which generic names were actually linked to HIT reports by using a small portion of the 2015 FDA MAUDE database. A similar approach was utilized in selecting a list of manufacturers for the filter. We started with a list of seven popular HIT manufacturers\(^{34}\) and then added 347 manufacturers of HIT software. The reports from the 2015 FDA MAUDE database related to those manufacturers were extracted and checked to determine the most relevant manufacturers.

To evaluate and improve the HIT filter, the filter was first applied to the 2015 FDA MAUDE database. Then a subset (10\%) of the reports screened by the filter was manually reviewed by two domain experts. The experts labeled each report with one of three labels: HIT, Not HIT, or Unsure. The reports with disagreements among the reviewers were resolved through group discussion. During the review, our team narrowed the HIT definition to identify the most clinically relevant and consequential HIT devices. Under our current understanding, an HIT device is any device that utilizes both hardware and software to facilitate health information exchange in order to aid in the diagnosis, treatment, or prevention of disease. Using this definition, priority is given to HIT systems that focus on information exchange such as electronic health records, computerized physician order entry, and picture archiving communications systems. Implantable devices, glucose monitors, defibrillators, and similar devices are excluded under this definition, as they do not actively facilitate health information exchange.

**Compare six classification algorithms based on the unstructured fields of FDA MAUDE**

Six popular machine learning classifiers including logistic regression, support vector machine (SVM), naïve Bayes, decision tree, JRip rules, and random forest were constructed using the unstructured data of the reviewed reports. Weka 3.8.1\(^{35}\) was applied for training and validating the classifiers. The unstructured data of 2015 FDA MAUDE was filtered by removing the words in the Rainbow stoplist\(^{36}\). Then each report in the labeled training set was treated as a vector of words and was weighted by a TF-IDF technique. The effectiveness of this word-based information retrieval approach has been proven effective in searches of patient records, which are often corrupted by misspelled words and conventional graphs or abbreviations\(^{37,38}\). Eq.1 shows how to calculate the weight of term \(x\) within document \(y\) using TF-IDF (\(tf_{x,y}\) is the frequency of term \(x\) in document \(y\), \(df_x\) is the number of documents containing term \(x\), \(N\) is the total number of documents). The six classifiers were evaluated using leave-one-out cross-validation (LOOCV) and their performances were weighted based on both their F-scores and ROC areas.

\[
w_{x,y} = tf_{x,y} \times \log \left( \frac{N}{df_x} \right)
\]

(Eq.1)

**Improve HIT classifier by using BTM**

TF-IDF only considers the information from a single word and its distribution across the whole corpus, but cannot capture the semantics information among the dataset. Topic models\(^{39}\) are a class of statistical machine learning algorithms that extract the semantic themes (topics) from a corpus of documents. These topics generated based on the document-level word co-occurrence patterns describe the thematic composition of each document and can thus capture the semantic similarity between topics and documents. Moreover, those generated topics have been widely used as features to improve document classification and information retrieval performance\(^{40,41}\).

The BTM\(^{33}\) that we used in this work to improve the HIT classifier is specifically designed for short text documents. In general, an HIT report is too short to provide enough word counts for conventional topic models, like PLSA\(^{42}\) and LDA\(^{43}\), to know how words are related, comparing to lengthy documents. Also, the limited contexts make it very difficult for topic models to identify the sense of ambiguous words in short documents. BTM overcomes those short text limitations by assuming that all the biterms (i.e. unordered co-occurring word pairs) are generated by a corpus level topic distribution to benefit from the global word co-occurring patterns. Informally, the “generative story” for BTM is as follows. Firstly, each topic’s word distribution is drawn over the vocabulary of the whole corpus. Then a corpus-level topic distribution is drawn to describe this dataset. To generate each biterm in the biterm set extracted from the whole corpus, one draws a topic from the corpus-level topic distribution and subsequently selects two words from this distribution across all vocabulary of the whole corpus corresponding to this topic. BTM uses this generative process to model the co-occurrence of a pair of words over the whole corpus to reveal the topics than just the occurrence of a single word, and then enhance the learning of topics. Specifically, it estimates the parameters that define the topic mixture over the whole corpus and the conditional probability of each word given each topic. The topic distribution of each document can then be naturally derived based on the learned model. Parameter estimation is done via Gibbs sampling approach.

The number of topics generated by BTM must be pre-specified. Determining the “right” number of topics for different data sets remains a challenge. When the number of topics increases, redundant and nonsense topics may be generated.
In this study, we conducted experiments with various numbers of topics ranging from 5 to 100. The performance in the classification tasks was quite consistent after a particular topic number threshold. Hence, it is likely that a BTM with a relatively large number of topics will capture all the key themes over this corpus and in further to improve the document classification task.

Results

HIT event filter based on structured data

Based on the analysis of pre-viewed FDA MAUDE reports and the discussion with two healthcare professionals, 58 keywords from generic names (39 software and 19 hardware keywords respectively) and 16 keywords from manufacturer names were determined to compose the filter for HIT related reports, as shown in Table 1. The filter was first applied to the 2015 FDA MAUDE database including 860,915 reports. 4871 reports (2479 software and 2392 hardware reports) were initially found. 490 reports (10%) were randomly selected according to the keyword distribution for expert review and labeling. 289 reports were identified as HIT related by experts, which means the filter can generate a report subset from original 2015 MAUDE database with about 50-60% HIT related reports. This proportion is much more practicable in terms of classifier training than that on the entire MAUDE database (0.4~0.9%)²⁹.

HIT Classifiers using TF-IDF model

The manually labeled reports (289 HIT and 376 non-HIT reports) from 2015 MAUDE database were applied as the training set of the classifiers. 1,541 words extracted from the unstructured fields were fixed as the feature set after removing stopwords. TF-IDF was calculated for each word in each report. A comparison was made among the classifiers trained using six popular classification algorithms: logistic regression, random forest, naïve Bayes, SVM, decision tree (J48), and JRip rules. As shown in Table 2 and Figure 1, random forest has the best performance in terms of accuracy, ROC area, and F-score.

HIT Classifiers using BTM

BTM was implemented to analyze the words of the unstructured fields of the training set and to discover the topics without any prior annotations or labeling of the reports. This statistical model reflects the intuition that narrative reports exhibit multiple topics. Each report exhibits the topics in different proportions; each word in a report is drawn from one of the topics, where the selected topic is chosen from the per-document distribution over topics. All the reports in the collection share the same set of topics, but each report exhibits those topics in different proportions. We applied the topics as the feature set and the weights of the topics as the features’ values. To figure out the best topic number, BTM was run for 20 times by setting topic numbers from 5 to 100 with an interval 5. Random forest classifiers were also trained for 20 times as the topic number changed. As shown in Figure 2, most BTM-based classifiers have higher F-scores than the TF-IDF-based classifier, while the ROC areas are not improved by BTM. The BTM-based classifiers with the best F-score and ROC were obtained when setting the topic number at 70 and 80. Therefore, we combined the features of BTM and TF-IDF at each of the two topic numbers and trained two additional classifiers respectively (the dots in Figure 2). The classifier combining TF-IDF features with 70 topics from BTM has the best performance with ROC area 0.920 and F-score 0.834, which are significant improvements comparing those of the original TF-IDF-based classifier.

A dataset with 97% HIT events

The original purpose of building the HIT filter and classifiers was not to identify all HIT related reports from the FDA MAUDE. Instead, we need an HIT exclusive database or a report dataset with a large proportion of HIT related events. In other word, we can tolerate the loss of recall to obtain a higher precision. Random forests build an ensemble of tree classification predictors using bagging. Each node of the trees only considers a small subset of features for the split. The classification is done by voting, which means a probability is calculated based on the voting result of all predictors.
Figure 3 shows the changes of true positive and false positive as the threshold of the probability changes. Based on the case review, we found that one third of the HIT related events are typical enough for learning purposes. Therefore, if setting the threshold at 0.7, we could get a high precision 0.97 and adequate true positive cases. By using this strategy, a report dataset with 97% HIT related events was derived from the original 2015 FDA MAUDE, which contains up to 0.9% HIT related events.

**Figure 3.** The effects of random forest probability

**Discussion**

**Initialize and grow an HIT database**

Learning directly from the AHRQ CF and FDA MAUDE is challenging since the two reporting forms are not HIT exclusive. This study provides an effective way to extract HIT related events from the FDA MAUDE and initialize an HIT event database. To establish and grow the database, meanwhile, further improve the HIT filter and classifier, we will apply the HIT event filter and classifier on the 2014 dataset. Only the cases that are identified as HIT will be manually reviewed. All the reviewed cases will be added to the training set, which will consequently help build a new classifier. The same process will, in turn, be retrospectively applied on the datasets from 2013, 2012, 2011, 2010, and beyond. At the end of each iteration, the four training methods will be re-evaluated based on the corresponding manual review, and the best method will be used in the classifier. The classifier is expected to be improved as more labeled cases are included. As the manually reviewed HIT events are accumulated, an HIT event database will be established and keep growing.

In our preliminary study, we prototyped a user-centered PSE reporting system based on a PSE knowledge base, which includes PSE reports, solutions, and their connections. Patient falls, another important PSE subtype, were applied to test the system. Users can either choose an existing fall case or report a new case, then the system retrieves similar cases and customized solutions based on the query and the reporter’s role (e.g., manager, clinician, staff, patient). The user preference may be diverse for different purposes. The system also allows the user to click the feedback button to indicate their preferences to a certain similar case or solution. All feedback will be returned to the algorithm implementation step in order to update the weights of similarity matrices and dynamically upgrade the system performance. This mechanism, similar to the ranking strategy of the Google search engine, will gradually stabilize the similarity matrices, making them more convincing as the feedback increases. The HIT identification strategy together with the TF-IDF and BTM features will be incorporated in this system to grow the database.

**Explore contributing factors and connections of HIT events for shared learning**

Intuitively, finding a way to compare two relevant HIT cases will be beneficial for learning from previous cases. The FDA MAUDE database is rich, broad and unique because it is a collection of errors of many HIT products from prevailing vendors such as Epic, Cerner, GE Healthcare, Allscripts, and McKesson; the connections among the reported errors will be helpful for their users and developers alike. The benefit once perceived would attract more HIT vendors and users to join the reporting and promote shared learning. The BTM can map the HIT events to the topic space that each event has an HIT topic rank according to the relationship between this event and each topic. We can observe how those topics changed over time and how they are connected to each other. Rather than finding reports
through keyword searches alone, we can find a small group of central topics as contributing factors and then examine
the reports related to the topics. More importantly, the topics can help compare and measure the vector-based similarity
between HIT reports, which could provide more targeted knowledge support to the reported cases in comparison with
similar or relevant cases. We can also extract the common characteristics of the HIT cases within a certain similarity
range, which will help us track the changes of HIT events and further improve the HIT identification strategy and
benefit healthcare professionals for shared learning.

Reduce the human labor

Manually reviewing all cases in the FDA MAUDE database was simply infeasible and that machine learning was
likely to be the only viable approach. Traditionally, the two paradigms of machine learning have been supervised (all
labeled data) and unsupervised learning (all unlabeled data). However, recently, much attention has been placed on
semi-supervised learning for its ability to utilize only a small amount of labeled cases combined with a large amount
of unlabeled cases to improve classification accuracy. In the case of HIT, this approach seemed to be well-suited as
the cost of labeling narrative text by manual review is quite high, while the cost of obtaining unlabeled reports is
minuscule in comparison. One of the simplest methods within semi-supervised learning is self-training. In self-
training, predictions made with high confidence by the classifier are added back to the labeled data, so that the
classifier keeps being updated and improved after each iteration. This approach seems to a viable method to extract
and classify HIT reports from large databases such as the FDA MAUDE.

Connecting structured and unstructured data is essential for patient safety data retrieval

The variety of reporting formats is the primary challenge to improving quality and connection of PSE reports. Our
preliminary work suggests that communication among PSEs can be established if we extract all the necessary
information and properly annotate it to the same hierarchical feature structure. However, when the quality of the
structured features is unsatisfactory (e.g., HIT related reports in AHRQ CF), we need to find more information in the
unstructured data (narrative reports) to ensure a comprehensive view. An analogy can be made with the U.S. National
Library of Medicine’s PubMed literature filtering, in which a controlled vocabulary, Medical Subject Headings (MeSH) was
developed to index MEDLINE articles. MeSH has been successfully used to improve PubMed query results, information retrieval, document clustering, and query refinement in “downstream” applications that use
PubMed abstracts. Similarly, a MeSH-like patient safety vocabulary holds promise in connecting structured and
unstructured features and in becoming the framework for the PSE knowledge base, the collection of PSE reports,
solutions, and the potential connections among them. The TF-IDF and BTM features in this study have the potential
to explore the “MeSH” in patient safety domain and standardize PSE reporting and management.

Benefits of shared learning and reporting systems

While all technology is fallible, technology-induced errors in healthcare may have far more serious repercussions than
those in other fields. Even with extensive testing, HIT may be especially vulnerable to failure due to the fast pace and
complexity of the healthcare system. As an example, many EHR systems perform well in testing when used by only
one user of each user category in an office setting. However, when released to the public, the EHR systems may
malfunction as a group of physicians from all areas of medicine may use them in a variety of settings. Manufacturers
of technology often do not have the resources to test their products on such a large scale and must instead rely on user
generated reports to inform them of possible defects with their products. Perhaps, most well-known, Microsoft’s error
reporting system (codenamed Watson) has allowed the company to collect and learn from billions of error reports all
across the world. Integrated into Windows, Watson automatically collects information on program crashes and sends
it to Microsoft. Microsoft analyzes each crash report, and if available, sends a solution back to the user. Watson has
played an integral role in helping Microsoft identify errors and has also helped the company prioritize its debugging
efforts.

Implementation of a similar system for HIT events could yield tremendous benefits. With the knowledge gained from
a shared learning system, patient safety experts could analyze the distribution of HIT events and identify common
underlying factors among the reports. Safety experts could then prioritize their efforts to generate actionable solutions
for the most important and pressing patient safety events. While healthcare systems have utilized event reporting in
the last decade to increase awareness of patient safety issues, several barriers still exist that prevent patient safety
reporting systems from reaching their full potential. These include the fact that many reporting systems are still paper
based, which prevents data sharing; many of the user reports may be hard to understand due to ambiguous and vague
language used; and much of the patient safety data is scattered across many reporting systems, which are challenging
to aggregate.

1030
Barriers of voluntary reporting systems

The proposed HIT database was built on the voluntary reports generated by clinicians, patients, or consumers. Such reports are indispensable for preventing future occurrences of these adverse events and help foster a healthcare culture driven toward a safer healthcare system. Unfortunately, according to the US Department of Health and Human Services, 86% of medical errors go unreported. Many barriers still exist that prevent safety reporting systems from reaching their full potential. Perhaps a primary reason safety events go unreported, regardless of the field they occur in, is that people feel their reports will not make a difference. The origins of their feelings are completely understandable. In a well-publicized incident, Toyota was fined 1.2 billion dollars for negligence in addressing known safety issues that caused unintended acceleration in their vehicles. Prior safety reports were not enough to cause the company to fix the safety issue, resulting in a series of tragedies. In one tragedy, Officer Mark Saylor was driving his car with his family when the accelerator became stuck. Unable to free the accelerator, Mr. Saylor called 911 to narrate his terrifying ordeal. However, it was too late and Mr. Saylor and his family died after crashing into an SUV.

In a high stakes field such as healthcare, it is critical that errors are reported and that manufacturers are held accountable for their products. In regards to HIT, the challenge to get healthcare providers to report these events may be especially high. With the massive spending and efforts taken to adopt HIT by hospitals and the government, there may be a positive bias toward reporting the benefits of HIT and a negative bias toward reporting adverse events caused by HIT. To make matters worse, even when safety events are reported, manufacturers may not have enough resources allocated toward diagnosing and fixing those issues. While the staggering pace of technology has driven much innovation in healthcare, the need to take a careful look at the adverse events caused by HIT has never been greater. Doing so may ultimately keep HIT on the right track toward becoming a safe and integral part of the healthcare system.

Limitations

There is no exact figure about the proportion of HIT related reports in the FDA MAUDE, because the proportion was only an estimation based on limited sampling and reviewing. After applying the HIT filter on the 2015 FDA MAUDE, a subset (10%) of the reports of the screened data was selected for manual review to save human labor. Thus, the ratio 50-60% representing the HIT related reports among the filtered data was estimated based on the 10% random chosen reports. There might be a bias when using the subset’s profile to predict the profile of the whole dataset. An effective approach to reduce the bias could be utilizing a semi-supervised learning to grow the HIT database. The classifier can be trained using an iterative approach, and cases that are labeled by the classifier with a high probability (e.g., >0.90) of being HIT related are added directly to the training set. Using this self-training semi-supervised learning approach, it is possible to introduce biases and for early mistakes to become compounded through subsequent rounds of training. Despite several rounds of error analysis can be performed to prevent such an outcome, selection bias toward certain HIT events cannot be completely eliminated.

Conclusion

A strategy to initialize and grow a database for HIT related event reports from the FDA MAUDE database was proposed by retrieving the information from both structured and unstructured fields. The strategy helps us connect up to 0.9% FDA MAUDE reports with HIT events. The creation of this database holds promise in aiding the understanding, characterization, discovery, and reporting of HIT related events.

Abstract

Despite unprecedented spending, US maternal outcomes have worsened drastically over the past decade. In comparison, maternal outcomes of many Low and Middle-Income Countries (LMIC) have improved. Lessons learnt by their success may be applicable to the US. We performed a literature review to identify innovations that had met with success across LMIC, and should be considered for adoption in the US. mHealth and patient facing alerts, Telehealth, patient controlled health records, inclusion of patient relationship data in health information systems and positioning empowered community health workers as catalysts of maternal care delivery were identified as innovations worthy of further evaluation. These innovations were categorized into several themes; knowledge, technology, patient/community empowerment, coordination and process change. Tools that place informed and empowered patients and community members at the center of maternal care has greatly improved maternal outcomes, and are suitable to be considered for the US healthcare system.

Keywords: Global health, Maternal health, Clinical Information Systems, Mobile health, Telemedicine

Introduction

US maternal care is currently in jeopardy. At $111 billion a year, US spending on maternal health is twice that of most other high-income countries [1]. US hospital deliveries may cost up to 8,802 USD per birth, compared to an average 2,050 USD in other OECD countries [2]. Despite this spending, a joint report by the World Health Organization (WHO), United Nations Children's Emergency Fund (UNICEF), United Nations Population Fund (UNFPA), the World Bank and the United Nations Population Division states that US Maternal Mortality Rates (MMR) have surged by 136% between the years 1990-2013, from 12 per 100,000 live births in 1990 to 28 per 100,000 live births in 2013 [3]. At over 52,000 cases per year, the risk of severe maternal morbidity (SMM) leading to life-long health problems is even greater [4]. American women are more likely to die during childbirth or related complications than women of any other high-income country [5] or middle-income countries such as Bosnia or Macedonia [6]. The main causes of maternal deaths in the US are non-cardiovascular diseases (15.3%), cardiovascular diseases (14.7%), infection or sepsis (12.7%), hemorrhage (11.3%), cardiomyopathy (10.8%), thrombotic pulmonary embolism (9.0%), and hypertensive disorders (7.6%). The main causes of SMM are maternal age, pre-pregnancy obesity, pre-existing chronic medical conditions, and cesarean delivery [7]. There is also significant discrepancy in outcomes across different populations [8] The MMR among African Americans (40.4 per 100,000 live births) is over three times greater than white parents (12.1 per 100,000 live births). MMR among woman of other races are 16.4 per 100,000 live births [9]. MMR rates of US states with high poverty rates were 77% higher than wealthier states [10].

Research indicates that with the exception of malaria and HIV, the main causes of maternal mortality in low and middle income countries (LMIC) are generally similar to those in the US [11, 12]. However, many of these countries have been able to significantly improve their maternal health outcomes. LMIC such as Timor Leste, Bangladesh, Ethiopia, Uruguay, and India have reported between 78% to 65% reductions in maternal mortality during the same 1990–2013 time period that saw US maternal death rates jump by 136%. [3]. Fortunately, evidence suggests that a majority of US based maternal mortality and morbidities are preventable, and can be addressed via early detection and care [13]. This aligns with the three delay model which recognizes three significant barriers women face in achieving timely and effective medical care; the delay in (a) decision to seek care, (b) reaching care, and (c) receiving adequate healthcare [14]. Informatics based solutions can address the three delays, thereby improving maternal health outcomes. Additionally, changes in healthcare delivery across LMIC during this period have included significant investments in healthcare infrastructure and informatics expertise to help mitigate these barriers. Considerable emphasis has been placed on the use of point of care technology, including mobile phones to deliver actionable information to providers, community health workers, caregivers, and patients, allowing them to address the three delays that cause maternal
mortality [15]. This indicates that such solutions may have contributed toward improving maternal outcomes. Thus, lessons learnt from LMIC may illustrate approaches to improve maternal outcomes in the US. However, not all innovations may be successful due to significant socio-economic and policy differences between the US and LMIC.

We evaluate maternal care based health informatics interventions adopted by LMIC, and determine which of these could help address maternal care challenges faced by the US. We do not seek to perform comprehensive evaluations of care models or correlating process changes brought about by informatics applications, but to recommend which approaches are most suitable to for consideration to address maternal healthcare needs in the US.

Materials and Methods

An introduction to reverse innovation

Traditionally, technological innovation originated, and was consumed by high-income countries. Such innovations were often considered too expensive or unsuited for LMIC needs. Often, product owners avoided expanding to LMIC as they perceived that marketing their solutions across underserved settings would be unfeasible due to high resource requirements. In many cases, innovations from high-income countries were 'whittled down', and produced with limited feature sets for use in low income countries [16]. This environment encouraged innovators from LMIC to develop frugal solutions that were suited for their own needs. However, thanks to qualities of frugality, low operating costs and robustness, innovations meant for LMIC can also be appropriate for adoption elsewhere, particularly in underserved populations in high-income countries. Reverse innovation is the identification of innovations that have already met success in LMIC and adopting these innovations for use in high-income countries [17].

Since its conception, reverse innovation has won widespread acceptance, and adopted by brands such as Microsoft, Nokia, Tata Motors, and Nestle. Products and services created through reverse innovations focus on reducing operating costs and bringing equity with minimal effort, both of which are significantly important for the US health care system. Reverse innovation has the potential to inform a wide host of healthcare challenges [18]. However, the applicability of adopting innovations from LMIC for use in the US healthcare system is relatively unknown, and further work, including implementation science research is necessary to advance the understanding and potential of diffusion of reverse innovations.

Study approach

We searched scientific literature to assess the maternal outcomes challenge in the US. However, searches across OVID medline and Web of Science produced a preponderance of evidence reaching thousands of publications and reports of various quality. To identify the most relevant and accurate literature, we focused on a subset of academic, research and development organizations engaged in improving or monitoring maternal outcomes in the US as sources of information. We searched the websites of these organizations to identify formal reports/publications that discussed major causes of mortality and morbidity. The results of this search were refined using content and discourse analysis methods to identify challenges that are most significant to the US. Next, we performed a literature review to identify how LMIC addressed each of these challenges, and what health informatics innovations could be leveraged to do so. By mapping the aforesaid challenges to successful health informatics innovations, we identified those suitable for further evaluation in the US. We elected to perform a literature review rather than a systematic review as a systematic review would be focused on a single research question, while a literature review would allow us to bring together a broad body of information on a given topic to draw our own conclusions [19].

Results

Based on the analysis of well-reputed information sources (Appendix A), we identified five major challenges affecting US maternal health outcomes;

(a) Lack of trained staff: Rural Americans and underserved populations such as American Indians and Alaska natives (AI/AN) suffer from significant shortages of healthcare providers due to (a) existing staff shortages and (b) tendency of physicians to relocate and practice at affluent urban or suburban areas [20, 21].

(b) Limited access to care: Lack of access to care is a significant challenge to African Americans, Latinos and other minority groups [22], at risk populations, immigrants and low-income earners [23].

(c) Limited sense of ownership/empowerment: Placing an informed patient at the center of their own care can address delays in seeking care, and empower the patient to be an active participants in their own healthcare.
Isolation/lack of community support: Lack of community support and feelings of isolation can lead to depression, stress and inability to manage other life threatening behaviors/conditions [24, 25].

Gaps in patient awareness/education: Lack of awareness leads to risky behavior, inability to manage harmful conditions such as pregnancy related complications [26], and contributes to delays in seeking care.

We performed a rigorous literature review across Ovid Medline, Web of science and EMBASE to evaluate health informatics innovations adopted by LMIC to address these challenges (Appendix B). Search results were refined using the literature inclusion/exclusion strategy presented below (figure 1).

The literature review indicated that efforts to improve maternal care delivery for LMIC had led to the development of numerous tools and approaches. Many informatics based innovations focused on delivery of actionable information to reduce the three delays. We also considered innovations that had failed due to technology, financial or policy based limitations. In the case of such failures, we assessed why they had failed, and determined if these innovations would survive, and help improve maternal outcomes in the US. These lessons were condensed into technological and system change innovations that could address one or more of the five aforementioned challenges, and were suitable for further evaluation by US based settings; (a) mHealth and Patient Facing Alerts, (b) Telehealth / Telemedicine (c) Patient controlled health records (d) Relationships within Health Information systems (e) empowered Community health workers (CHW) as catalysts of healthcare delivery (table 1).

mHealth and Patient Facing Alerts

The role of actionable information in improving health outcomes is well documented [27, 28]. The rapid penetration of mobile networks across Africa and Asia has made mHealth efforts a strong success. Examples of success in using mHealth – using mobile devices in health service delivery, to enable maternal care in emergency medical support in Bangladesh, Ghana, Uganda and India, point of care support in Pakistan and Indonesia, and health promotion in Tanzania, Ethiopia, Serbia and Thailand [29-31]. Research indicates that standard care with reminders, disease monitoring and management, and education through cell phone voice and short message service has helped improve health outcomes [32]. mHealth applications also enable better communication between health workers and leverages social networks to improve health outcomes [33]. mHealth based approaches have proved useful in helping address the three delays. mHealth improves maternal outcomes through (a) empowering women to contact health services and access information [34] (b) access emergency obstetric care [35] (c) giving patients knowledge of where to go and (d) enabling lesser trained health workers to provide the ‘right health care’. Despite the success of maternal care applications such as text4baby [36], mHealth and patient alerting tools have failed to undergo widespread penetration in the US due to (a) questions on quality of existing health apps [37] and (b) lack of adequate research to keep pace with ever changing technological progress [38]. However, work in LMIC indicates that a consistent messaging system integrated into the health care delivery model with the right information and a pathway to ‘receive the right care’ has positive impacts on maternal outcomes, especially across underserved populations [31, 39].

Telehealth/Telemedicine

Telehealth/Telemedicine plays an integral role in providing medical care across space and time via telecommunication technologies ranging from the telephone to robotics. It is widely perceived as a method to share medical knowledge in settings where trained staff is scarce. Telehealth is not a new concept to the US. It was widely used by the US military [40]. However, the lack of broadband infrastructure and financial, legal and healthcare policy barriers posed a significant challenge to the early advancement of telemedicine [41], leading health policymakers to relegate Telehealth to a secondary role [42]. However, these barriers are coming down. The Affordable Care Act (ACA) and the American Recovery and Reinvestment Act (ARRA) of 2009 has reduced barriers around the utilization of Telehealth [43]. These together with CMS telemedicine reimbursement changes and state level policy changes promise significant potential for the increased adoption of Telehealth systems [44]. Telehealth is widespread across LMIC, especially for maternal and child health delivery [45, 46]. While we are aware of the significant use of telemedicine within the US, we note that LMIC are creating unique uses for telemedicine using ubiquitous mobile platforms to enable low bandwidth solutions focused on improving maternal care by creating awareness and enabling better care delivery. Based on these advances, we propose that Telehealth, using more ubiquitous platforms such as mobile phones, should be given the place of prominence that it deserves within the US healthcare system.

Patient controlled health records

Patient controlled health records were introduced over two decades ago as a means of creating online repositories where patients could collect and control access to their healthcare data [47]. While revolutionary in its time, projects such as Google Health and Microsoft Health Vault that aimed to operationalize this concept were unsuccessful due to failure to win vendor support, low trust and potential risks [48]. There has been a gradual re-emergence of patient portals integrated into the larger health information systems over the past decade. Unfortunately, these do not create longitudinal patient records as they can only access a single health care system. In comparison, LMIC have developed alternate versions of longitudinal patient controlled health records in the form of smart cards or plastic cards that contain an embedded computer chip to store data [49] as well as paper based medical 'books' that are retained by the patient. While Europe has embraced smart cards for health care, the network centric nature of the US healthcare culture hampers the widespread adoption of Smart cards [50].

One purpose of granting control of their own health record to the patient is to ensure that they become the locus on control in managing their own healthcare. To do so, healthcare networks must uniquely identify each patient. This necessity led to the development of national patient identifiers and Master Patient Indexes (MPI) that serve as registers and resolvers of patient identities in many LMIC. MPI's have been successfully implemented across many LMIC [51]. In comparison, the US has chosen to not embrace a universal patient identifier system due to concerns of privacy [52]. However, rejecting a universal patient identifier has led to limitations in interoperability and data sharing. If implemented correctly, patient controlled health records have the potential for improved shared decision-making between the clinician, caregivers and patient. They also enable early recognition of maternal complications and / or warning signs through access and control of patient records, ultimately contributing to the reduction of the three delays.
Relationships within Health Information Systems

Healthcare is a team sport that depends on collaboration between providers, patients, payers, families, health care teams and communities. When a provider identifies a patient’s need, that need might be reported to a different participant who is able to take appropriate action. Cost of healthcare services and lack of trained staff often result in at least some parts of patient care being delegated to members of their immediate family. However, proper communication and collaboration is essential to make such efforts successful. Relationships between health care teams and family members cannot bring value to a patient unless they are easily discoverable within a healthcare system. Many EHR systems lack support to persist structured patient relationship information, a weakness identified and addressed by developers of the OpenMRS platform, an Open Source Medical Record System designed for use across underserved settings. To date, multiple sites in LMIC have adopted this feature for managing patient relationships with success [53]. We perceive that the need to technologically incorporate critical patient, family and provider relationships within health information systems will be increasingly important to the US as it moves toward a more comprehensive quality based care reimbursement mode, and that efforts should be made to capture and manage such data within a patient’s health record.

Empowered Community health workers (CHW) as catalysts of healthcare delivery

The success of adopting health information infrastructure depends on how information derived from these systems is used impact healthcare delivery. While providers play a crucial role in decision-making, their ability to prevent the three delays outside of a healthcare setting is very limited. CHW’s are frontline public health workers with a close understanding of the community they serve. Their links to the community allow them to reach out to patients at their homes and communities, and improve the quality and cultural competence of service delivery. CHW programs are widespread across LMIC, where they are a predominant topic in discussions around primary health-care delivery. Success stories in using CHW’s for improving healthcare are reported from Uganda, Ethiopia and Tanzania [54]. These successes have encouraged the governments of Brazil, Pakistan, and India to make CHWs a cornerstone of scaling up community health delivery, especially for providing maternal care [55].

CHW’s are not an entirely new concept to the US. They have significant potential to improve maternal outcomes in the US, as demonstrated by successful projects driven by the Indian Health Service and Tribally Operated Health Programs such as the Alaska Community Health Aide Program (CHAP) [56]. Unfortunately, many US based CHW initiatives are short-term, grant-funded projects and grassroots volunteer community initiatives [57]. Unlike many developing countries, US health policy administrators have relegated CHW to a secondary role. However, lessons learned from underserved settings offer much promise for the introduction and use of empowered CHW who are capable of reaching out to pregnant women at the grassroots level. CHW also have the potential to be far more cost efficient, and reduce treatment costs via early evaluation and detection, appropriate referrals, and longitudinal support.

Discussion

Enabling better seeking of care, access to care, and receiving the right care at the right time can significantly reduce maternal mortality and morbidity across both high-income and low-income settings. In both LMIC and the US, these factors are hindered by the scarcity of economic, physical and human resources, or the inability to make them available to the right people at the right time. While US health information infrastructure is more than capable of supporting high quality care where ample resources are available, it falls short of meeting the needs of underserved populations such as minorities, low-income communities and rural areas.

Our research identified five informatics based solutions successfully adopted by LMIC countries, and suitable for adoption in the US; (a) mHealth and patient facing alerting (b) Telehealth (c) Patient controlled health records (d) Relationships within Health Information systems and (e) Community health workers as catalysts of healthcare delivery. In examining these innovations, we found that some of these had already been considered by the US in the past, but failed/impeded by inherent differences in the US healthcare system. However, recent changes in US infrastructure, law and policy aimed at reducing healthcare costs and making healthcare services more accessible [58] and a commitment to comprehensive care models are breaking down these barriers, and improving the potential of adopting these innovations in the US. We found that many of the proposed solutions were strongly interrelated, and that successful maternal care innovations often consisted of combinations of the aforementioned innovations. As shown before, CHW networks in underserved settings depended on information received and integrated via mHealth solutions to guide much of their work. Similarly, efficient persistence and retrieval of relationships, entered into medical records at the point of care, also helped CHW networks. Having improved patient ownership of clinical data enables better dissemination and data integration for use in clinical care, with CHWs, clinicians, other health providers.
and family and community members. We also found that, while the five proposed innovations were dependent upon technology, technology was insufficient by itself. Common themes of knowledge, technology, patient and community empowerment, coordination and process change emerged (figure 2).

**Figure 2.** Enabling better maternal care outcomes. Potential innovations and general themes

The findings indicate that the proper use of health information could play a significant role in improving US maternal outcomes, as well as reducing associated healthcare costs. Many of the innovations that we recommended for evaluation in the US could be used for a wide range of healthcare services over and above maternal care delivery. Investigation of the underlying themes show that the key to maternal care is to place informed patients at the center of their own care. Traditionally, US healthcare delivery is known for its rigid health infrastructure, workflows and provider centric care. Clearly, this approach has done little to address worsening US maternal care outcomes. In comparison, successful innovation across LMIC countries seem to focus on creating and empowering informed patients and their communities to act on their own needs. If so, informatics solutions will be expected to play a crucial role in integrating patients and communities into the healthcare delivery process, informing them, and empowering them to take action on their own needs.

It could be argued that the US still suffers from significantly lesser maternal mortality and morbidity than LMIC despite of the 136% rise in maternal outcomes from 1990-2013, and that many LMIC reported significant improvements in maternal outcomes during this same period starting from comparatively high baseline measures. In other OECD countries, the same measures have remained relatively constant with significantly lower costs of care, suggesting that the rise in maternal mortality and morbidity is a significant concern. More so because a majority of these outcomes were preventable, and because health outcomes worsened despite of significant increases in financial spending in the US, which indicates the need to re-think current healthcare focus areas. Additionally, health IT based interventions have demonstrated their ability to reduce preventable maternal mortality and morbidity in LMIC [59, 60], indicating that they may be able to do the same in the US. Furthermore, every challenge identified in table 1 could be addressed via health informatics innovations. Another possible area for debate would be contextual changes between LMIC settings and the US. US based healthcare is far more expensive than LMIC or even other high-income countries. However, the most adversely hit populations in the US are at-risk populations and the poor, who also benefit from compatible state funded health programs. Additionally, maternal care is very well funded, with multiple welfare/aid options for those in need. Therefore, adoptations of LMIC based approaches for the US is feasible. As future steps and further validation of our findings, we propose the evaluation of each of the innovations identified by our study using the Technology Acceptance Model (TAM) [61]. The TAM model presents how target users accept and use a given technology, and thus, will further evaluate the potential of successfully adopting such innovations across the US.

**Conclusion**

Our study identified significant potential for adopting reverse innovations to help address weak maternal care outcomes in the US. Many restrictions that historically hampered these innovations have already been removed, leading to improved chances for their success. Recent US policy and administrative changes aimed at reducing
healthcare costs and creating comprehensive health care delivery models are also making these solutions more realistic. General themes that drive these innovations indicate that the key to better maternal care outcomes is to place patients at the center of their own care by empowering informed patients and their community to act on their own needs. While the role of these factors and themes in enabling improved health outcomes is widely recognized, the importance of a holistic model that includes, but is not limited to informatics is often disregarded. We highlight the intersections of technology and process changes that have been shown to improve care in LMICs. We believe that there is ongoing evaluation and future work in this area that needs to occur, including a rigorous comparison of multi-country implementations, and an evaluation of the return on investment of these identified innovations. However, recognizing that LMIC have developed appropriate technological and process solutions that can benefit underserved settings in high-income countries is critical. Adversity itself can be a springboard for innovation. In many cases, technological solutions developed and lessons learned in LMIC are applicable and beneficial to the high-income countries. It behooves us to identify, evaluate and incorporate appropriate solutions, regardless of their origin, as we continue to seek global health equity.

Modes of De-identification

Mehmet Kayaalp, MD, PhD
Lister Hill National Center for Biomedical Communications

Abstract

De-identification of protected health information is an essential method for protecting patient privacy. Most institutes require de-identification of patient data prior to conducting scientific studies; therefore, it is important for clinical scientists to be cognizant of all modes of de-identification and all services provided by their de-identification tools. In this article, we discuss eight different modes of de-identification that yield de-identified data at different levels of quality. Most of these modes can be used in combination to achieve the best performance.

Introduction

De-identification is a process of detecting identifiers (e.g., personal names and social security numbers) that directly or indirectly point to a person (or entity) and deleting those identifiers from the data. Health information containing personal identifiers that are linked to the subject of the information is defined as protected health information and is protected under the federal law. The deleted personal identifier (e.g., “James Smith”) can be replaced with information describing the type of identifier (e.g., [Personal Name]) or with fake identifiers called pseudonyms (e.g., “John Doe”). Replacing personal identifiers in the clinical data with non-identifying terms minimizes the chance of re-identification of the patient during the use of the data for scientific purposes; hence, it is one of the most essential tools for protecting patient privacy.

According to the Privacy Rule of the Health Insurance Portability and Accountability Act (HIPAA), the de-identification process can be accomplished using two separate pathways: Safe Harbor method and Expert Determination approach (see Figure 1). The Safe Harbor method requires all 18 personal identifiers to be eliminated. The latter approach uses the preservation of certain personal identifiers (usually dates and demographics) combined with an expert’s assurance that these identifiers could not be used to re-identify the patient. Note that the Privacy Rule neither defines the qualifications of the expert or the expertise nor sanctions any set of methods that would yield such a determination.

If dates, ages over 89 years, and/or detailed geographic information (five-digit ZIP code or at the town level of details) are required in the study, Safe Harbor method can be used along with another HIPAA Privacy Rule provision called Limited Data Set. Under this provision, researchers can access those pieces of information if they agree to sign a data use agreement established by the data-providing institute. Compared to the Safer Harbor, the expert determination approach is less definitive, so we do not consider it here. For this article, the term de-identification implies the Safe Harbor method only.

Anonymization is closely related to de-identification. It is sometimes used interchangeably and confused with de-identification. Although both anonymization and de-identification aim to protect the privacy of the subject of information, they are semantically different concepts. As a federal regulation, HIPAA Privacy Rule defines 18 types of personal identifiers. State laws and institutional review board (IRB) regulations that are more stringent than the Privacy Rule may require the removal of an additional set of identifiers such as provider identifiers and specimen slide numbers. However, in all cases, the process of de-identification is defined explicitly; that is, finding specific identifiers and deleting them. Thus, de-identification is a well-circumscribed process with explicit specifications of what needs to be done. The same cannot be said for anonymization. Anonymization is not a method per se but a goal, which may be achieved using different methods and strategies. Anonymization does not imply a standard nor does it specify what needs to be done to attain that goal.

Another crucial difference between anonymization and de-identification pertains to the claim of the outcome. The Department of Health and Human Services (DHHS) “is cognizant of the increasing capabilities and sophistication of

* Although the secondary use of clinical information may go beyond scientific purposes, such as financial analysis, fraud detection and marketing. American Medical Informatics Association. A Taxonomy of Secondary Uses and Re-Uses of Healthcare Data. Policy Meeting, 2007. Our scope is limited to non-commercial scientific use only.
electronic data matching used to link data elements from various sources and from which, therefore, individuals may be identified” (see Federal Register p. 53232). The de-identification process minimizes the risk of re-identification but has no claim to make it impossible. On the other hand, methods for anonymization found in the literature such as aggregations of microdata are almost always applicable to tabular data only and attempt to guarantee a certain level of anonymity usually as a function of aggregation.

Figure 1. Two pathways for de-identification of protected health information as sanctioned by HIPAA Privacy Rule as depicted in the guidelines prepared by the Office of Civil Rights, Department of Health and Human Services

Automatic De-identification

We can de-identify tabular datasets manually if we know which fields contain personal identifiers. Unfortunately, de-identifying narrative text is significantly more challenging than de-identifying tabular data. Narrative text has neither a schema nor enumerated set of fields to guide the process. Narrative report structures tend to differ randomly in location and labeling among different providers. Moreover, the ambiguous nature of natural languages makes the problem of narrative text de-identification especially difficult.

Automatic text de-identification tools can de-identify clinical text with high accuracy comparable to the performance of human annotators. Furthermore, automatic de-identification is fast and inexpensive. Unlike human annotators, computers do not get tired but instead, consistently produce the same level of quality for every document as long as these documents do not differ from each other in style and context.

Modes of Operations

A software application may be used in different configurations, forms or modes, e.g. batch vs. interactive mode, text vs. graphic mode, beginner vs. expert mode. In the literature, there are plenty of de-identification papers about automatic clinical text de-identification systems, but there is little information on how to use them to get the best de-identification results. In this paper, we discuss different modes of de-identification, each of which may yield results at different levels of quality.

Most IRBs require de-identification as a prerequisite for clinical research using retrospective patient data; therefore, it is important for every clinical scientist to be cognizant of all options and services provided by de-identification systems.
Institutional Responsibilities

De-identification plays a crucial part in protecting patient privacy by enabling institutions to share a large volume of clinical information for clinical research while maintaining patient privacy. However, de-identification alone is not sufficient for protecting patient privacy. This is a difficult task that can only be achieved through a close collaboration of all parties in the healthcare system chain who create, handle, store, and transmit health information. Furthermore, institutions have overarching responsibilities to establish the right policies and monitor their compliance through IRBs. Institutions have to ensure that the data leaving their control has been properly de-identified.

As part of this responsibility, data managers in clinical institutions should make the necessary efforts to provide requisite patient and provider information to their de-identification system for achieving the highest de-identification rate possible. For example, an automatic de-identification system capable of accepting patient and provider identifiers as inputs should be provided to the system, if possible, so that institutions are not left with subpar de-identification results. Similarly, a de-identification system that requires annotated clinical reports for training should be provided with the requisite training dataset. To ensure that the training dataset is large enough, the machine learning system should be continuously fed with new sets of annotated reports until the de-identification performance increases become negligible. Furthermore, this process should be repeated in scheduled cycles as clinical practice, use of terminology, reporting styles and reporting physicians tend to change over time.

Different Modes of De-identifying Reports Using Automatic De-identification Systems

In this article, we consider any automatic de-identification application as a black box and remain indifferent to the methods used inside the box. The focus is on the process of de-identification from the perspective of the user. The user needs to provide a set of input to the system, so we are interested in the variety of information that the system is capable of taking as input and how the user can operate a given de-identification system to achieve the best patient privacy protection while preserving the integrity of de-identified data. We discuss eight modes of de-identification (see Table 1).

| A. Repository-wide batch de-identification |
| B. On-demand cohort-specific de-identification |
| C. On-demand de-identification of query results |
| D. De-identification with patient and provider identifiers |
| E. Scientist involved de-identification |
| F. Patient involved de-identification |
| G. Physician involved de-identification |
| H. Online de-identification by honest brokers |

Repository-wide batch de-identification. This is the simplest among all the alternative processing methods; thus, perhaps the most commonly used among institutions. When institutions obtain a de-identification system, some may immediately create a de-identified version of their entire repository, so that researchers with proper credentials can quickly access what they need in a de-identified format.

On-demand cohort-specific de-identification. An alternative to the repository-wide batch de-identification method is providing on-demand de-identification for a defined cohort of patients at the request of the scientist. Unlike the repository-wide batch de-identification approach, the de-identified data is not ready to be provided to the research group, but given the speed of modern systems, automatic de-identification is almost instantaneous. The time difference between these two approaches can be negligible compared to the selection of the cohort reports.

On-demand de-identification of query results. If the de-identification system is attached to a clinical database querying system, the de-identification can also be obtained on the fly. This approach would probably be much faster than the cohort-specific approach, since there would be no need to wait for the availability of the data manager who, in the previous two modes, de-identifies the data and provides the de-identified data to the scientist. In this mode, the data manager is out of the loop.
De-identification with patient and provider identifiers. Research results indicate that providing patient and provider identifiers likely to be in the report yields significantly better de-identification results. Personal identifiers can be provided to a de-identification system in four different ways: report-specific identifiers, cohort-specific identifiers, repository-wide identifiers, or a combination of the above. For provider identifiers, repository-wide mode, purging all provider identifiers listed in the institution’s file is an attractive approach, because each patient can be seen by many of the providers who may be mentioned in the patient’s reports.

Patient identifiers are the most important identifier that need to be detected and eliminated from reports. Each report in an electronic health record system (EHR) is typically tied to many patient identifiers. The de-identification system can take advantage of that information and can detect those identifiers in the text at the highest sensitivity level. For example, if the last name of the patient is Cushing, the de-identification system would not overlook the word by erroneously presuming that it refers to Cushing’s disease.

In certain record types, specifically in HL7 v.2 records, additional personal identifiers, such as the patient’s address, telephone number, medical record number, and next of kin identifiers are also available as part of the PID and NK1 segments.

In some circumstances, providing patient identifiers for each report may not be feasible but the identifiers of the patients retrieved for a specific research cohort could be provided as a single set of input to the de-identification system.

Identifiers of providers who dictate and sign reports are also found in EHRs. Inputting both repository-wide and report-specific provider information may improve de-identification results.

Scientist involved de-identification. Clinical text de-identification systems are not perfect. Because their primary goal is to remove all possible words and other alphanumeric strings that might identify the patient, they tend to favor sensitivity (for identifiers) over specificity, and may inadvertently remove non-identifying health information in the process. Users of the de-identification systems (i.e., scientists, directly or data managers, indirectly) can compensate for the problem by providing clinical terms that they would like to preserve from excessive de-identification. A capable system may automatically increase its sensitivity level when it receives such clinical metadata.

Patient involved de-identification. Many clinical institutions allow patients to access their health information stored in EHRs or personal health record systems. As today’s consumers become more and more suspicious of how their data have been shared by Internet companies without their knowledge, the transparency in the healthcare sector could alleviate such concerns. Institutions can recruit patients who volunteer to help de-identify their health records and/or verify that their personal identifiers have been properly purged from their data. Although it is not in current practice, we suspect some patients would demand this level of transparency and the option of self-verification from their providers in the near future.

Note that some identifying information can be inferred from context of the narrative or through circumstantial information instead of just personal identifiers. For example, “the examination of his injury that he endured during his US championship match today...” We call such information personally identifying context, which is hard for any automatic de-identification system to detect. The patient’s assistance would be very valuable for de-identifying such information.

Physician involved de-identification. Patients’ names and chart numbers get into narrative reports because physicians use patient identifiers when they dictate. In a few special cases, e.g. pathology reporting, a requirement exists to dictate both the patient identifying information and the specimen number into the report to tie that report securely to the specimen and the patient. For most dictated reports, however, recording the patient’s identifiers in the body of the report is not needed because the patient is usually identified to the transcriber prior to the dictated note. But from their habits in conversation with patients or other care providers, many providers often say “Mr. Jones,” or “Fred Jones” instead of simply “the patient.” Medical schools and professional societies should discourage the recording of patient names, or identifiers in the body of the dictation. De-identification systems can highlight names and identifiers in transcribed dictation pre signature, which may help providers to break this habit.

Online de-identification by honest brokers. With the advances on big data, scientists start accessing larger patient cohorts than what is available in their own institutes. As this trend continues, we can expect some of the big data

† Provider identifiers are not necessarily part of the protected information, at least according to HIPAA Privacy Rule, but other laws, regulations and policies may require their elimination through de-identification.
processes, including de-identification, are going to be centralized. At that point, de-identification of clinical data can be provided as an online service by these centers. Small research institutes with less funding may also find this option attractive as they can rely on external expertise for proper de-identification. These centers can act as honest brokers providing expertise and assistance to scientists and clinical institutions for their de-identified data needs.

Discussions

We have introduced eight distinct modes of de-identification. Each of these modes comes with advantages and disadvantages, which we discuss in this section.

Institutes with smaller budgets for de-identification may find repository-wide batch de-identification attractive because of its simplicity, but they may not repeat the de-identification process on the same repository data. Since automatic clinical text de-identification systems improve continuously, the quality of the de-identified data improves over time; therefore, the repository data de-identified a number of years ago may not be on par with the current standards. Relying solely on this mode has the danger of stale data, which contain too many intact personal identifiers and too many false positives in the “de-identified” data according to state-of-the-art. If an institution would like to use this mode alone, the IRB should impose a policy for daily or weekly de-identification of new incoming data and cyclical re-de-identification of the repository data using the latest version of the automatic de-identification software.

On-demand de-identification practices solve the stale data problem since the institution could use the latest technology available to produce up-to-date de-identification. Furthermore, the de-identification output can be tailored according to the scientist’s needs. For example, if certain demographic information is necessary, it can be preserved in the output, producing a limited data set. If the de-identified data is produced via batch mode, the output would be either a fully de-identified set (hence the scientist’s needs could not be addressed) or a particular type of limited data set. In other words, the batch mode would be a generic one-size-fits-all approach.

On the other hand, producing a liberal limited dataset may be a viable, middle ground solution for those institutions, if their IRBs allow it. Due to the complexity of natural languages, no de-identified clinical report should be considered safe to share openly except for trivial cases; thus, even fully de-identified clinical reports should not be shared without a data use agreement, which is imposed by HIPAA Privacy Rule for all limited data sets. Because scientists, including those who would receive fully de-identified reports, should sign into a data use agreement as if they were receiving limited data sets, the institution may develop a policy to produce limited data sets only. Since limited data sets comprise PHI, this approach would not be in accord with the Privacy Rule for entities covered by HIPAA. Privacy Rule establishes the standard called the “minimum necessary” indicating limiting the content of PHI to the necessary minimum. 45 CFR 164.502(b): “When using or disclosing protected health information or when requesting protected health information from another covered entity or business associate, a covered entity or business associate must make reasonable efforts to limit protected health information to the minimum necessary to accomplish the intended purpose of the use, disclosure, or request.”

Institutes that use an on-demand de-identification mode can employ a separate batch mode as well. Before submitting a research protocol to their IRBs, scientists need to analyze existing datasets to understand whether available datasets are suitable to their research needs. A de-identified copy of the entire repository would be beneficial for scientists at this stage of their research. A policy that would require such a research repository would better protect patient privacy.

On-demand de-identification of query results can be done quite easily due to the fast de-identification performance of modern automatic de-identification systems such as NLM-Scrubber, which de-identifies a typical report in a fraction of a second, much faster than the time required for a person to read the same text. The downside of this mode is that it is more difficult to integrate a standalone application to an EHR. On the other hand, if the de-identification system is integrated to the EHR, not only this particular mode but also the other two modes in which physicians and patients are involved, can be put in practice. When all of these modes are used in parallel, the performance of de-identification can be maximized.

Cohort-specific on-demand de-identification requires more time to access the data than the query results de-identification, but some institutions may prefer this approach, since the data manager could provide oversight to the de-identification process and monitor the level of privacy protection.

Properly providing patient and provider information to the de-identification system is necessary for better de-identification if the de-identification system is capable of accepting them. This mode requires extra steps from the institutions and data managers. Those steps might not be taken unless the institution establishes a policy to require these actions and the IRB monitors the compliance.
De-identification may inadvertently eliminate some informative clinical terms (e.g., newly introduced gene names) that mimic personal identifiers. A modern de-identification system should be capable of accepting new lists of words and concepts and set the bar of their removal higher to preserve the integrity of the content. If a repository-wide batch de-identification is adopted, it would be more difficult to introduce such functions.

If a de-identification system is used with the repository-wide batch mode, it would have to employ a single set of sensitivity and specificity levels to maximize the utility of the system. When the designer of a de-identification system (and in capable systems, the user of the system) adjusts the de-identification sensitivity of the system to eliminate all personal identifiers, the number of false positives could increase in tandem. If an on-demand de-identification mode is adopted and the scientists provide their metadata, the system can perform at a higher sensitivity level to eliminate all personal identifiers.

Online de-identification mode has a promising future. Large non-profit research organizations such as NIH or State Cancer Registries can employ the requisite expertise and human capital and provide these services to other research institutes free of charge. The benefits of this mode are that the de-identification can be improved and stringent policies for patient privacy can be employed. Furthermore, the data from a number of institutions can be hosted at these sites or in the cloud; thus, scientists can access much larger cohorts and conduct research on big data. Since these datasets for cancer have already been collected at the state level, cancer registries can take this responsibility if necessary funding can be provided. At some point in the future, this could be achieved at the federal level as well, but governance of the data at the federal level could be more complicated and may require new laws and regulations as well as a lot of convincing before allowing data to be shared across states and institutions.

Note that a number of these modes can be used in parallel. Consider the following as a possible scenario. An institute may use repository-wide batch de-identification so that the scientists at the institution can study the repository data for preliminary research. Since the preliminary study was done on de-identified data, some clinical terms could be deleted by the de-identification process and the scientist might not have retrieved all patient cases. During the study, the scientist can query the original data containing personal identifiers and receive the fully de-identified results. After studying the data and observing the eliminated terms, the scientist can provide a list of terms to preserves the data and may request certain date and age information be preserved. The data manager can repeat the de-identification by using patient and provider information as well as the list of clinical terms as inputs to the system and adjust the system to preserve date and age information. After the data manager’s review of the results, the scientist would receive the resulting limited data set with all pertinent clinical information preserved. If available, the scientist can repeat this process by accessing a clinical data warehouse in the cloud to enhance the patient cohort using big data. This process can be improved further by involving patients and physicians in the de-identification process.

Conclusions

There are many different ways to perform de-identification. Most of these modes of de-identification operations can be combined in order to reach ideal results. The success of the de-identification process depends not only on the competency of the automatic de-identification systems, but also on the competency, dedication, and discipline of the institution that is responsible for de-identification of protected health information. Users of de-identification systems need to learn how to operate the different modes properly, recognize and obtain all available patient and provider identifiers, gather the terminology needs of the scientist, and tailor the de-identification to achieve the highest quality of research data and patient privacy.

Comparison of algorithm advice for post-acute care referral to usual clinical decision-making: examination of 30-day acute healthcare utilization

Susan K. Keim MS, MSN, CRNP1, Kathryn H. Bowles, PhD, RN, FAAN, FACMI 1, 2
1University of Pennsylvania, Philadelphia, PA 2Visiting Nurse Service of New York, New York, NY

Abstract
Objective: Compare patient characteristics and acute healthcare utilization between patients identified as in need of post-acute care (PAC) by the clinical decision support (CDS) algorithm yet were discharged home without services, to those where the CDS and hospital clinicians agreed on no referral.
Methods: Retrospective analysis of hospital administrative and clinical data for 1,366 patients.
Results: 30-day acute healthcare utilization rates are significantly higher for those patients flagged as in need of PAC referral. There are also significant differences in patient characteristics based on referral risk.
Discussion: Clinicians were blinded to the algorithm enabling the comparison of usual care to decision support. Future work will examine the effect of sharing algorithm advice with clinicians on PAC referral rates and utilization.
Conclusion: The CDS algorithm clearly identified patients with high-risk characteristics and those who will go on to utilize acute care resources. Providing CDS to discharge planners may improve patient outcomes.

Background and Significance
Efforts to reduce 30-day inpatient (IP) hospital readmissions continue to garner attention since the 2013 inception of Medicare reimbursement penalties to hospitals with above-average rates for high-volume conditions e.g., heart failure (HF), pneumonia, and acute myocardial infarction (AMI).1, 2 Although readmission rates have declined from 18.1 per 100 patients in 2011 to 17.3 per 100 in 2013,3 concerns remain that many Medicare readmissions are potentially preventable,4, 6 cost $12 billion annually,4 and could be lowered through better discharge planning (DP) processes.7 Furthermore, approximately one in five patients presents to the emergency department (ED) within 30 days of an IP hospitalization,8 and over half of these patients, especially if Medicare beneficiaries, are readmitted for an IP or short-term observation (OBS) stay.8-12 Efforts to mitigate this acute healthcare utilization in the post-discharge period include improved coordination of post-acute care (PAC) services i.e., home healthcare (HHC) or facility-based care (skilled nursing facilities or long-term care institutions).13, 14

PAC services comprise one of the fastest growing sectors for Medicare spending,15 but referral decisions are frequently based on non-standardized DP practices,16 resulting in the potential for misaligned utilization. Over-utilization of PAC services incur significant costs to Medicare,17 and under-utilization can leave patients at risk for poor outcomes including hospital readmission.19 DP is a multifaceted and complex process requiring the collaboration of a multidisciplinary healthcare team i.e., physicians, nurses, social workers physical therapists, in partnership with patients and their caregivers. Due in part to shortened lengths of hospital stays (LOS), clinicians often do not have the time or information necessary to make optimal decisions regarding PAC referrals.20 Despite efforts to begin this process early within the hospital stay, most discharge decisions are rushed and made close to the time of discharge.21 Shortened planning time can impact the ability to effectively arrange for HHC visits or facility placement. In a recent web-based national survey of hospitals enrolled in the Hospital-to-Home (H2H) quality improvement initiative, only 34.6% reported that they formally estimate the risk of readmission for HF and AMI patients,22 and less than one quarter reported arranging home visits for most or all patients with these high-risk conditions after discharge.23

Studies have shown that early24 and coordinated DP is more effective than usual care at reducing IP readmission risk.25 However, discharge plans should be tailored to patient’s needs,26 and consistently employed by the multidisciplinary team.27-29 Clinical Decision Support (CDS) tools can aid in improving and standardizing DP,30, 31 and in identifying the need for PAC services.32, 33 A navisHealth® proprietary discharge referral decision support software (IDENTIFY), analyzes data from a validated risk algorithm developed by Bowles and colleagues,31, 34 and notifies discharge planners of PAC risk early in a patient’s hospital stay. Although recommendations for specific PAC locations were not included in this algorithm, IDENTIFY implementation has resulted in significantly lower 30-day IP readmissions for high-risk older adults.35, 36

An expanded CDS algorithm, developed by Bowles and colleagues,37 not only identifies patients in need of PAC referral, but also recommends specific PAC sites (HHC or facility). This algorithm was created from expert panel analyses of 1,496 nationally representative case studies38 of hospitalized patients age 55 and older from six hospitals in
the Northeast, Midwest and Mid-Atlantic regions of the United States. The expert panel, comprised of clinicians from multiple disciplines e.g., physicians, nurses, social workers, physical therapists, identified those cases in need of PAC referral, and if applicable, the specific location for PAC services. Regression modelling was performed to develop a 2-part automated 29-item (21 are unique variables) risk algorithm. The first part of the algorithm (16 variables) flags the need for PAC referral and the second part (13 variables) recommends the optimal site of care. Validation with a holdout sample produced areas under the curve of 91.5 and 89.7 respectively for each part of the algorithm indicating very good to excellent models. Now also a proprietary technology, this algorithm computes a risk score based on a variety of patient characteristics that are routinely collected during a hospital admission including measures of activities of daily living (ADLs), LOS, number of comorbidities, fall risk assessment, and pressure ulcer risk. This score is available within 24 hours of admission and can aid healthcare providers and discharge planners in proactively identifying high-risk patients therefore allowing time for effective DP.

The overall purpose of this study is to compare patient characteristics and acute healthcare utilization between patients identified in need of post-acute care (PAC) by the clinical decision support (CDS) algorithm, yet were discharged home without services, with those where the CDS and hospital clinicians agreed on no referral for PAC services. The specific aims and hypotheses (H) of this study are:

Aim 1: In patients discharged home without services, compare the patient characteristics of those flagged versus those not flagged by the algorithm for PAC services.

H 1: Patients discharged home without services will have more limitations in patient characteristics if flagged versus not flagged by the algorithm.

Aim 2: In patients discharged home without services, compare the rate of 30-day acute healthcare utilization in those flagged versus not flagged by the algorithm for PAC services.

H 2: In patients discharged home without services, those flagged by the algorithm will have a significantly higher rate of acute healthcare utilization compared to those not flagged for PAC services.

Methods
Design
A secondary analysis is performed using de-identified data acquired from the control phase of a multi-center study of quasi-experimental pre-post design (NR01007674) aimed at measuring the effectiveness of the algorithm on PAC referrals and patient outcomes. During the control phase, clinical and administrative data were collected retrospectively from two suburban mid-Atlantic, teaching hospitals within one health system, totaling 800 IP beds with 48,000 admissions and 132,000 ED visits annually. Data was collected on patients’ index hospitalizations from May 8, 2015 through September 11, 2015 with an additional 30-day follow-up period to measure post-discharge acute healthcare utilization. During the control phase, clinicians were blinded to the algorithm scores, and approaches for usual clinical decision-making were utilized with respect to discharge planning and disposition.

Hospital administrative and admission, discharge and transfer (ADT) databases are utilized to collect the number of comorbidities, employment status, admission/discharge dates, primary diagnoses (ICD-9-CM codes) as well as the acute healthcare utilization variables: 30-day hospital readmission or 30-day ED/OBS visit. Clinical data extracted from the electronic health record (EHR) supply Morse (fall risk) and Braden (pressure ulcer) scores, changes in ADLs, number of prior hospitalizations within six months, level of self-rated health, depression assessment, and additional socio-demographic data (algorithm components).

Sample
Eligible patients were age 55 and older, admitted for an initial IP stay and discharged alive during the study period. Patients were excluded from the initial control cohort if they were admitted for an OBS stay only or were missing greater than seven algorithm variables determined to be key through sensitivity testing in the parent study. Primary diagnoses not relevant to the sample e.g., perinatal codes, and those potentially related to seasonality impacting the intervention phase of the parent study e.g., fractures, were omitted from the sample. In the overall final control cohort of 3,302 patients, those who received a referral from the hospital and therefore discharged with PAC services, were excluded, yielding a final sample of 1,336 patients, for this secondary analysis.

Statistical Analysis
The study sample, which represents those discharged to home without PAC services, was subdivided into two groups (Figure 1): those whom the algorithm flagged for PAC services (n=895), and those who were not flagged (n=441).
These subsets were compared using descriptive statistics with non-parametric (Chi-square, Fisher-Exact, or Kruskal-Wallis) tests as appropriate. Acute healthcare utilization was examined using Kaplan-Meier survival analysis with log rank tests to measure significance between subsets by algorithm flag. Finally, risk for acute healthcare utilization between subsets was calculated using Mantel-Haenszel weighted risk-ratio (RR) estimates and stratified based on socio-demographic and clinical factors.44, 45

Figure 1. Diagram of Sample Derivation

Results
In the 1,336 sample, patients were on average 71.8 years old (11.15 SD, range 55-103), predominantly white (84%), and slightly more than half were male (51%). Greater than 50% had higher than a high school education, 56% were married/partnered, and approximately 60% were retired. They tended to rate their health as average-to-good (78%) and most had not had a prior admission six months before the index hospitalization (70%). Among a number of ICD-9-CM categories, the most common primary diagnoses were classified as diseases of the circulatory (27%), digestive (19%), and respiratory systems (11%) and the average number of comorbid conditions were 3.0 (1.79 SD, range 3-14). The index hospitalization mean LOS was 3.3 days (2.17 SD range 1-21). Nursing staff identified 54% of patients at moderate risk for falling, and 89% at low risk for pressure ulcer development; less than 20% had any decline in ADLs during their admission. Finally, 67% (895/1336) were flagged by the CDS algorithm for PAC referral but were discharged home without services; of these, the algorithm recommended 36% (322/895) for HHC services and 64% (573/895) for facility-level care.

Differences in Patient Characteristics by Algorithm Flag
Hypothesis one was supported: Patients discharged without hospital PAC referral, have significant differences in various patient characteristics based on whether they were flagged versus not flagged by the algorithm for PAC services. Comparative analysis of eight socio-demographic characteristics (Table 1) revealed significant differences based on algorithm flag for PAC referral. Those 895 patients who were flagged for PAC services, tended to be older, single, unemployed/retired, and resided in an assisted living, or some type of, facility prior to index hospitalization (p<0.001). Those 441 who were not flagged were more often male, married, and well-educated (p<0.001).

Table 2 displays the comparison of clinical characteristics and Table 3 the comparison of ADLs, by algorithm referral flag; those patients who were flagged for PAC services were at a significantly higher risk for falls, and had more comorbidities (p<0.001). They rated their health status lower (p<0.001), and had more hospitalizations in the past six months (p<0.001). A higher level of decline in ADLs was observed in those flagged for referral (p<0.001) and although there was no significant difference seen in feelings of hopelessness (p=0.93), slightly more patients noted they had lost interest in those activities usually found interesting to them prior to hospitalization, a symptom of depression (p=0.03). There were no significant differences in primary diagnosis classifications with the highest percentage of index hospitalizations due to diseases of the circulatory system in both groups.

Acute Healthcare Utilization

Hypothesis two was supported: In patients who were discharged home without services, those flagged by the algorithm had a significantly higher rate of acute healthcare utilization compared to those not flagged for PAC services.

IP Readmission: In the 1,366 sample, 10.3% (141/1336) of patients whom the hospital discharged home without services were readmitted to the hospital within 30-days of discharge. Of these, 77.3% (109/141) were flagged as needing a referral, and ultimately sustained a 12.2% 30-day IP readmission rate; 22.7% (32/141) were not flagged by the algorithm with a significantly lower readmission rate of 7.3% (p=0.006) (Figure 2). Those patients whom the hospital discharged home without services but were flagged by the algorithm for PAC services, had a 67.8% higher risk of having a 30-day IP readmission than those who were not flagged (RR=1.68, 95% CI=1.15-2.45, p=0.006). Within each patient characteristic, there were no statistically significant differences in relative risk for readmission across strata between those flagged and not flagged for PAC services referral.

![Kaplan-Meier IP Readmission Rate by Algorithm Referral](image)
**Discussion**

Our data show differences in socio-demographic and clinical factors between patients who were flagged versus those not flagged by the algorithm for PAC referral. The majority of patients who were flagged for PAC services were recommended for facility-level care, suggesting that they are amongst those most at-risk for poor outcomes, yet they went home without services. These patients had more overall limitations as they were on average six years older, had poorer self-rated health, and greater chronic illness burden as evidenced by more comorbidities, prior hospitalizations, higher fall risk and greater decline in ADLs during the index hospitalization. Furthermore, they were more often single or widowed which may leave them more vulnerable than those who live with others who can surveil changes in health status. More females were flagged by the algorithm for PAC services but did not receive them; this may be related to discharging clinicians perceiving women as more capable of providing their own caretaking, although older females are more likely to use HHC services than males, due almost entirely to greater health needs. Studies have demonstrated that there is great variability in clinician risk tolerance and decision-making for PAC referrals especially given the lack of standardized DP processes.  

Despite algorithm flag, the hospital did not refer patients who were more frequently unemployed or retired which may be due to insurance type/coverage. Insurance status is an important predictor of hospital disposition and PAC services, with uninsured patients less likely to have full access to services. It is also conceivable that patients refused services; Topaz and colleagues found that 28% of patients refuse PAC services but have twice-higher odds of 30- and 60-day readmissions, compared with those that accept PAC referral.  

When the hospital and algorithm agreed on no need for PAC services, patients were more often well-educated and therefore may be perceived as better able to understand discharge instructions. Moreover, males were not flagged by the algorithm as frequently as their female counterparts; this may be confounded due to 64% of males in the sample being married as compared to females. In a chart review of patients who refused PAC services, the most frequent reason cited by males was that their spouse would serve as caregiver.
Acute healthcare utilization rates were significantly higher for those patients who were flagged by the algorithm but discharged home without services. Those in need of PAC services per the algorithm, had a significantly greater risk of either IP readmissions or ED/OBS visits within 30-days of hospital discharge. Since flagged patients who went home without services were readmitted at a rate of approximately five percentage points higher than those not flagged, there is considerable potential for cost-savings. The average cost of a hospital readmission is $13,800 for Medicare beneficiaries aged 65 and older, which is 5 percent higher than for an index admission in the same population. Potentially preventable readmissions may be avoided by aligning PAC services for those most at risk.

There were no differences, in risk of IP readmission or ED/OBS visit by strata within characteristics, demonstrating the complexity of risk prediction for post-discharge acute healthcare utilization. An intricate interaction of patient factors contribute to these risk scores emphasizing the importance of CDS tools to aid clinicians making DP decisions.

Study limitations include data acquisition from one health system in a suburban region yielding a sample that was homogenous with respect to race/ethnicity. As with any observational study, no conclusions regarding causality are possible; also there is always concern about unobserved bias (no instrumental variable was available to mitigate this bias). There are also limitations in examining same-hospital readmissions which may potentially underestimate rates although this is less likely given that neither hospital within this health system are major referral centers. There are frequently challenges in using clinical data extracted from the EHR including concerns regarding the accuracy of data output, much effort was spent during the parent study to reduce this risk. Lastly, we were unable to measure the extent to which patients refused PAC services rather than hospitals not making referrals.

Conclusion
These results indicate that the algorithm is identifying patients who are likely to have poor discharge outcomes and that there is the potential to improve outcomes by referring them for appropriate PAC services. As observed in this analysis, the mean index admission LOS of three days affords healthcare team members a narrow window in which to assess PAC referral and for discharge planners to actualize these plans. Since the algorithm provides decision support soon after admission, there is an opportunity to optimize these DP processes. Future intervention studies are warranted to examine the effect of sharing algorithm advice with clinicians on PAC referral rates, and acute healthcare utilization in the early post-discharge period.

Exploiting Unlabeled Texts with Clustering-based Instance Selection for Medical Relation Classification

Youngjun Kim, MS¹, Ellen Riloff, PhD¹, Stéphane M. Meystre, MD, PhD²
¹School of Computing, University of Utah, Salt Lake City, UT, USA;
²Medical University of South Carolina, Charleston, SC

Abstract

Classifying relations between pairs of medical concepts in clinical texts is a crucial task to acquire empirical evidence relevant to patient care. Due to limited labeled data and extremely unbalanced class distributions, medical relation classification systems struggle to achieve good performance on less common relation types, which capture valuable information that is important to identify. Our research aims to improve relation classification using weakly supervised learning. We present two clustering-based instance selection methods that acquire a diverse and balanced set of additional training instances from unlabeled data. The first method selects one representative instance from each cluster containing only unlabeled data. The second method selects a counterpart for each training instance using clusters containing both labeled and unlabeled data. These new instance selection methods for weakly supervised learning achieve substantial recall gains for the minority relation classes compared to supervised learning, while yielding comparable performance on the majority relation classes.

Introduction

Electronic health record (EHR) systems are becoming more prevalent in the U.S.¹ This growth has resulted in very large quantities of clinical patient data becoming available in electronic format, which holds tremendous potential for benefitting clinical research, quality improvement, and surveillance. A substantial proportion of patient-specific information in the EHR is only found in narrative, unstructured clinical notes.² Natural Language Processing (NLP) enables fast, scalable, and accurate extraction of structured and coded information from these clinical notes.³ As part of this information extraction task, identifying semantic relations between concepts is essential to provide accurate and complete information about the concepts and their meaning. For example, extracting relations between mentions of a medication and mentions of allergy symptoms enables differentiation between situations when a medication causes the symptoms and situations when a medication is prescribed to alleviate symptoms.

Given a pair of medical concepts found in a sentence, a relation classification system must determine the type of relation that exists between the two concepts. Our research focuses on the relation classification task introduced in 2010 for the i2b2 Challenge Shared Tasks⁴. This task involves recognizing eight types of relations between pairs of three types of medical concepts: problems, treatments, and tests.

A key challenge of this task is the extremely skewed class distribution across relation types. For example, five types of relations are defined between problems and treatments plus a no relation category (None), but two of these categories (None and TrAP (treatment administered for problem)) account for 86% of the instances in the i2b2 Challenge data. Four relation types (TrCP (treatment causes problem), TrIP (treatment improves problem), TrWP (treatment worsens problem), and TrNAP (treatment not administered because of problem)) are distributed across the remaining 14% of the data. Each of these “minority” relations appears in just 2-6% of the data. Identifying these minority relations is extremely important from a practical perspective because they hold valuable information. For example, the dominant relations between problems and treatments are TrAP (administration of treatment) and None (no relation at all). In contrast, the minority relations (TrCP, TrIP, TrWP, TrNAP) represent situations where a treatment causes, improves, worsens, or is contraindicated for a problem, so they are arguably more important types of situations to recognize.

The most successful methods used for relation classification include various supervised machine learning algorithms.⁴ Extremely skewed class distributions pose substantial challenges for supervised machine learning (ML) because only a small number of labeled examples are available for training. As a result, ML classifiers can achieve high accuracy for the dominant classes but often perform poorly with the minority classes. Manually annotating more data is not a viable solution because of the high cost of manual annotation by medical experts. Also, because the minority classes are relatively rare, each batch of new annotations would provide only a relatively small number of new examples. There is substantial cost for low reward.
Our research aims to improve relation classification in clinical texts with an emphasis on minority classes by exploiting large amounts of unlabeled clinical texts, which are readily available in abundant quantity. We present two new methods to selectively choose unlabeled instances for self-training in an iterative weakly supervised learning framework. Both methods apply a clustering algorithm to group instances into clusters based on similarity measures. The first method, called Unlabeled Data Prototypes (UDP) Selection, uses clusters containing only unlabeled instances and identifies one “prototype” instance from each cluster to use as additional training data. Intuitively, this method aims to identify the different types of instances that occur in the unlabeled data and selects a representative subset of them. The second method, called Labeled Data Counterparts (LDC) Selection, uses clusters containing both labeled and unlabeled data. For each labeled instance, this method identifies its closest counterpart in the cluster by selecting the unlabeled instance that is most similar to it. Intuitively, this method is designed to acquire a new set of training instances that mimic both the class distribution and semantic content (based on feature similarity) of the original training instances. Our experimental results show that these two instance selection methods produce classifiers that can identify minority relation classes more often and more accurately than traditional supervised learning or self-training.

**Background**

The relation classification task was defined as part of the Fourth i2b2/VA Shared Task Challenge in 2010. Our research involves relation classification for pairs of medical concepts, assuming that the terms corresponding to the two concepts have already been identified. The task is to identify how medical problems relate to treatments, tests, and other medical problems in clinical texts. Many sentences contain multiple pairs of concepts, so the challenge includes identifying which pairs are related, as well as identifying the specific type of relation. This task has been typically cast as a supervised learning problem, where a classifier is trained with manually annotated data. Rink et al. used supervised learning to produce the highest micro-averaged $F_1$ score, 73.7%, for this relation extraction task. Their system utilized external resources including Wikipedia, WordNet, and the General Inquirer lexicon as part of their feature set. To improve recall, they set much lower weights to the pairs of non-related concepts (i.e., negative examples) when training an SVM (Support Vector Machine) classifier.

Previous work has presented micro-averaged $F_1$ scores, which assess performance over all of the positive instances regardless of which class they belong. However, micro-averaging obscures performance differences across the classes. For example, it is often possible for a system to achieve a high micro-averaged $F_1$ score by performing well on the majority class but recognizing few, if any, instances of the minority classes. Our research aims to shed light on the performance differences across relation classes, with the goal of comparing the ability of different methods to recognize the minority classes. So we will present macro-averaged $F_1$ scores in the rest of this manuscript.

The Rink et al. system reached macro-averaged scores of 51.7% recall, 55.8% precision, and 53.7% $F_1$ score (not officially reported in Rink et al. but calculated by taking the average of the reported recall and precision of the different sub-classes). de Bruijn et al. explored effective features also applicable to other clinical NLP tasks. In addition to supervised classification, they applied self-training on the provided unlabeled data. Their approach yielded a 73.1% micro-averaged $F_1$ score. The macro-averaged scores for their submission reached 43.7% recall, 66.8% precision, and 51.2% $F_1$ score. These results were calculated by the authors of this manuscript based on the output of de Bruijn et al.’s system. Their subsequent research using composite-kernel learning improved the accuracy of relation classification with a higher micro-averaged $F_1$ score of 74.2%. As an effort to overcome the class imbalance problem, they used down-sampling of negative examples before training the models. D’Souza and Ng presented an ensemble approach exploiting human-supplied knowledge to set up individual classifiers. Their weighted-voting system outperformed a single classifier using the full set of features exploited by different members. Their best-scoring ensemble system produced 69.6% micro-averaged $F_1$ score. Note that their result is not directly comparable with the works described above because of different training data sizes.

In the biomedical and clinical domains, annotating data is especially expensive because of the need for domain experts. Consequently, most systems are trained with relatively small amounts of labeled text, even though much larger amounts of unlabeled text are readily available. Weakly supervised learning, also called semi-supervised learning, has been shown to benefit from training on both labeled and unlabeled data for other NLP tasks, including document classification, named entity recognition, and noun phrase chunking. As a general framework, starting with a small set of initial labeled data, the learner outputs entities from unlabeled data with assigned entity types. Then, the detected entities are collected as new training instances for subsequent iterations. Iterative bootstrapping methods that use seeding heuristics to produce an initial set of training instances have also been a popular choice. Theilen and Riloff showed that semantic lexicons could be learned with extraction patterns from unlabeled texts by...
bootstrapping algorithms. Rosenberg et al.\textsuperscript{14} used self-training to build object detection models and they pointed out that the choice of the initial seeds has a large effect on performance.

There has also been previous work on the relation classification task exploiting unlabeled data. Zhang\textsuperscript{15} proposed a bootstrapping algorithm using random feature projection. Multiple classifiers were trained with randomly selected features from labeled data and they voted to assign labels to the unlabeled data. Mintz et al.\textsuperscript{16} used Freebase\textsuperscript{17}, a large knowledge database, to train a learner with “distant” supervision. Sun et al.\textsuperscript{18} presented a weakly supervised learning method with large-scale word clustering. They augmented the features derived from the word clusters to compensate for the absence of lexical features in labeled data. Related to medical relations, Wang and Fan\textsuperscript{19} collected training data using a clustering algorithm. To minimize the manual annotations, the most representative instances with the highest average similarity to other members of each cluster were chosen for annotation.

**Materials and Methods**

*Labeled Data Description*

We used the i2b2/VA 2010 Shared Task corpus for our research, which consists of a training set of 349 annotated clinical notes and a test set of 477 annotated clinical notes. This test set contains 45,009 annotated medical concepts with 9,069 relations that occur in the same sentence. Relations were defined as follows\textsuperscript{20}:

Medical problem—treatment (Pr-Tr) relations:
- Treatment *improves* medical problem (TrIP).
- Treatment *worsens* medical problem (TrWP).
- Treatment *causes* medical problem (TrCP).
- Treatment is *administered* for medical problem (TrAP).
- Treatment is *not administered* because of medical problem (TrNAP).
- Relation that does not fit into one of the above defined relationships (NoneTrP).

Medical problem—test (Pr-Te) relations:
- Test *reveals* medical problem (TeRP).
- Test *conducted to investigate* medical problem (TeCP).
- Relation that does not fit into one of the above defined relationships (NoneTeP).

Medical problem—medical problem (Pr-Pr) relations:
- Medical problem *indicates* medical problem (PIP).
- Relation that does not fit into PIP relationship (NonePP).

The test set contains 6,949 Pr-Tr pairs that occur in the same sentence, of which 3,463 are positive examples (participate in a relation) and 3,486 are negative examples (NoneTrP). Pr-Te relations include 3,620 positive and 2,452 negative examples (NoneTeP). Pr-Pr relations include 1,986 positive and 11,190 negative examples (NonePP). As seen in Figure 1, the class distributions across Pr-Tr and Pr-Te relation types are extremely skewed.

![Figure 1. Distribution of treatment (Pr-Tr) and test (Pr-Te) relation types in the test set](Image)
Among Pr-Tr relations, four “minority” classes, TrCP, TrIP, TrWP, TrNAP, are distributed across 14% of the data. Each of these relations appears in just ~2-6% of the data. Among the Pr-Te relations, TeCP is the minority class, accounting for < 10% of the instances. Our goal is to improve relation classification with an emphasis on these minority classes by exploiting large amounts of unlabeled clinical texts. Since there is only one type of Pr-Pr relation (PIP), we focused exclusively on the Pr-Tr and Pr-Te relations in our efforts.

Unlabeled Data Preparation for Weakly Supervised Learning

For this research, we also used texts from the MIMIC II Clinical Database, which contains various types of clinical notes: discharge summaries, nursing progress notes, cardiac catheterization notes, ECG reports, radiology reports, and echocardiography reports. From this data set, we used 26,485 discharge summaries after filtering out notes with insufficient text content (<500 Bytes).

For weakly supervised learning preparation, we had to identify the medical concepts in our unlabeled data and classify the assertion of each medical problem concept. Assertion classification aims to determine the assertions of the problem concepts by assigning one of six categories: present, absent, hypothetical, possible, conditional, or not associated with the patient. For concept extraction, we used our previous system consisting of a stacked learning ensemble. We slightly modified the feature set of the individual classifiers by adding skip-grams and word embedding features. For assertion classification of medical problems, we also added new word embedding features to our assertion classifier and retrained the SVM model. As computed by the i2b2 Challenge evaluation script (class exact match), our stacked ensemble achieved 84.4% recall, 89.1% precision, and 86.7% F1 score for concept extraction on the i2b2 test set. The assertion classifier reached 94.5% micro-averaged F1 score. Using the predicted concepts assigned to the unlabeled data, we created a large set of relation pairs to generate feature vectors for weakly supervised learning and clustering.

We used CLUTO, a data clustering software that has been widely used in various tasks, to create clusters containing both labeled (i2b2 training) and unlabeled data: 517,689 pairs of Pr-Tr relations and 455,272 pairs of Pr-Te relations. The same feature vectors generated for SVM classification were re-used with the clustering algorithm. To determine the number of clusters, we use the root-mean-square standard deviation (RMSSD). RMSSD is a measure of homogeneity within clusters and large RMSSD values indicate that clusters are not homogeneous. We ran a series of clustering processes with different numbers of clusters, K, and calculated the RMSSD for each K. We tried 20 different cluster sizes aimed at having the average number of members per cluster ranging from 40 to 800 (i.e. K = the number of instances × n, n = 1/800, 2/800,…, 19/800, 20/800). When we set n to 1/800 and 20/800 (= 1/40), we expected that on average 800 and 40 members would exist in each cluster, respectively. For each of the Pr-Tr and Pr-Te, we then detected the shift point (also known as the “Knee” point) of its RMSSD curve based on the Satopää et al. method. The cluster sizes of 4,529 and 3,414 were identified as the Knee points for the Pr-Tr and Pr-Te relation clusters respectively. In the following paragraphs, we will describe our supervised classification models and then present the instance selection methods based on clustering unlabeled data.

Supervised Relation Classification

We created three supervised learning classifiers (one for each category of concept pairs: Pr-Tr, Pr-Te, and Pr-Pr) using a rich set of features. We applied the Stanford CoreNLP tool for tokenization, lemmatization, part-of-speech (POS) tagging, and phrase chunking. We trained Support Vector Machine (SVM) classifiers with a linear kernel using the LIBLINEAR (Library for Large Linear Classification) software package. The multi-class SVM classifiers use five types of features associated with a pair of concepts <C1, C2>:

- **Assertion**: For each medical problem concept, we create a feature for the assigned assertion type. Assertion categories are considered in a pre-defined order of precedence (e.g., Possible takes precedence over Absent.)

- **Context**: To compensate for the absence of assertions for treatment and test concepts, we incorporated the ConText algorithm at the sentence level to detect three types of contextual properties for each concept: negation, hypothetical, and historical. We also created a second set of ConText algorithm properties restricted to the six-word context window around C1 and C2 (three words on the left of C1 and three words on the right of C2).

- **Distance**: We created several features to represent the distance between concepts C1 and C2 by counting the number of words, concepts, and phrases (e.g., noun phrases and adjective phrases) between them. The number of concepts appearing before or after the pair was also measured. These features were designed to
help the classifiers distinguish between concept pairs that probably have a relation and distant pairs that probably have no relation between them.

- **Lexical:** Lexical features have been very effective for many NLP tasks. We create lexical features for the words contained in $C_1$ and $C_2$, the head words of $C_1$ and $C_2$, two preceding and two following words of $C_1$ and $C_2$, and the words between the two concepts. Also, we defined features for verbs that precede, follow, or occur between the concepts.

- **Syntactic:** POS tags of two words on the right of $C_1$ and POS tags of two words on the left of $C_2$.

- **Word Embedding:** We used the Word2Vec software to perform $K$-means clustering on the word embeddings. We created 1,000 clusters of semantically related words within the unlabeled data (i.e., MIMIC II Clinical Database) with default parameters. Then, we used the cluster identifier of each word between the two concepts as a feature. We also used the cosine similarity of the word embedding vectors for the heads of $C_1$ and $C_2$.

We randomly selected 200 documents from the training set for development purposes. We tuned LIBLINEAR’s parameters to maximize the micro-averaged F1 score with the held-out development data. After experimenting with different values on the development data, we set the cost parameter $c$ to 0.06 for Pr-Tr, and 0.02 for Pr-Te and Pr-Pr. Also, the weights of negative examples were set to 0.2 for Pr-Tr and Pr-Te and 0.3 for Pr-Pr. The lower the weight for instances with no relation, the higher recall was obtained on held-out data.

Although the classifiers showed good performance under the micro-averaged scoring metrics, performance on the minority classes was weak. As shown earlier, the class distributions are extremely skewed and the minority classes are relatively rare. To reduce the performance gap between the dominant classes and the minority classes, we also experimented with retraining the model by assigning higher weights to the minority classes to increase the importance of minority classes being classified correctly. It did not yield an increase in macro-averaged F1 score and more detailed results will be reported in the results section. To improve performance across the different relation classes, we extend our methods to weakly supervised learning described in the following paragraphs.

**Exploiting Unlabeled Data for Relation Classification**

To take advantage of the large amounts of unlabeled clinical notes that are available, we explored an iterative weakly supervised learning framework. We developed two novel methods for instance selection that are specifically aimed at improving performance on minority classes. Our general framework involves the following steps: (1) a classifier is trained with supervised learning using the labeled training data, (2) the classifier is applied to the unlabeled data so that each unlabeled instance receives a predicted label, (3) a subset of the unlabeled instances is selected and then added to the set of labeled data (using the classifier’s predictions as the labels), and (4) the classifier is retrained using the (larger) set of labeled data. This process repeats until a stopping criterion is met (e.g., for a fixed number of iterations or until no new instances can be labeled).

This paradigm is generally known as self-training, where the most common method for instance selection (step 3) sorts the instances based on the confidence scores produced by the classifier (i.e., confidence in the predicted labels) and then selects the most confidently labeled instances. This traditional self-training approach, however, tends to select instances of the dominant classes much more often than the minority classes because the classifier is more confident in its predictions for the dominant classes.

This issue motivated us to explore new methods for instance selection that try to create a diverse and representative set of new instances from the unlabeled data. Consequently, we developed two new methods for instance selection that first cluster the unlabeled data to identify groups of similar instances. Both methods generate clusters and assign labels to the instances in the same way. First, the labeled and unlabeled instances are combined into a single dataset and the clustering algorithm (described previously) is applied. Once the classifier predicts the label of each unlabeled instance, we consider the instances with a high confidence score as candidates for selection. In each iteration, we sort the instances based on the confidence scores produced by the classifier and an instance can be selected when it is ranked in the top 25% per class.

The first instance selection method, called Unlabeled Data Prototypes (UDP) Selection, selects instances from clusters containing only unlabeled data. We compute the purity of each cluster and identify clusters where the highly confident cluster members have the same positive relation type (i.e., cluster purity $= 1$). We discard clusters with purity $< 1$ because the instances are similar but the classifier’s predictions are inconsistent, so the predictions are
suspect. The most representative instance from each cluster is then selected as additional training data, based on average cosine similarity with other cluster members. We assumed that instances selected from these clusters are different from the training instances and they are also dissimilar to each other. Therefore, they could represent some new type of information found in the unlabeled data. This method is illustrated in Figure 2(a). Green-colored instances represent unlabeled data.

Assuming that unlabeled data will be similar to labeled data when they co-exist in the same cluster, our second method, called Labeled Data Counterparts (LDC) Selection, selects instances from the clusters containing both labeled and unlabeled instances. For each instance labeled with a positive relation type, the unlabeled instance most similar to it in the same cluster is selected. Our intuition is that this approach will acquire new training instances that share features with the original labeled data and maintain the same class distribution. This method is illustrated in Figure 2(b). Red-colored instances represent labeled data and green-colored instances represent unlabeled data. In the next sections, we compare the performance of self-training with confidence-based instance selection against our new UDP and LDC instance selection methods.

Results

We have conducted an extensive set of experiments to evaluate the performance of supervised classifiers and weakly supervised learning with different instance selection methods. We evaluated performance with relation data from the i2b2 Challenge test set. We used the official i2b2 Challenge evaluation script to calculate micro-averaged measures. For macro-averaged measures, we created a new script to obtain average values for each relation type. The macro-averaged $F_1$ score is the harmonic mean of the macro-averaged recall and precision.

Supervised Learning Results

Table 1 shows the results produced with the supervised classifiers, which were trained to optimize for micro-averaged measures. This baseline supervised learning system was trained with the i2b2 training data and achieved micro-averaged scores of 74.9% recall, 73.7% precision, and 74.3% $F_1$ score.

Although our supervised classifiers achieve overall performance comparable to state-of-the-art relation classification systems, performance on the minority classes lags far behind the dominant classes. The F₁ score of \( TrWP \) was only 7.6% with a recall of 4.2%. Most of the \( TrWP \) instances were misclassified because of the very low prevalence of their cases. For example, a \( TrWP \) case from the test set, “She has a known diagnosis of myelodysplasia that has become recalcitrant to Procrit”, the medical problem ‘myelodysplasia’, the treatment ‘Procrit’, and possibly a keyword ‘recalcitrant’ never appeared in the training data. Based on macro-averaging, this system reached 50.2% recall, 63.6% precision, and 56.1% F₁ score.

We also experimented with decreasing the weights of negative examples to help increase recall on minority classes. This did not yield an increase in macro-averaged F₁ score because of a substantial drop in precision. Adjusting the importance of different relation types by assigning different weights also did not affect performance very much.

Comparing Supervised Learning and Weakly Supervised Learning Results

We evaluated the performance of self-training with traditional confidence-based instance selection (called Self-training below), and instance selection with our new UDP and LDC methods. We ran all of the weakly supervised learning methods for 20 iterations.

For self-training, we only selected positive examples (pairs of concepts with relations) from the unlabeled data to augment the labeled data. For each iteration, we added \( K \) newly labeled examples, where \( K \) is the number of positive examples in the original training data. Our intention was to be conservative in adding new examples and maintain the importance of labeled data. To keep the class distribution of the labeled data, we imposed that the number of newly labeled examples for each positive class should not exceed the number of examples in the original training data.

Table 2 shows results for each class and macro-averaged F₁ scores for the \( Pr-Tr \) and \( Pr-Te \) relations. For each relation type, the best results appear in boldface. We used paired t-tests to measure statistical significance. Results that are significantly different from the supervised learning results at the 95% significance level are preceded by an asterisk (*). Self-training with confidence-based instance selection produced the best F₁ score on \( TrCP \) and \( TrNAP \) classes. For \( TrWP \) and \( TeCP \), self-training’s performance was significantly different than supervised learning.

</table>

Both the UDP and LDC instance selection methods produced higher macro-averaged F₁ scores than Self-training. The UDP method (third column of Table 2) produced the best F₁ score of 49.3% on the TrIP class. The F₁ scores for TrIP and TeCP were significantly higher than for supervised learning. The LDC method (last column of Table 2) produced the highest F₁ scores on most of the relation classes. It obtained the best macro-averaged F₁ scores for Treatment and Test. For TrIP, TrWP, TeRP, and TeCP, the performance of LDC method was significantly better than supervised learning.

Finally, we tried to combine the UDP and LDC methods. New instances were selected separately by the UDP and LDC methods and then the combined set of instances was added to the labeled data. However, this system produced an F₁ score of 58.3%, so did not outperform the LDC method on its own.
In another set of experiments, we performed ablation testing of the supervised learning system to evaluate the impact of each feature set based on micro-averaged and macro-averaged scores, separately. If some features have more impact for macro-averaged scores than micro-averaged scores, then our hypothesis is that they are especially important features for minority classes. The row header in Table 3 specifies the feature set that has been ablated. The columns named “Impact” in Table 3 present the F1 score difference between the ablated classifier and the complete system. Every feature set contributed to the performance of the supervised classifiers except that syntactic features did not increase macro-averaged F1 score. The macro-averaged F1 score dropped the most when the lexical features were removed. This suggests that exploiting unlabeled data could be especially beneficial for the minority classes by bringing in new lexical features. The F1 scores of TrIP, TrNAP, and TeCP decreased from 42.4%, 33.3%, and 55.3% to 29.4%, 21.9%, and 42.4% respectively without the lexical features.

**Analysis**

We carried out an empirical analysis of self-training with confidence-based instance selection to better understand its limitations. After clustering the unlabeled data, we counted the number of instances selected from each cluster during the first iteration. We found that most instances were selected from a small subset of the clusters: about 10% of the clusters provided over 78% of the newly selected unlabeled instances. This shows that selecting instances based only on confidence scores tends to yield a relatively homogenous set of new instances that is low in diversity.

Table 4 displays the Recall, Precision, and F1 results of LDC instance selection along with the total counts of true positives (TP) and the number and percentage of true positive gains (compared to supervised learning) in the rightmost column. The numbers in parentheses in the Recall, Precision, and F1 columns indicate the difference between the supervised classifier and the LDC method. Results significantly different from supervised learning at the 95% significance level are preceded by an asterisk (*).

</table>
Table 4 shows that most of the minority classes benefitted substantially from the LDC method. The largest percentage gain came for TRWP where LDC correctly identified 17 instances but the supervised learner only produced six true positives, resulting in a gain of 11 (183.3%). The majority classes also achieved slightly higher F1 scores. The LDC method appears to be an effective way to improve recall on minority relation classes while maintaining good performance on the majority classes.

Conclusion

We showed that clustering-based instance selection from unlabeled text data could improve performance on minority classes for relation type classification between medical concepts. Experimental results show that our clustering-based methods outperformed supervised classification and traditional self-training from unlabeled texts. We believe that this approach offers a more robust solution for classification problems when the data has a highly skewed class distribution, acquiring manual annotations is expensive, but large quantities of unannotated text data are available.

Acknowledgments

The de-identified clinical records used in this research were provided by the i2b2 National Center for Biomedical Computing funded by U54LM008748 and were originally prepared for the NLP Shared Tasks organized by Dr. Özlem Uzuner and colleagues.

References

De-identification of psychiatric notes is a special case of named entity recognition. Supervised machine-learning (ML) algorithms have achieved promising results for this task. However, ML-based de-identification systems often require annotating a large number of clinical notes of interest, which is costly. Domain adaptation (DA) is a technology that enables learning from annotated datasets from different sources, thereby reducing annotation cost required for ML training in the target domain. In this study, we investigate the use of DA methods for de-identification of psychiatric notes. Three state-of-the-art DA methods: instance pruning, instance weighting, and feature augmentation are applied to three source corpora of annotated hospital discharge summaries, outpatient notes, and a mixture of different note types written for diabetic patients. Our results show that DA can increase de-identification performance over the baselines, indicating that it can effectively reduce annotation cost for the target psychiatric notes. Feature augmentation is shown to increase performance the most among the three DA methods. Performance variation among the different types of clinical notes is also observed, showing that a mixture of different types of notes brings the biggest increase in performance.

INTRODUCTION

Clinical narratives contain detailed information of patients and are a valuable data source for clinical research. However, they often contain protected health information (PHI) such as names and addresses, that have the potential risk of revealing the patient’s identity. Therefore, de-identification (removing PHI) of clinical documents is often required. As manual review to remove PHI is time-consuming and costly, significant effort has gone into developing automatic de-identification methods.

Early de-identification systems were often rule-based, using hand-coded rules and specialized dictionaries to identify PHI mentions in clinical notes. More recent systems have adopted supervised machine learning (ML) algorithms, treating de-identification as a token classification or a sequence labeling problem. Various ML algorithms have been studied, including conditional random fields, support vector machines, decision trees, hidden Markov models, and recurrent neural networks. Often, the ML-based systems are augmented with rule-based parts, forming hybrid approaches. Such ML-based de-identification systems have shown high performance, similar to annotation quality done by humans.

Community challenges on de-identification have also been held. In the 2006 i2b2 challenge Task 1, a set of discharge summaries were provided for training and testing de-identification systems. The discharge summaries were annotated with eight PHI categories, which comprised a subset of the eighteen categories listed by HIPAA (the Health Insurance Portability and Accountability Act). The Track 1 of the 2014 i2b2/UTHealth shared task also addressed a de-identification task where PHIs were to be removed in clinical notes of diabetes patients. Unlike the challenge in 2006, a stricter set of PHI categories was used, defining seven main PHI categories and 30 sub-categories. The most recent community challenge on de-identification is the 2016 CEGS N-GRID Track 1, where a set of psychiatric notes were provided for system development. In these challenges, ML-based systems have shown the best performances. We participated in the 2016 challenge, and developed an ML-based hybrid system that achieved second best performance.

However, ML-based systems depend heavily on large amounts of training data that is highly similar to the test data. This is problematic for clinical text, which consists of diverse types of clinical documents with different writing styles across institutions. For instance, a de-identification system trained on discharge summaries may show much lower performance on psychiatric notes, or a system trained on discharge summaries from one hospital may show much lower performance on discharge summaries from a different hospital. To achieve optimal performance, it is
ideal to annotate individual training sets for each type of clinical note. However, manual annotation of clinical text is expensive and complicated\cite{riedel_metaseq_2015}, thus making such extensive annotation approaches unrealistic and prohibitive for wide adoption of ML-based de-identification systems. Therefore, methods that can leverage existing annotated corpora to quickly build a de-identification system for any target domain of interest are highly desirable.

Here we propose to use domain adaptation (DA) technologies to address this problem. Domain adaptation maximizes the use of existing data (source) for the data of interest (target) by learning useful aspects of source data and largely ignoring the source aspects that cannot contribute to the model. Through domain adaptation, ML-based de-identification systems can efficiently leverage existing de-identification corpora from other sources to quickly build high-performance models using less annotated samples from the target domain, thus reducing the annotation cost.

Domain adaptation has been applied for various natural language processing tasks in the biomedical domain. Dahlmeier and Ng\cite{dahlmeier_evaluating_2016} evaluated three domain adaptation methods for semantic role labeling (SRL) task in biomedical literature. A general domain SRL corpus was used as the source, and a biomedical domain SRL corpus was used as the target. Their result shows that domain adaptation can leverage existing general domain SRL resource and greatly improve the performance of SRL in the biomedical domain. Zhang et al.\cite{zhang_domainless_2018} also conducted a similar set of experiments for SRL of clinical notes. An SRL corpus of biomedical literature as well as general domain corpora were used as sources. Their result also shows that domain adaptation can boost the SRL performance through utilization of existing out-of-domain data. Ramesh et al.\cite{ramesh_domain_2018} applied domain adaptation for automatic discourse connective detection in biomedical text. Here, a general domain corpus was used as the source. They also showed that combination of different domain adaptation methods can further improve the performance.

In this study, we propose to investigate how to leverage three existing corpora (source domains) to improve de-identification in psychiatric notes (the target domain). We implement three domain adaptation algorithms: instance pruning, instance weighting, and feature augmentation for this task. The de-identification system that we developed for 2016 challenge is utilized for this study\cite{riedel_metaseq_2015}. Our study shows that domain adaptation can boost the de-identification performance when it is compared with baselines that use only the psychiatric notes or simply combine annotated data from target and source, indicating that it can effectively reduce annotation cost. Moreover, we also find that feature augmentation performed better than the other two DA methods and existing data from different source domains contribute differently to de-identification of psychiatric notes. To the best of our knowledge, this is the first detailed study on domain adaptation for automatic de-identification of clinical text.

METHODS

Datasets

As target data, a corpus of psychiatric notes provided by the 2016 CEGS N-GRID shared task Track 1\cite{riedel_metaseq_2015} is used (Psychiatric notes). The corpus is divided into a training set, a development set, and a validation set, for training,
parameter optimization, and measurement of final performance, respectively. Three different source corpora are used: 1) discharge summaries from the 2006 i2b2 de-identification challenge Task 1\textsuperscript{17} (Discharge summaries), 2) outpatient notes from the University of Texas Health Science Center at Houston (UTHealth) with manually annotated PHIs (Outpatient notes), 3) diabetes patients’ notes from the 2014 i2b2/UTHealth shared task on de-identification (Track 1)\textsuperscript{15}, consisting of a mixture of different types of clinical notes such as admission notes, emergency visit notes, and discharge summaries (Mixture notes). These three source corpora have different samples sizes (Table 1), which may affect the performance. To compare them fairly, we decided to use equal sample size for each source corpus. As outpatient notes from UTHealth is the smallest corpus, we reduced the sizes of the other two source corpora to contain similar numbers of tokens as that of outpatient corpus, by randomly sampling notes from the original corpora. Table 1 shows the statistic of the four corpora used in this study. As there are slight differences among annotation guidelines for these four corpora, we define a common set of PHIs for all four datasets that consists of eight PHI categories, or Date, Doctor, Phone, Patient, Location, ID, Hospital, and Age.

**ML-based de-identification system**

A modified version of the de-identification system that was developed for the 2016 CEGS N-GRID challenge\textsuperscript{18} is used in this study. The system employs a single conditional random fields (CRF) model. CRF is a standard model widely used in many state-of-the-art de-identification systems\textsuperscript{7,9,21-23}. Our system first pre-processes the notes using the CLAMP tokenizer (http://clamp.uth.edu), OpenNLP POS tagger (http://opennlp.sourceforge.net), and a dictionary-based section parser that uses a dictionary of standard section names in clinical notes (a modified version of CLAMP section parser). After pre-processing, a token-based CRF tagger is employed to identify PHI mentions using the BIO tagging scheme. CRFSuite (http://www.chokkan.org/software/crfsuite/) is used as the implementation of the CRF algorithm. Features shown to be effective in 2016 challenge are employed, excluding those that are applicable only to psychiatric notes, or relevant only to PHI categories not targeted in this work\textsuperscript{25}. Table 2 shows the features.

**Domain adaptation methods**

Three state-of-the-art domain adaptation methods are implemented. The domain adaptation methods are described below. Note that we focus on supervised domain adaptation methods that require small amount of labeled (annotated) target data for training, as opposed to unsupervised domain adaptation methods that utilize unlabeled target data.

**Instance weighting:** Instance weighting\textsuperscript{36} assigns higher weights to instances from target data than to instances from source data. The weighted instances from both the target and the source are combined into a single training dataset to train a classifier. The assumption is that the data distribution in the source domain does not match well
to the data distribution in the target domain, and the weights guide the ML algorithms to learn more from the target domain than from the source domain.

**Instance pruning:** Instance pruning\(^35\) first trains a classifier using only the labeled target data, and uses the classifier to predict labels for the source data. Then, it selects top \(k\) instances that are wrongly predicted from the source data ranked by the prediction confidence, and removes the \(k\) instances from the source data. The modified source data is then directly combined with the target training data to train the final classifier. The intuition is that the top \(k\) wrongly classified instances are very different from the target data.

**Feature augmentation:** A feature augmentation algorithm named EasyAdapt\(^36\) is employed. The algorithm augments features from the target and the source data with general version features. Formally, given a target feature vector \(X_t\) and a source feature vector \(X_s\), EasyAdapt generates augmented features \(EA(X_t)\) and \(EA(X_s)\) described as follows:

\[
EA(X_t) = <X_s, X_s, 0 > \\
EA(X_s) = <X_t, 0, X_t >
\]

where 0 is a zero vector of length \(|X|\). As a result, three versions of feature sets are produced: general, source-specific, and target-specific. The general features are expected to get higher weights for instances that are common for both target and source. On the other hand, the target-specific or the source-specific features are expected to gain weights for unique instances for target or source.

**Experimental setup**

In order to validate our CRF-based de-identification system, in-domain performance of the system is measured. The original datasets of the three sources (without subset sampling) are used to perform 10-fold cross validation of the system on source domains. In-domain performance on the target psychiatric notes is measured by training the system on the training set and evaluating on the validation set, to provide a baseline before any DA method is applied.

The three domain adaptation algorithms are evaluated on each of the three sources. The algorithms are compared to three baselines: “target only” (TO), “source only” (SO), and “source & target” (S&T). For TO, no source data is used and the CRF is trained on the psychiatric notes training set only. For SO, only the source data is used for training, without any labeled target data. Finally, for S&T, the source data and the target data are simply merged together without applying any domain adaptation method.

In order to determine the extent of savings conferred by the domain adaptation methods in terms of annotations of the target data, performance of domain adaptation methods as well as the TO and the S&T baselines are reported at different amounts of labeled target data – with an increase of 10% of psychiatric training data. Learning curves that plot the amount of labeled target data and the performances of the de-identification systems (F-score) are reported.

For all the experiments, the psychiatric notes training set is used as the labeled target data, the validation set is used for measuring the performance, and the development set is used for parameter selection, including \(k\) for instance pruning (top \(k\) instances to remove), and \(w\) for instance weighting (weight \(w<1\) to be assigned to the source instances).

**Evaluation**

For evaluation, we follow the method used in previous de-identification challenges\(^15,17\). Micro-averaged precision, recall, and F-score are reported. System outputs are considered to be correct only when both the type and the character offsets match the gold standard. Statistical significance is determined by approximate randomization test\(^37\) using \(N=9999\) and \(\alpha=0.1\).

Results

In-domain de-identification performance

Table 3 shows the performance of CRF-based de-identification systems when trained and tested on data from the same domain. For outpatient notes, discharge summaries, and mixture notes, the system shows performance comparable to the results from previous studies (e.g., F-score 93.23 for HIPPA-PHI categories by the third best system in the 2014 i2b2 challenge).15

De-identification performance using domain adaptation

Table 4 shows the de-identification performance with domain adaptation methods using the three sources. When trained only on the psychiatric notes training set (i.e., the TO baseline), the system shows an F-score of 89.88. When only the source corpora are used (i.e., the SO baseline), the performance dropped down to 59.51 (outpatient notes). Simply merging source and target (i.e., the S&T baseline) improves the performance in the case of mixture notes (compared to TO), but is worse than TO for outpatient notes and discharge summaries. DA methods have varied performance: but feature augmentation method shows statistically significant performance increase over both the S&T baseline (with outpatient notes or discharge summaries as source) and the TO baseline (for all three sources), achieving best F-scores for all three sources. Overall, the highest F-score 90.40 is achieved when feature augmentation is applied using mixture notes as source.

Table 4 also shows that the three sources exhibit quite different performance, even though they are equal-sized. With the SO baseline, mixture notes shows the highest performance, followed by discharge summaries, and then outpatient notes (statistically significant difference by approximate randomization test with N=9999 and α=0.1). This performance gap among equal-sized sources indicates that mixture notes may be the most similar to the psychiatric notes and outpatient notes may be the most different. The performance difference between outpatient notes and discharge summaries disappears when S&T or feature augmentation domain adaptation is applied. However, mixture notes still has significantly higher performance than outpatient notes or discharge summaries even when S&T or feature augmentation is applied.

Table 5 compares the performance of the TO baseline and feature augmentation for each PHI category. When outpatient notes or mixture notes is used as source, feature augmentation improves performance for all PHI categories. In particular, ID category shows the biggest improvement over the TO baseline (4.04 increase in the F-score with outpatient notes, and 6.04 with mixture notes). Note that ID is one of the sparsest categories in the psychiatric notes training set (0.58% of all the PHI mentions). Discharge summaries shows somewhat different result than outpatient notes and mixture notes. While most of the PHI categories show performance increase, ID and Phone show performance drop. Lastly, note that the F-score for Age category is 0.00 regardless of which domain adaptation method is applied or which source is used. We conjecture that this is due to the severe sparsity of Age PHI mentions even after addition of source data through domain adaptation; Age constitutes less than 0.1% of all PHI mentions in all the four corpora.

Figure 1 compares de-identification performance of feature augmentation with TO and S&T, for the three sources, with increasing amounts of target training data. When outpatient notes or discharge summaries is used as source, S&T outperforms TO when the amount of target training data is smaller (30% to 40% of the whole target training dataset), but S&T shows lower performance than TO as the amount of target training data increases. When mixture notes is used as source, S&T shows higher performance than the TO baseline regardless of the amount of target training data, but the performance of S&T converges to that of TO as the amount of target training data approaches to 100%. Feature augmentation improves performance over both the TO and S&T baselines regardless of the amount of target training data, when outpatient notes or discharge summaries is used as source. Interestingly, with mixture notes as source, S&T shows higher performance than feature augmentation when less than or equal to 60% of the target training data is used. However, feature augmentation starts to show better performance than S&T when more than 60% of target training data is used. According to Figure 1, if we want to achieve an F-score of 89 for the target domain, it will require annotating 80% of training samples when only target domain data is used. However, if we apply feature augmentation to existing annotated sources such as discharge summaries, it only requires approximately 65% of annotated training samples from the target domain, indicating a 18.8% saving on annotation effort.
Figure 1. Learning curves of the de-identification systems for TO, S&T, and feature augmentation (FA) for three sources: outpatient notes, discharge summaries, and mixture notes. X-axis denotes the percentage of labeled target training data, and Y-axis denotes de-identification F-score.
DISCUSSION

In this study, we proposed to use domain adaptation techniques to maximize the use of existing annotated datasets for de-identification of clinical notes. Psychiatric notes, an important but understudied type of notes, are used as the target. Three existing corpora, each consisting of discharge summaries, outpatient notes, and a mixture of various types of notes written for diabetes patients, are used as sources. Three state-of-the-art domain adaptation methods, instance weighting, instance pruning, and feature augmentation, are tested. It is shown that feature augmentation can increase de-identification F-score over the TO and the S&T baselines, indicating the potential of reducing annotation cost for building ML-based de-identification systems. We also find that the performance increase by domain adaptation could depend on which type of clinical notes is used as source.

In previous work that employs domain adaptation for natural language processing (NLP) tasks in the biomedical domain, general domain datasets or biomedical literature were used as sources. In contrast, in this work, clinical notes of other types than psychiatric notes are used as sources, which might be regarded as being “in the same domain” as the psychiatric notes. However, in most of the cases, simply combining annotated notes of different types does not show any improvement over the TO baseline. On the other hand, feature augmentation domain adaptation method is shown to be able to improve over both the TO and the S&T baseline. This indicates that different note types should indeed be considered as separate domains for the de-identification task.

Based on the results of our experiments, the best domain adaptation algorithm for de-identification task among the three algorithms is shown to be feature augmentation. While instance pruning and instance weighting do not show performance improvement over the TO baseline, feature augmentation achieves statistically significant performance improvement over the TO baseline regardless of the type of source notes. Such performance difference among the domain adaptation algorithms may come from the fact that feature augmentation allows adaptation per feature basis, as opposed to the other two methods that perform adaptation per instance basis. However, previous work that evaluates similar sets of domain adaptation algorithms for different biomedical NLP tasks reports different results than this work. Instance pruning shows the best performance for semantic role labeling (SRL) of biomedical literature, feature augmentation for SRL of clinical notes, and instance weighting for discourse connective detection in biomedical literature. Thus, it seems that the performance of domain adaptation algorithms varies depending on the characteristics of both the source and target datasets and the NLP task at hand.

It is observed that different types of notes contribute differently for de-identification of psychiatric notes. In this task, mixture notes show the biggest performance improvement through domain adaptation, achieving significantly better performance than outpatient notes or discharge summaries. Moreover, when target data size is small, simply merging mixture notes and target data works better than domain adaptation methods. This finding is interesting and requires further investigation to provide more insights. One notable fact is that psychiatric notes and mixture notes are both from the same organization, the Partners Healthcare System; while discharge summaries and outpatient notes contain documents from other institutions than Partners. We leave further investigation on domain similarities among different types of clinical notes as future work.

The size of the target corpus used in this study is much larger than those of the source corpora (in terms of number of tokens). This is different from the typical use cases of domain adaptation, where the size of source is much larger than the size of target. While it is interesting to see that domain adaptation can increase de-identification performance even when source sample size is much smaller than the target size, we expect a larger size of source data to achieve even higher performance increase through domain adaptation. In fact, an additional experiment using feature augmentation with a combined source of all existing datasets shows F-score 90.67, the highest among all the experiments done in this study. However, the effect of much larger source to de-identification of psychiatrics notes through domain adaptation is still to be investigated.

We compared de-identification errors produced by systems with domain adaptation to errors produced by the TO baseline system. While less number of errors is produced when domain adaptation is used, the distribution of the error types is not changed much. For instance, with or without domain adaptation, acronyms of hospital names such as “MBH” or “SAH” is one of the major sources of errors. For future work, we plan to test combinations of different domain adaptation algorithms as well as to incorporate domain similarity between target and source into the domain adaptation processes.
CONCLUSION

In this paper, we investigated the use of domain adaptation methods for de-identification of psychiatric notes. Three state-of-the-art domain adaptation methods were evaluated and three source datasets consisting of discharge summaries, outpatient notes, and a mixture of different types of clinical notes were studied. Our results show that domain adaptation can achieve better performance than simply merging the source and the target data, indicating the potential of domain adaptation to reduce the annotation cost when building automatic de-identification systems for new types of clinical notes.

A Framework for Data Quality Assessment in Clinical Research Datasets

Kathleen Lee, MPH,1 Nicole Weiskopf, PhD,2 Jyotishman Pathak, PhD1
1Weill Cornell Medicine, New York, NY; 2Oregon Health & Science University, Portland, OR

Abstract
The wide availability of electronic health record (EHR) data for multi-institutional clinical research relies on accurately defined patient cohorts to ensure validity, especially when used in conjunction with open-access research data. There is a growing need to utilize a consensus-driven approach to assess data quality. To achieve this goal, we modified an existing data quality assessment (DQA) framework by re-operationalizing dimensions of quality for a clinical domain of interest - heart failure. We then created an inventory of common phenotype data elements (CPDEs) derived from open-access datasets and evaluated it against the modified DQA framework. We measured our inventory of CPDEs for Conformance, Completeness, and Plausibility. DQA scores were high on Completeness, Value Conformance, and Atemporal and Temporal Plausibility. Our work exhibits a generalizable approach to DQA for clinical research. Future work will 1) map datasets to standard terminologies and 2) create a quantitative DQA tool for research datasets.

Introduction
In recent years, with increasing availability of electronic health record (EHR) data for research, studies frequently integrate EHR data with insurance billing and claims data to study health outcomes and cost-effectiveness.1–3 Large-scale multi-institutional studies, such as pragmatic clinical trials and comparative effectiveness research, rely on accurately defined patient cohorts to ensure that findings are valid. As more and more clinical data derived from EHRs, claims, and other sources are being collected and stored in publicly accessible repositories, such as the Database of Genotypes and Phenotypes (dbGaP)4 and the Biologic Specimen and Data Repository Information Coordinating Center (bioLINCC),5 there is an overwhelming need to harmonize these datasets and assess their quality.6,7

Several studies have looked at quality issues in clinical research data, such as the lack of data standardization, missing or incomplete clinical data, incompatible representations of data types and elements, and identified three primary challenges to evaluating the quality of a research dataset.8–11 First, data quality assessment (DQA) is often subjective and is dependent on the evaluative task or objective, which is particularly problematic because clinical research datasets are often phenotype-specific, requiring a unique patient cohort, or may cater to a specific set of participating medical centers. Moreover, data within the EHRs may be sufficient for clinical purposes, but not for research, which are typically more objective-driven. For example, the clinical concept “History of Cerebrovascular Accident” can be found in the EHR, and would provide actionable information for patient care. A particular research dataset, however, might require the presence of “History of Cerebrovascular Accident Within 3 years of Encounter.” In other words, data quality is context-dependent.12 Second, although there are certain assurance checks that researchers can conduct to ensure data quality, this process is frequently time-consuming and cumbersome, and the results of these assessments may not be meaningful without a thorough understanding of the researcher’s intended goal. Evaluating data missingness, distributions, and accepted values do not entirely paint a full picture of the quality of the dataset as described by the research objective, and manually evaluating quality in this fashion is a resource-intensive task. Finally, there are no consistent evidence-based or community-driven metrics for assessing the quality of research data. Study investigators frequently develop ad-hoc metrics that are specific to the study, and cannot be replicated.13,14

Objective
It is crucial to quantitatively analyze the quality of a dataset to ensure reproducibility in research studies. To encourage implementation of the recommended concepts of quality assessment, rules and conditions are required to
formulate an assessment framework that is related to a task or specific phenotype of interest. This is a more challenging task when evaluating quality in research datasets as they are often task- or domain-specific.

The present study sought to promote the development and utilization of large, multi-institutional research datasets based on existing data sources. Specifically, we inventoried and assessed the quality of common phenotypic data elements (CPDEs) for heart failure research, enabling a reusable framework development process for other researchers looking to use or contribute to this composite dataset. Our first aim is to modify an existing DQA framework by re-operationalizing the definitions of several data quality dimensions. The framework will be dependent on a particular research goal, which in this case are studies identifying novel biomarkers for heart failure diagnosis, prognosis and treatment. The second aim is to create an inventory of CPDEs derived from the research datasets. In this study, we limit our scope to heart failure biomarker studies in the following open-access databases: dbGaP and BioLINCC. The third and final aim is to evaluate the data element inventory using the modified DQA framework. The task-oriented approach will evaluate, based on the necessary data elements for a study design or goal, the Completeness, Conformance, and Plausibility of the CPDE inventory.

Materials and Methods

Prior Work in Quality Assessment Frameworks

Data quality frameworks and harmonized assessment terminologies have been created to evaluate EHR data. Prior research in DQA defined broad dimensions of data quality. However, in a growing field of data quality research, inconsistent definitions make it difficult to uniformly compare results across data sharing partners and institutions. Efforts to harmonize these concepts are necessary to promote interoperability in the field of data quality research. A harmonized and revised DQA terminology framework was developed to encompass quality concepts that have been defined by other researchers. The proposed harmonized framework takes the categories of Conformance, Completeness, and Plausibility and expands on each.

- **Conformance** is defined by whether data values adhered to pre-specified standards or formats. Conformance was separated into three distinct sub-categories: Value Conformance (whether recorded data elements agree with constraint-driven data architectures, such as data models or rules defined in a data dictionary), Relational Conformance (determines if data elements agree with structural constraints of the physical database that stores these values, hinging on the importance of primary key and foreign key interactions within relational databases), and Computational Conformance (focuses on the correctness of the output value of calculations that were made from existing variables, either within the dataset or between datasets). Although Value Conformance can be ascertained at both the data element and data value levels, Computational Conformance can only be properly assessed at the value level. The scope of this study focused only on single datasets, typically in flat files, such as Excel or CSV formats. As a result, Relational Conformance is not applicable at the data element level for this study.

- **Completeness** evaluates data attribute frequency within a dataset without reference to the data values. It does not consider its structure or its plausibility, but instead looks at the absence of data at a specific point in time agreeing with a trusted standard, common expectation, or existing knowledge. This dimension is applicable to both higher-level data element and more granular data value levels of assessment.

- **Plausibility** is defined by whether or not the values of data points are believable when compared to the expected representation of an accepted value range or distribution. Plausibility was separated into Uniqueness Plausibility (values that identify a particular object—person, institution, etc.—are not duplicated), Atemporal Plausibility (data values adhere to common knowledge or are verified by an external source), and Temporal Plausibility (whether time-varying variables also have changing values, based on gold standards or existing knowledge). All sub-categories within Plausibility are applicable to both data element and data value levels.
**DQA Framework Modification**

The study team used a consensus-driven approach to finalize the framework creation to redefine the harmonized DQA terminology from Kahn et al.\textsuperscript{12} to the specific research task. In particular, the concepts of *Conformance*, *Completeness*, and *Plausibility* were operationalized to be specific to heart failure biomarker research. Table 1 includes definitions of the harmonized data quality assessment terms and examples.

* Rows marked with an asterisk indicate exceptions to the dimensional applicability at that particular data level. *Relational Conformance* requires a SQL database or relational database structure. While *Relational Conformance* can be applied at the data element level, it requires a specific structure of tables beyond the scope of the study. Similarly, *Temporal Plausibility* requires time-varying data elements, which were not included within the ‘Demographics’ and ‘Medications’ categories in the current CPDE inventory.

In our modified framework, *Value Conformance* measures that assessed the adherence of data values to internal constraints necessitated the evaluation of acceptable ranges for data elements like patient sex, blood pressure, or cholesterol levels. *Completeness* compared the data element inventory to the aggregated data elements within literature.\textsuperscript{17–19} These studies compiled cardiovascular EHR data elements, and in particular, key heart failure data elements, that have research utility and maximum clinical impact. *Plausibility* required the evaluation of data values
specific to cardiovascular disease, and understanding that patients with a heart failure diagnosis should have statistically similar distributions for certain data elements compared to patients without a heart failure diagnosis.

**Conformance** for research data is still defined by whether data values adhered to pre-specified standards or formats. We also separate conformance into three sub-categories. Value conformance in research data would be determining whether elements are represented according to some standard medical terminology or appropriate clinical nomenclature. External standards can be applied as well, such as units of measurement or ranges of accepted values. Relational conformance determines if data elements agree with structural constraints of the physical database that stores these values. Relational conformance deals with how a data model represents reality via metadata descriptions or database rules. **Computational conformance** within research datasets include validation checks that are consistent with EHR validation checks, such as whether body mass index (BMI) calculations for data elements like, “Patient Body Weight” and “Patient Height” should yield the same values for the data element, “Body Mass Index”.

**Completeness** evaluates the presence of data elements within a particular dataset. It does not reference data values and it compares the dataset to an existing standard knowledge or common expectation. Because of the subjective nature of compiling a “complete” research dataset for a given disease domain, we compared the data element inventory against cardiovascular data elements aggregated through literature guidelines. Although these were EHR data elements, they were compiled to create a list of attributes that had research utility in clinical settings. This was in line with our focus for heart failure biomarker research studies.

**Plausibility** is whether or not the values of data points are believable when compared to the expected representation of an accepted value range or distribution. **Uniqueness plausibility** ensures that values are not duplicated or represented by another entity within the dataset. At the research data element level, we ensure that data elements are not duplicated or represented by another data element or attribute. At the data value level, we ensure that each data point is not duplicated within another data element. **Atemporal plausibility** determines whether or not data values adhere to common knowledge or are verified by an external source. This extends to research data elements with metadata descriptions that align with existing knowledge. For example, a data element representing “Chronic Kidney Disease Stage 2” should have metadata descriptions consistent with Chronic Kidney Disease stage 2 criteria, such as appropriate laboratory values for glomerular filtration rate (GFR) and blood urea nitrogen (BUN). Values should be consistent with external standards of acceptable ranges or distributions of values. **Temporal plausibility** is whether time-varying variables also have changing values or follow sequentially, based on gold standards or existing knowledge. For example, do values vary over time as expected, such is the case for spikes in flu diagnosis in emergency room or outpatient visits during flu season? Similarly, recruitment dates into the research study should not come before patients’ dates of birth. A follow-up date should not precede the recruitment date for the study. These values follow for other variables that require follow-up dates within a study.

**Common Phenotype Data Element Inventory Creation**
We conducted a retrospective review of open-access cardiovascular disease datasets in order to identify CPDEs related to heart failure. We focused our literature search on studies identifying biomarkers and risk factors for heart failure diagnosis, prognosis and treatment. Several cardiovascular research studies, particularly focusing on heart failure, from dbGaP and BioLINCC were aggregated to compile an inventory (work was led by co-authors KL and JP) of commonly used phenotype data elements. Our inclusion criteria for studies were: 1) focus on heart failure or congestive heart failure biomarker research; 2) use of clinical data in addition to genotype or sequencing data; and 3) inclusion of demographics, diagnostic test, patient history, physical examination, and medications variables. Authorized access was obtained for these research datasets. Data elements for the inventory were selected based on their relevancy to heart failure biomarker research, research utility in clinical settings, and their presence in EHR systems. **Figure 1** illustrates the process for collating CPDEs from dbGaP and BioLINCC.
The development of our data element inventory consisted of a two-pronged approach. First, we aggregated CPDEs that we found in heart failure biomarker research studies in dbGaP and BioLINCC. In aggregating appropriate CPDEs from the studies, we focused on those that had greater generalizability for heart failure studies. Elements like indices of social support networks, for example, were not included in our inventory, as they were not deemed to be generalizable to most heart failure research studies that utilized EHR data. We followed guidelines from literature that enumerated relevant data elements present in EHR databases that could be repurposed for clinical research. Based on these guidelines, social elements were excluded from the inventory. Second, following similar data element guidelines from literature, clinical variables with high research utility, such as diagnostic tests and medical history, were prioritized over those that are more attuned to specific research designs, such as insurance, government aid sources, and billing zip codes. Of particular usefulness in our aggregation of data elements were a report from the American College of Cardiology Foundation and the American Heart Association Task Force on Clinical Data Standards, which focused on harmonizing existing data standards with newly published ones, and to establish terms that are available in every general purpose EHR, and are extendable and reusable in clinical research, a report from the Data Standards Workgroup of the National Cardiovascular Research Infrastructure Project, which attempted to create or identify and harmonize clinical definitions for a general set of cardiovascular data elements, and a report from the American College of Cardiology and American Heart Association Task Force on Clinical Data Standards reviewed key data elements for heart failure management in clinical research.

**Results**

*Finalized Data Element Inventory for Heart Failure Research*

We created an inventory of 100 data elements from the following studies: the Cardiovascular Health Study (CHS), the Jackson Heart Study, the Framingham Heart Study, the Heart Failure Network (HFN) CARdiorenal Rescue Study in Acute Decompensated Failure (CARRESS), and the Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT). Data elements were selected based on comprehensive coverage of cardiovascular conditions, test results, and clinical presentations that would best reflect the breadth and variety of commonly occurring heart failure biomarker research data elements in clinical research. The final data element inventory is available as an online
Our review of relevant guidelines led to the identification of six categories of frequently utilized and clinically meaningful phenotypic data elements:

- **Demographics**: All research datasets have at minimum a demographics category for patient records. Commonly occurring data elements within this category included the Date of Birth, Sex, Race, and Ethnicity. Four demographic data elements were included in the inventory.

- **Physical Examination or Baseline Observation**: This category can often be fairly detailed depending on the research study. Data elements related to systemic observations of the body and functions include measurements of height, weight, body mass index, blood pressure, and heart rate. We included ten data elements in this category.

- **Diagnostic Tests**: Diagnostic and therapeutic procedures, as well as laboratory tests are included in this category. Units of measurement in their metadata description often accompany these variables. Data elements resulting from electrocardiograms, bypass graft surgeries, echocardiograms, and stress tests are included, as well as laboratory values like cholesterol, glucose, creatinine, and blood urea nitrogen measurements. Twenty-six data elements were included in the inventory.

- **Patient Medical History**: Typical data elements in this category include prior history of disease or diagnoses, prior surgeries or hospitalizations, history of tobacco use, drug use, and alcohol use, and family history of disease. These data elements are often categorical, such as the data element, “Type of stroke”, which takes on values, “Hemorrhagic,” “Nonhemorrhagic,” and “Unknown.” Twenty-seven medical history items were included in the data element inventory.

- **Clinical Diagnoses or Presentation**: This category is limited to the patient’s current status. In research datasets for heart failure biomarker research, patients are often diagnosed with heart failure, or another cardiovascular disease to be included in the study cohort. Inclusion of clinical presentations was considered for this section as EHR systems record current statuses of patients differently. Data elements, such as Myocardial Infarction, Chest Pain (Angina), Heart Failure, Syncope, and the like, were included. Eight patient assessment data elements were included in the inventory.

- **Medications**: Types of medication, such as beta blockers, ACE inhibitors, and statins were included, as well as data elements describing usage, such as Medications Held or Discontinued, Contraindications, and timepoints of usage were added to the inventory. The inventory contained twenty-five medications-related data elements.

**Assessment of Data Element Inventory Against Modified DQA Framework**

Having redefined the DQA framework and creating an inventory of accepted data elements for comparison, we were able to evaluate the quality of our collected data element inventory. **Table 2** displays the results of the inventory against the framework. The inventory was assessed at the data element variable level. For some DQA concepts that are more suitable for assessing variable values, we evaluated the appropriate variables based on their ability to capture the significant aspect. For instance, to evaluate particular data elements on *Temporal Plausibility* at the data element variable level, we assessed their ability to capture temporal aspects, such as continuity of data collection and whether or not they were defined by a numeric date, where appropriate.

**Discussion**

This work is not an exhaustive list of modifications to a DQA framework for research datasets. Although there are many ways that research data and EHR data coincide in terms of data quality, the applications for verification and validation can be quite different. While we understand that the data element inventory was created to obtain a “model” for accepted variable values that work within our modified DQA framework, we acknowledge the potential limitations for its application as a comparison to other research datasets that may have a broader or narrower focus even within the scope of heart failure biomarker research studies. Our goal was to adapt a harmonized DQA framework to a clinical domain, such as heart failure, and inevitably to compile a working DQA framework that can be reusable in clinical research.

Although harmonized frameworks are typically evaluated at the data value level, we attempted to apply it at a broader element level for this study. All data elements met the criteria for *Value Conformance* by being thoroughly represented by appropriate units of measurement in their metadata descriptions. However, mapping data elements to a standard terminology, such as the Systematized Nomenclature of Medicine (SNOMED)\textsuperscript{25,26} would further ensure that data elements adhered to the best practices for research data management. There remains a subjective aspect to our approach. 88.4% of the Diagnostic Test data elements met the criteria for *Completeness*. Including dates for certain diagnostic procedures that may vary over time might have led to a more complete list. For example, including the date of “Radionuclide Ventriculography Findings” typically helps investigators track a patient’s disease progression over time if more tests are conducted at different time points.

The data elements in the inventory are considered a complete collection of appropriate variables to be included in a research dataset for heart failure biomarker research as it includes elements that encompass demographics, physical examination, tests, patient medical history, and medications. Collating the data elements for the inventory involved consulting guidelines set in literature for high research utility clinical variables in heart failure studies, as well as evaluating commonly occurring data elements that are present in open-access clinical research datasets. Some studies included other lifestyle factors, such as sources of social support, eating habits, or scales for depression and anxiety. We considered these data elements to be not as generalizable in heart failure studies according to literature guidelines previously set for EHR data elements. These guidelines included only common elements that had high clinical research utility, and as a result, the aforementioned social indices were not included in our data element inventory. *Uniqueness Plausibility* ensures that elements are not duplicated and values are not dually represented within a dataset. 85.2% of Medical History data elements adhered to the concept of *Uniqueness Plausibility*. Certain data elements, such as Family History of Coronary Arteriosclerosis, Family History of Cardiomyopathy, and Family History of Sudden Cardiac Death shared some overlapping definitions and descriptive criteria.

Because our data element inventory is presented in a single table, and there are no relationships between the data elements themselves (for example, as one would observe in an Entity-Relationship model), it did not qualify to be assessed for *Relational Conformance*. There are no additional tables in the data element inventory, although some research datasets may have separate tables for categories of measurements. Additionally, we are unable to evaluate *Computational Conformance* as we are only evaluating at the data element variable level, which provides no output variable values for us to calculate on. *Temporal Plausibility* was incalculable for Demographics and Medications.
categories as the elements were not expected to vary over time. Should there have been prescription dates for Medications, perhaps Temporal Plausibility might have been more applicable. In our inventory, however, Medications were only listed as drug classes.

Limitations
The first limitation is that there are certain data quality concepts that cannot fully apply to research data. Relational Conformance, for example, deals with the ability to navigate between different tables, which may not be necessary if the table in question is a research study data dictionary. These are structured differently and are typically not stored in the same manner as EHR systems tables.

Second, to properly assess Value Conformance, it is often necessary that data elements in research datasets are mapped to standardized biomedical terminologies. An underlying data quality issue in research data is the inability to be readily integrated or linked to relevant datasets due to a lack of standardization. This can be addressed by mapping data elements to terminologies or models to further ensure that the data elements are represented appropriately. In addition, string variables present a familiar challenge for researchers working with ontologies as mapping these terms can be difficult when compiling EHR data and when transforming data from one schema to another. We aimed to include values within a string variable that contain more structured response options. For a variable, such as “Lung (pulmonary) examination”, the values could take the form of free-text responses, which would present a challenge for data mapping. Its values, however, include structured responses, like “Clear or normal, Rales (height of rales when patient sitting upright should be noted), Decreased breath sounds or dullness, Rhonchi, or Wheezing,” which can more easily facilitate mapping to standard terminologies.

Third, because data quality assessment is a subjective task, it is necessary to have an external gold standard for comparison. We used literature guidelines that focused on EHR heart failure data elements with high research utility to create our data element inventory. The objective of this study, after all, is to evaluate data quality within open-access research datasets that focus on biomarker discovery, which are often linked to EHR data. Fourth, our methodology for assessing data quality was limited only to the data element variable level: were the data elements complete and in line with a set of external standards or common knowledge? Focusing only on evaluating data quality at the data element variable level, much like assessing a data dictionary, restricts our ability to look at the variable values and understand its accepted distributions, ranges, and completeness or missingness. Further, we were unable to conduct validation checks that may enable us to assess for computational conformance.

Future Work
Assessing data quality at the higher-level data element phase was a necessary first step in determining the ability of clinical research data to adhere to a harmonized DQA framework. To more comprehensively evaluate the utility of our harmonized framework, future projects will adapt the framework at the data value level as well. We anticipate that including data values will produce more criteria with which to better assess quality, most likely producing less adherence than what our current results exhibit. In addition, we anticipate that the addition of data elements, such as social support and insurance and billing procedures may provide us with a richer set of criteria to broaden our DQA dimensions. Incorporating more granular data values may involve either a more comprehensive data element inventory, or data transformation of several datasets to a common model so that they have a similar baseline for comparison. The latter exercise of data transformation into a common data model can also help alleviate the mapping challenges of string variable responses that can be particularly difficult to standardize. Evaluating the framework against differing granularities can more appropriately showcase its ability to be repurposed continuously in research, independent of clinical domain. Our eventual goal is to create an assessment tool to better quantify data quality using this framework. The first step is to create a stepwise script that can run on a statistical program, such as R or SAS. This would enable researchers to go through their appropriate data elements within their data dictionary and check for missingness and completeness, appropriate ranges, and distributions. They can also check Computational Conformance in this way. The second goal is to create a stepwise tool that can assess the overall

Abstract
Avian influenza viruses have caused infections and deaths in wild birds, commercial poultry, and humans. It poses an increasing threat of a pandemic. To understand the transmission dynamics of avian influenza viruses and assess the effectiveness of different containment strategies, we develop a flexible modeling framework based on multi-layer compartmental models for digital disease surveillance and response in combating pandemics. The model can accommodate other disease outbreaks under diverse settings. We demonstrate its usage on avian influenza and derive the basic reproduction number and spread characteristics. We contrast the effectiveness of different containment strategies and their combination effect in protecting both the human and the bird populations. Our system, a digital surveillance and response system (RealOpt-ASSURE), can record, monitor, and predict avian influenza outbreaks. It combines with intervention strategies to return policies and on-the-ground operations/actions that are needed for best population protection. RealOpt-ASSURE can accept heterogeneous types of surveillance data. It can help decision makers to evaluate the risk of a pandemic and choose proper containment strategies to rapidly mitigate the outbreak.

Introduction
Avian influenza is caused by infection with avian influenza Type A viruses. These viruses were first isolated from common terns in South Africa1, and were later extensively studied. They occur naturally among wild birds and can infect domestic poultry and other animal species, including cats and swine. The highly pathogenic avian influenza (HPAI), and the very virulent types of avian influenza Type A viruses (majorly subtypes H5 and H7), are fatal for birds nearly 100% of the time2. They do not normally infect humans, but sporadic human infections with avian flu viruses have been reported, with approximately 50% mortality rate3. There is no clinical evidence that avian influenza can be directly transmitted between humans4, but such possibility exists due to mutant avian influenza viruses, and should be closely monitored to reduce the infections and mortalities among humans5.

From 1959 to early 2000, primary outbreaks of HPAI in poultry have been reported 17 times2. The more recent outbreaks started in 2003, when multiple avian influenza cases in wild birds, domestic poultry, and humans were reported worldwide. The H5N1 influenza outbreak in Southeast Asia in 2003 infected more than 130 people in Vietnam, Thailand, and Cambodia and killed more than half of them6. The same subtype appeared in wild birds and domestic poultry in China afterwards, causing human infections as well7–9. It was estimated that by 2005, this outbreak had caused more than $10 billion in losses to the Southeast Asian poultry industry9. Large outbreaks in commercial poultry farms in industrialized countries in Europe and United States have also been reported10, 11, indicating that avian influenza is not only a threat to human health, it also jeopardizes the poultry industry and has significant impact on the economy. Predicting the trend of an avian influenza outbreak and implementing an optimal intervention strategy to achieve early containment is crucial. Pandemic planning and large-scale surveillance are essential in promoting effective responses12, with real-time analysis of surveillance data being critically important to detect and predict an outbreak in a timely manner.

Numerous mathematical models have been developed to describe the spread of an epidemic to facilitate decision making using surveillance data. During the past two decades, various models were proposed for general influenza and avian influenza. Probability-based quantitative analysis was used to estimate the risk of an emerging pandemic strain of avian influenza13. Agent-based simulation of individual and community activities was developed to prevent and control influenza pandemics14. Stochastic models were developed to predict the worldwide spread of pandemic influenza based on global travel information15, 16. Compartmental models remain a popular method for pandemic studies. Ordinary differential equation-based methods were used to interpret the mutation process of avian influenza17, model the dynamics of human infections18, and investigate nonlocal epidemics19.
In this paper, we introduce a modeling framework for infectious diseases based on the compartmental modeling concept. Instead of specifying a set of compartments and a certain transmission and development structure, this modeling framework is highly generic and flexible, and can accommodate diverse types of infectious diseases. Analyzing the model using avian influenza, we perform sensitivity analysis to understand the risk of infection, and evaluate efficiency of different containment strategies in terms of both human and bird infections. We demonstrate the design of a general purpose “digital disease surveillance and response” system, RealOpt-ASSURE, for tracking the avian influenza outbreaks and predicting future disease trends; and discuss how the system can assist in decision making to control and prevent outbreaks.

Methods and Designs

Our general purpose modeling framework is based on compartmental models that combine both the disease characteristics and the response operations. Consider a homogeneous group in a compartmental model, and let \( \Phi \) denote the collection of all stages. We use the following two ways to categorize stages:

- **Passive/Active stages**: Passive stages are those under which an entity will not change its status spontaneously; while active stages are those under which an entity will change its status spontaneously. Let \( \Phi_P \) denote the collection of passive stages, and \( \Phi_A \) denote the collection of active stages. \( \Phi_P \cup \Phi_A = \Phi \).
- **Vulnerable/Contagious stages**: Vulnerable stages are those under which an entity can still be infected; and contagious stages are those under which an entity can infect other entities who are vulnerable. Let \( \Phi_V \) denote the collection of vulnerable stages, and \( \Phi_C \) denote the collection of contagious stages. We have \( \Phi_V \cup \Phi_C \subseteq \Phi \).

Define the vector \( \mathbf{y}_\phi = (\phi(t))_{\phi \in \Phi} \) as the number of entities in each compartment at time \( t \). Let \( \mu_\phi = (\mu_\phi)_{\phi \in \Phi} \) be the vector of transition rates of all stages in the model. Note that only the active stages have well-defined transition rates, thus for completeness, we define \( \mu_\phi = 0 \) for all \( \phi \in \Phi_P \). Similarly, let \( \mathbf{b}_\phi = (\beta_\phi)_{\phi \in \Phi} \) be the vector of baseline infection rate of all vulnerable stages in the model adjusted by the total population. For non-vulnerable stages, define \( \beta_\phi = 0 \) for all \( \phi \in \Phi_V \). For simplicity, we define a function \( s \) on \( \Phi : s(\phi) \) returns the set of all successor stages of \( \phi \). Let matrix \( \mathbf{C} = (c_{ab})_{a \in \Phi, b \in \Phi} \) denote the disease contagious matrix, where \( c_{ab} = -1 \) if \( a \in \Phi_V \) and \( b \in \Phi_C \), and \( c_{kb} = 1 \) for all \( k \in s(a) \) if \( a \in \Phi_V \) and \( b \in \Phi_C \). Finally, let matrix \( \mathbf{D} = (d_{ab})_{a \in \Phi, b \in \Phi} \) be the disease transition matrix, where \( d_{ab} \) is the transition probability from stage \( b \) to stage \( a \). Then the ordinary differential equations for the compartmental model with one homogeneous group can be written compactly as follows:

\[
\mathbf{y}' = (\mathbf{D} - \mathbf{I})\text{diag}(\mathbf{\mu})\mathbf{y} + \text{diag}((\mathbf{D} + \mathbf{I})\text{diag}(\mathbf{b})\mathbf{y})\mathbf{C}\mathbf{y}
\]  

(1)

where \( \mathbf{I} \) is the identity matrix. The first part of the equation models the change in compartments due to the development of disease, and the second part models the effect of new infections. If we take the natural changes of the group population independent of the disease outbreak into consideration, we may add a term \( \lambda(\mathbf{y}) \) to equation (1), where \( \lambda \) is a function of current population and depicts the natural changes in population.

The modeling framework for avian influenza consists of two parts: the compartments for human, subscripted by \( H \); and compartments for birds, subscripted by \( B \). The infections among birds are associated with contacting infectious birds, while the transmission from the susceptible to the infectious in human is associated with contacting infectious birds, as well as their saliva, mucus, and feces. The spread of avian influenza \( A \) viruses from one ill human to another is rare. However, because of the high possibility of viruses to mutate and gain such an ability, the human-to-human transmission is also included in the model. Incorporating the above features and applying formula (1) on the human and bird group individually will result in our generic modeling framework for avian influenza:

\[
\mathbf{y}_H' = (\mathbf{D}_H - \mathbf{I})\text{diag}(\mathbf{\mu}_H)\mathbf{y}_H + \text{diag}((\mathbf{D}_H + \mathbf{I})\text{diag}(\mathbf{b}_H)\mathbf{y}_H)\mathbf{C}_H\mathbf{y}_H + \lambda_H(\mathbf{y}_H)
\]  

(2-1)

\[
\mathbf{y}_B' = (\mathbf{D}_B - \mathbf{I})\text{diag}(\mathbf{\mu}_B)\mathbf{y}_B + \text{diag}((\mathbf{D}_B + \mathbf{I})\text{diag}(\mathbf{b}_B)\mathbf{y}_B)\mathbf{C}_B\mathbf{y}_B + \lambda_B(\mathbf{y}_B)
\]  

(2-2)

where \( \mathbf{b}_H \) and \( \mathbf{C}_H \) are the baseline infection rate vector and contagious matrix between the group human and bird.

In this study, we apply an SEIRD (Susceptible, Exposed, Infectious, Recovered, Deceased) model to describe the disease spread among the human population. The human population is assumed to follow a logistic growth with carrying capacity \( K_H \) and growth rate \( r \) during the outbreak. The virus transmission among birds is modeled with an SID (Susceptible, Infectious, Deceased) model. The bird population is assumed to have a constant death rate \( v \) and a variable birth rate \( \Lambda(t) \) such that the total population is constant \( K_B \). Figure 1 shows the transition diagram. Assume the probability of a human recovering from an infection is \( p \), and the basic contact rate between humans is \( \beta_H \). Under this assumption, the matrices in formula (2) for the human compartments are:
The basic contact rate between birds is $\beta_B$. The matrices for the bird compartments are

$$\mu_B = \begin{pmatrix} 0 \\ \mu_{HI} \\ 0 \\ 0 \end{pmatrix}, \beta_B = \begin{pmatrix} \beta_B \\ 0 \\ 0 \\ 0 \end{pmatrix}, D_B = \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & p & 0 \end{pmatrix}, C_B = \begin{pmatrix} 0 & 0 & -1 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}.$$ 

Further, we assume the basic contact rate between human and bird is $\beta_{HB}$. The matrices for the interaction term between human and bird are

$$\beta_{HB} = \begin{pmatrix} \beta_{HB} \\ 0 \\ 0 \\ 0 \end{pmatrix}, C_{HB} = \begin{pmatrix} 0 & -1 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}.$$ 

Figure 1. Transition diagram of the compartmental model. The dashed lines refer to the contacts that cause infections.

To derive the basic reproduction number for this system, we apply the method of next generation matrix. By arranging the compartments corresponding to infections as $S_H, E_H, I_H$ and evaluating the components of next generation matrix at equilibrium, we obtain

$$F = \begin{pmatrix} 0 & \beta_H K_H & \beta_{HB} K_H \\ 0 & 0 & 0 \\ 0 & 0 & \beta_B K_B \end{pmatrix}, V = \begin{pmatrix} \mu_{HE} + r & 0 & 0 \\ -\mu_{HE} & \mu_{HI} + r & 0 \\ 0 & 0 & \mu_{BI} + \nu \end{pmatrix}.$$ 

Therefore, the basic reproduction number for the system is the spectral radius of the next generation matrix $FV^{-1}$:

$$R_0 = \rho(FV^{-1}) = \max \left\{ \frac{\beta_H K_B \mu_{HE}}{(\mu_{HE} + r)(\mu_{HI} + r)}, \frac{\beta_B K_B}{\mu_{BI} + \nu} \right\}.$$ 

The first component in the equation is the basic reproduction number within the human compartments, and the second component is the basic reproduction number within the bird compartments. Since human-to-human infection of avian influenza is inefficient and rare, we can conclude that $\beta_H K_B \ll \beta_B K_B$, thus the basic reproduction number of the system is determined by the infections among the birds. To quickly contain an avian influenza outbreak, it is desirable to reduce the basic reproduction number such that $R_0 < 1$ so that an infected bird produces less than one new infection during its infectious period. This can be achieved by either reducing the adjusted basic contact rate $\beta_B$ by quarantining the poultry farms with confirmed cases, or reducing the bird population $K_B$ by slaughtering infectious birds, both wild and live poultry.

To examine the performance of the model and understand the effectiveness of containment strategies, we perform sensitivity and scenario analysis using the 2010 avian influenza data in Egypt. We vary the contact rate between birds ($\beta_B$), and the duration of infection in birds ($\mu_B$). We report the estimated number of infections in both birds and humans, as well as time to reach containment. The simulation is performed until an asymptotic behavior is achieved, i.e., when no new cases are reported.

**Results**

**Egypt.** Egypt is considered an important poultry producer in the Arab world with 1.5 million permanent workers and 1 million temporary workers in poultry production. The combination of commercial poultry, backyard birds, and live-bird markets exposes Egypt to the danger of avian influenza outbreak. Evidence shows that stable lineages of H5N1 viruses have been established among chickens and humans in Egypt, and the control efforts and international cooperation is in urgent need. We use the data of reported infections in live poultry of an HPAI outbreak in Egypt during January to June 2010 for our analysis. The total number of reported cases in live poultry was 317,400 by containment.

Figure 2 contrasts the reported cases in live poultry against the simulation result by varying the contact rate ($\beta_B K_B$) and the duration of infection ($\mu_{H}$) in live poultry. The results suggest that Table 1 provides good estimates for the reported cases (green solid curve from simulation against red dotted curve of reported cases). When the basic contact rate increases from 56 per day to 58 per day (dotted against the dashed green curves), the cumulative infections in bird compartments increase from 0.22 million to 0.46 million by June 2010 (110% increase). Varying the duration of infection in birds seems to have a larger impact on the trend of the outbreak (the three solid lines). When increasing the bird infection time from 9 days to 11 days, not only the total infections at containment sees a 4-fold increase (0.16 million to 0.6 million), the time to containment is delayed by two months as well (April 2010 to June 2010). Therefore, reducing the infection duration of birds plays a crucial role in controlling the trend of the avian influenza outbreak. This can be achieved by providing medical countermeasures to affected poultry farms, or quickly removing/isolating infectious live poultry upon identification of an outbreak.

Figure 2. Varying contact rate and duration of infection in birds and its effect on infection and containment.

Next, we focus our analysis on the infections among humans using the parameters from Table 1 and investigate the effectiveness of three containment strategies: 1) reducing contact rate to live poultry ($\beta_{HB}$), 2) slaughtering infectious live poultry ($I_B$), and 3) quarantining infectious humans ($I_H$). Each strategy is assumed to be in effect starting on February 20, 2010. Without any intervention, the total infection reaches 540 and will be contained by June 2010. Figure 3(a) shows that reducing contact rate by 20% will reduce the total infections to 453 (16% reduction), although it does not significantly improve the time of containment. However, the containment will be achieved by May 2010 with 278 infections when the contact rate is reduced by 60%. This shows that reducing contact rate is highly effective in minimizing the total infections and containment time. This strategy is also easy to implement: residents should be advised to avoid contacting birds or their saliva, mucus and feces; and poultry farm workers should be advised to use proper protective equipment while working close to the poultry.

Figure 3(b) suggests that slaughtering infectious live poultry is equally effective. It has similar efficient frontiers as reducing contact rate in controlling human infections. However, it also controls the outbreak within the live poultry. Unlike reducing contact rate, which works totally independent of the bird compartments, reducing infectious poultry also reduces the danger of susceptible birds being exposed to the virus. This leads to earlier containment within the live poultry. However, there are practical difficulties with this approach: the management of the bird carcasses and the potential economic impact. Incineration of the dead birds has been a common practice.
Figure 3(c) shows that with the current baseline infection among humans at $1.5 \times 10^{-7}$, the effect of human-to-human infection is negligible: all 5 curves are almost the same. But this could become a threat due to the high mutation probability of avian influenza viruses. Mutant species which can be easily transmitted among humans may emerge; hence epidemiologists and healthcare leaders should closely monitor such a possibility.

Figure 3(d) shows the combination effect of reducing contact rate and reducing infectious poultry. When both strategies are implemented at 20% level, the total number of infections at containment is approximately 400. Since implementing a single strategy at a high effective level may be inherently difficult, combination strategies are appealing and can generate satisfactory containment results.

A significant concern to public health officials is to understand when the intra-human infection of avian influenza will pose a major threat to public health. By varying the baseline infection rate between humans ($\beta H p_H$) while keeping other parameters fixed as given in Table 1, Figure 4 shows that the trend of avian influenza outbreak in human remains insignificant, unless the baseline infection rate is increased from $1.5 \times 10^{-7}$ to 0.15. Although such a possibility is small, it will result in more than 5,400 infections in humans at containment, 7 times more when compared to the original scenario. Since the human mortality rate is very high, it is imperative that epidemiologists and healthcare officials are vigilant in monitoring the mutations of avian influenza viruses, and take proper and timely actions should such high infectivity mutations occur.

**United States.** In this scenario, besides the factors discussed in the previous section, we also explore the impact of transportation and migration of infectious birds on disease trend of an avian influenza outbreak. For brevity, we only consider infections among birds. To model the change of bird population in each state due to commercial transportation or migration, we introduce a transportation matrix $\Omega_{N \times N} = (\omega_{ab})_{1 \leq a,b \leq N}$, where $\omega_{ab}$ represents the percentage of birds transported from state $a$ to state $b$ in a unit time, and $N$ is the total number of states considered in this setup. Each state is assigned a unique instance of equation (2-1) with its own initial bird populations, and the transportation matrix $\Omega$ is used to connect all the states. More rigorously, let $Y_{m \times N} = [y_1, y_2, \ldots, y_N]$ be the collection of stage vectors of all
states, where $m$ is the number of total compartments for birds in formula (2-1). Then the ordinary differential equation with the transportation and migration of birds can be written as

$$Y' = (D_B - I)\text{diag}(\mu_B)Y + \sum_{k=1}^{N} \text{diag}((D_B + I)\text{diag}(\beta_B)Y_k)C_BY_k\epsilon_k + \lambda_B(Y) + Y(\Omega - \text{diag}(\Omega \cdot 1))$$

where $\epsilon_k$ is the $k$th basis vector. In this scenario, we assume that the initial infection starts in Ohio with 30,000 infectious birds. If no restrictions are placed on the transportation of live poultry and no interventions are implemented, the spread of the virus is shown in Figure 5. By day 100 of the outbreak, the virus has already spread to neighboring states and most of the northeast region. By day 300, the virus has spread to the midwest and southern regions, and the trend of the outbreak is still increasing, as shown in the light green solid curve in Figure 6. The cumulative number of infections in birds in the entire United States will reach 1.8 million by day 300, and some states with high poultry production will be severely affected, causing potential dangers to the health of poultry farm workers as well as residents.

Figure 4. Sensitivity analysis of baseline infection rate between humans

We will examine two intervention strategies for this scenario: 1) reducing the probability of transporting infectious birds to other states by enforcing strict regulations and examinations on the transportation of live poultry and/or poultry products; 2) reducing the population of infectious birds by slaughtering infectious poultry and wild birds. Both strategies are assumed to be implemented one month after the initial outbreak.

Figure 5. Outbreak trend in US at different number of days after the initial outbreak; the colors refer to the number of infectious birds in each state (upper panel: real-time infections; lower panel: cumulative infections).

Figure 6(a) shows the effect of reducing transportation of infectious live poultry and controlling the migration of infectious wild birds. Without any intervention, the outbreak will start to show signs of containment by day 700, and the
total number of infectious birds at containment will be near 2.6 million. If a 20% reduction of infectious transportation is achieved, the containment will start on day 200, and the total infections in bird population at containment will be 1.1 million, a 58% reduction. If this strategy is implemented at 80% level, the outbreak will start to be contained by day 120 (almost one and a half years earlier compared to no intervention), and the total infection in bird population at containment will be 0.6 million, a 77% reduction. This result demonstrates that by imposing strict regulations and examinations on live poultry transportation, the containment will be reached earlier, and the total number of infected birds will be reduced significantly. Another advantage of this strategy is that it can confine the outbreak within a small region so that it is easier to implement other types of interventions.

**Figure 6.** Contrast of cumulative number of infected birds in US under two containment strategies.

Figure 6(b) shows the effect of slaughtering infectious birds one month after the initial outbreak. Although slaughtering infectious birds alone is not as effective as reducing transportation and does not change the disease trend significantly, it does reduce the number of infections at containment. For example, when 40% of infectious birds are slaughtered after one month of initial outbreak, the cumulative number of infections at containment will be 1.67 million, a 36% reduction compared to no intervention. The number of infections at containment will be 0.74 million, a 72% reduction, when 80% of infectious birds are slaughtered. However, this strategy has both environmental and economic concerns, and the disposal of carcasses of slaughtered birds remains a difficult problem to solve. Combination of containment strategies will be effective and promising, as shown in Figure 7. Implementing both strategies at 20% level will reduce the number of infections by containment to 0.95 million, a 63% reduction. When both strategies are implemented at 30% level, the cumulative number of infected birds will be 0.75 million, a 71% reduction.

**Figure 7.** Illustration of the effect of combination strategies in US.

**Designing A Digital Disease Surveillance Response System (RealOpt-ASSURE).** We develop a digital disease surveillance response system for infectious disease outbreaks within the architecture of RealOpt-Regional. In addition to the global operational and response capabilities inherited from RealOpt-Regional, RealOpt-ASSURE has three major functionalities: 1) recording and displaying the current reported cases, 2) predicting future infections based
on the transportation matrix \( \mathbf{A} \), and 3) determining the optimal number of partitions (point-of-dispensing sites, PODs) to dispense medical countermeasures to the affected poultry farms. To achieve real-time decision capability, the computationally intensive general-purpose disease model within RealOpt-ASSURE is approximated using a simplified inclined decay with an exponential adjustment (IDEA) model\(^{13}\).

Based on the geographical distribution of current infections, the migration patterns of wild birds, the commercial transportation of live poultry, and the location of large poultry farms which are most likely to be the victims of avian influenza outbreaks, we apply RealOpt-ASSURE to determine the operational requirement for rapid and effective containment. Figure 8(a) shows the heat map of infected sites during the 2015 avian influenza outbreak in Iowa. Figure 8(b) highlights the optimal partitions for dispensing medical countermeasures to protect the poultry farms in one of the affected locations. After establishing the dispensing partitions, decision makers can design the processes and optimize the throughput with minimum healthcare resources using RealOpt-POD\(^{34,35}\). Point-of-dispensing for human population protection can be established as walk-through or drive-through facilities or through mobile vehicles. For the live poultry, dispensing should be performed simultaneously across all partitions to ensure the maximum and most effective coverage.

With the support of the RealOpt-ASSURE digital surveillance tool and the RealOpt enterprise systems, emergency planners can prepare in advance and respond rapidly (and improvise if necessary) to local avian influenza outbreaks to achieve early disease mitigation and containment for both human and bird populations.

**Figure 8.** Screenshots of the digital surveillance tool, RealOpt-ASSURE, designed on top of RealOpt-Regional\(^\circ\). Figure 8a shows the 2015 H5N1 infected sites in Iowa. Figure 8b shows the partitions for dispensing medical countermeasures to protect live poultry. The icons represent the walk-through or drive-through point-of-dispensing sites for dispensing medical countermeasures to the human population if officials decide to initiate prophylaxis.

**Discussion**

This work describes the design of a “digital disease surveillance and response” system, RealOpt-ASSURE, in preparing for and responding to pandemic outbreak. RealOpt-ASSURE is a general-purpose modeling framework that couples compartmental models (with separate groups of compartments for human and carrier populations) with human behavior and operations processes. We demonstrate its usage in analyzing avian influenza. The RealOpt-ASSURE modeling framework is capable of tracking the development (and interplay) of epidemics in both human and carrier groups. It also incorporates the natural population growth and effect of migration and transportation. We analyze avian influenza outbreaks and investigate parameters that have significant impact on epidemic severity. We study the effect of average contact rate between birds and average time that birds stay infectious.

Analyses are performed using the 2010 H5N1 outbreak data in Egypt. Our analyses show that the trend of avian influenza outbreak is sensitive to both contact rate and infectious duration. Accurate parameter estimation of the biology of the avian influenza viruses is crucial to the model performance. We explore three containment strategies to mitigate and minimize infections among humans: 1) reducing human contact rate to birds, 2) slaughtering infectious birds/live poultry, and 3) quarantining infectious humans. The first two strategies show similar effectiveness in containing the outbreak and reducing the number of infections in humans; while quarantining infectious humans has marginal effect. This confirms that reducing human-bird contact and controlling infection among birds are key factors in containing the outbreak. The human-to-human infections effect of avian influenza is low; however, it is possible that mutations may lead to more significant intra-human infections.
Analysis is also carried out using the poultry farm and production data in the United States. Two containment strategies are contrasted: 1) reducing transportation or migration of infectious birds, and 2) slaughtering the infectious bird population. Both strategies are effective, with the former confining the outbreak within a localized region for more manageable containment operations. These findings indicate that regardless of the objectives, the outbreak in the bird population should be tackled first, and the containment strategy should be determined based on environmental and demographic information, as well as transportation/movement and bird migration patterns.

The RealOpt-ASSURE system enables decision makers to track the outbreak status, and predict possible future disease trends to assess its severity. It provides a decision support framework for policy makers to estimate the potential risk of an outbreak and contrast the cost-effectiveness of different containment strategies. Combination strategies are practical and cost-effective in achieving a disease-free equilibrium. Healthcare officials should select a strategy portfolio based on the local environment, demographics, and the composition of bird population. To further expedite the containment, the public should be educated and informed of the knowledge regarding avian influenza, as human behaviors have a profound impact on the virus transmission.

This modeling framework is highly generalizable and flexible. The modeling framework does not depend on the mechanism of the disease transmission or the biological development. It can accommodate various setups for modeling other pandemic outbreaks. For example, the model can accommodate the spatial distribution and movement of humans for global trend estimation. Other interactions as a result of human behavior, social media, and/or public policies can also be incorporated. It can also handle heterogeneous groups. For example, formula (2) consists of two sets of equations: one for the human population, and one for the bird population. Another group can be incorporated readily by adding a different set of equations with properly defined contact and disease contagious matrices.

This modeling framework can also be used for general vector-borne diseases. In Lee et al., we demonstrate its first usage for Zika virus analysis. The Zika analysis includes both human and alternate hosts.

A closer look at formula (2) shows that it only models the infection from birds to humans, but not the reverse. This reflects the reality of avian influenza. In general vector-borne diseases, infection from humans to vectors is possible. In this case, we can add the corresponding term to the carrier equations by properly defining the reverse disease contagious matrix $C_{BH}$ and contact rate vector $\beta_{BH}$. Then the equation for carrier population (2-1) becomes

$$y_H' = (D_B - I)\text{diag}(\mu_B)y_B + \text{diag}((D_B + I)\text{diag}(\beta_B)y_B)C_By_B + \text{diag}((D_B + I)\text{diag}(\beta_{BH})y_B)C_{BH}y_H + \lambda_B(y_B)$$

Combined with the equations for human population, we obtain a modeling framework for general vector-borne diseases, which can be used to model ZIKV, dengue, etc. Our previous model for ZIKV can be perfectly represented in this framework. As more biological facts of different pandemics are discovered, new stages and updated parameters can be fed into RealOpt-ASSURE continuously instead of building the entire model from scratch. This feature is particularly appealing in real-time operations and decision making, as rapid implementation of appropriate containment strategies can drastically change the overall disease trend and the outcome of an outbreak.

Informatics and social media play an important role in tracking disease spread and supporting epidemiology modeling and containing disease outbreaks. They have already demonstrated their capability in helping prevent influenza outbreaks. The most challenging part is to recognize how classical mathematical models fit and perform in this digital era. RealOpt-ASSURE allows incorporation of different levels of data within the modeling environment. It is also highly sustainable with the support of modern information technologies, which provide valuable inputs to our model. With continuous data input, the model can adjust the parameter estimations to better predict the potential outcomes of pandemics, reflect changes in the environment, human behavior, and public policies as the outbreak develops. It can provide meaningful insights to the containment strategies in real-time to better facilitate the decision-making process. It can also be adapted readily to accommodate newer disease propagation structures, additional stages introduced by intervention or hospitalization, and changes in the pattern of disease transmission, making it sustainable both theoretically and practically.

There are limitations to our study. Although the modeling framework we proposed is flexible and capable of modeling complicated scenarios, we used a relatively simple setup in the examples with homogeneous bird and human populations without any treatment or vaccination effects. Different bird species should have different infectivity rates for avian influenza, and the contact rate to birds differs between poultry farm workers and general humans. Antiviral drugs and vaccines against avian influenza also exist, and could be added to the model. These components require more parameters to estimate and may possibly lead to overfitting. However, with the availability of such data, these effects can be included in our modeling framework with additional compartments in both carrier and human populations.

Exploring the Design and Role of Mobile Apps for Healthcare Providers to Find Teratogenic Information

Lily Lei¹, Vishwas Shetty¹, Karan Gupta¹, Janine E. Polifka, PhD¹, Glen Markham, MBA², Sarah Albee², Carol Collins, MD¹, Gary Hsieh, PhD¹
¹University of Washington, Seattle, WA; ²RightAnswer.com, Midland, MI

Abstract

Healthcare providers (HCPs) caring for pregnant patients often need information on drug risks to the embryo or fetus, but such complex information takes time to find and is difficult to convey on an app. In this work, we first surveyed 167 HCPs to understand their current teratogen information-seeking practices to help inform our general design goals. Using the insights gained, we then designed a prototype of a mobile app and tested it with 22 HCPs. We learned that HCP’s information needs in this context can be grouped into 3 types: to understand, to decide, and to explain. Different sets of information and features may be needed to support these different needs. Further, while some HCPs had concerns about appearing unprofessional and unknowledgeable when using the app in front of patients, many did not. They noted that incorporating mobile information apps into practice improves information access, can help signal care and technology-savviness, in addition to providing an opportunity to engage and educate patients. Implications for design and additional features for reference apps for HCPs are discussed.

Introduction

Uncertainty about drug safety for pregnant women is a significant problem. Birth defects are common and affect approximately 120,000 children in the United States each year.¹ There is a high incidence of comorbidities such as diabetes, depression and autoimmune diseases in women of child bearing age. Thus, it is not surprising that nine out of 10 women are prescribed one or more drugs during pregnancy.² The use of prescription medications during the first trimester of pregnancy has increased more than 60% over the last three decades².

Healthcare providers (HCPs) who care for pregnant women are concerned about the quality and accuracy of the information that is available to their patients. If the information is inappropriately frightening, women may become unnecessarily anxious about the health of their fetuses and avoid taking a medication that actually improves the likelihood of a successful pregnancy. In extreme cases, a woman may unnecessarily terminate a normal, wanted pregnancy out of fear that an exposure may have harmed the fetus³. In other circumstances, a pregnant woman may have a teratogenic exposure that could have been avoided if she or her HCP had understood the hazard more fully.² Thus, those who care for pregnant patients need to stay abreast of current teratology information treat their patients’ illnesses effectively with minimal risk to the fetus, and address their patients’ concerns appropriately.

Keeping up with the constant flow of medical research can be a daunting task for any HCP because of time constraints. Mobile devices have become an indispensable tool for HCPs in the management of disease, health data sharing and patient communication. Their portability is perfectly suited to the vagaries of the clinical setting, where HCPs can access information resources at the point-of-care (or from anywhere) any time of day. Mobile devices can provide HCPs with immediate access to evidence-based information when access to personal computers is not always feasible, such as in exam rooms or visits in clinics. But would these apps be merely mobile ports of existing teratogenic risk databases? How might we leverage mobile devices to help meet the information needs of HCPs within the time constraints of a clinic visit? Further, while much prior research has examined how the use of Health IT affects patient-provider interaction⁴⁻⁸, relatively little is known about how providers perceive and adapt mobile apps for information seeking in front of patients. To answer these questions, we (1) conducted an online survey of HCPs evaluating their teratology information needs and their use of mobile apps for seeking this type of information, (2) developed a prototype mobile application based on what we learned from the survey, and (3) tested our prototype by asking local HCPs to think aloud while completing four clinically-relevant tasks.

Background: Pregnancy Drug Risk Information Seeking

HCPs use a variety of resources to stay current on drug information, such as books, colleagues, the primary literature, online databases and internet search engines. Large electronic databases such as Micromedex®, UpToDate®, Epocrates®, and Lexicomp® are used by many HCPs to obtain information about the risks associated with the use of drugs during pregnancy. These databases provide an evidence-based summary of the available literature on the teratogenic risks associated with the use of medications during pregnancy. But this
information is a subset of the broader clinical information and therefore does not always provide a comprehensive review and evaluation of the teratology studies that have been published. Moreover, the expertise of the individuals who have summarized the teratogen information for these databases is not always transparent to the consumer. These large databases are distributed on a paid subscription basis to major hospital and university libraries; so HCPs who do not have affiliations with these institutions are limited in their ability to access this information.

A few databases exist that are designed specifically for HCPs with pregnant patients (e.g. Briggs Drugs in Pregnancy and Lactation®, Reprotox®, Shepard’s Catalog of Teratogenic Agents®, and TERIS®). These databases provide an expert review and comprehensive, evidence-based summary of the fetal risks associated with the use of specific medications during pregnancy and lactation. However, most HCPs are not aware that these databases are available through some of the larger publishers, such as Lexicomp®, Micromedex®, RightAnswer.com®, and ToxPlanet® or that they even exist.

We utilize data from the TERIS® (Teratogen Information System) database for the primary content in our app. TERIS® is a computerized, peer-reviewed database designed to assist physicians or other HCPs in assessing the fetal risks associated with exposures to drugs or chemicals in pregnant women. The database consists of a series of agent summaries, each of which is based on a thorough review of published clinical and experimental literature.

**Background: The Use of Mobile Apps in the Clinical Setting**

A 2012 survey by Manhattan Research suggests a high adoption rate of smartphones for US physicians: 81% of those surveyed own a smartphone, and 87% of them use a smartphone or tablet device in their workplace. One of the key uses of mobile devices and apps is for reference and information gathering.

However, despite their increased usage and potential, a 2012 review paper on smartphone usage among physicians and students in medicine concludes that “very few high quality-studies exist to help us understand how to best use this technology [for physicians and students].” Much of existing studies about smartphone usage in the health context focus on smartphone use for telemedicine or from the patients’ perspective for self-tracking, self-care and communication with providers (e.g.,). There are much fewer studies on HCPs’ use of smartphones for decision-making in the clinical setting, and specifically there are “very limited data” on the use of reference apps by HCPs.

Research on more traditional forms of technology does suggest that the use of smartphone apps for HCPs can improve the quality of care. Studies on the use of PDAs for data management have found that PDAs facilitated the access of patient information during ward rounds. A study on nursing student’s use of PDAs also found that “the use of the PDAs in clinical practice enhanced communication skills and contributed to the quality of care they delivered.” It both enhanced their ability and their confidence to provide clear and quality information, quickly. Recent research on the use of other Health IT, such as EMR has also generally shown positive outcomes from use, especially supportive in terms of information related tasks. However, one important drawback is that their use had a negative impact on patient centeredness; reducing eye-contact and losing rapport with patients. Insights to address these drawbacks on desktop usage include improving HCP’s technology skills and changing their behavioral style. Others have also noted that collaborative viewing, or showing the screen to patients, can create a “common information space” to facilitate interaction between patient and doctors.

**Methods: Survey**

We began our work by developing and deploying a survey targeted to HCPs. The goal of this survey was multi-fold. First, we sought to understand HCPs’ teratogen information needs and behaviors when it comes to prescribing medication for pregnant women or counseling those who have been inadvertently exposed. In addition, we sought to explore the use and role of mobile apps for teratology information seeking by HCPs.

For the open-ended questions, three of the authors who have expertise in human-centered design and clinical teratology, analyzed the responses separately to generate category codes. They then discussed each of the responses and followed an iterative process of applying open coding and axial coding to discover relationships among emerging concepts until a consensus is reached.

**1. Recruitment and Participants**

We emailed our survey link to members enrolled in the Washington, Wyoming, Alaska, Montana and Idaho medical education network, the Washington Academy of Physician Assistants, Washington State Obstetrical Association, the Midwives’ Association of Washington State, the Washington State Perinatal Regional Network, Washington State Pharmacy Association, University of Washington Department of Psychiatry and Behavioral Sciences,
MotherToBaby of Arizona, MotherToBaby Utah, and Department of Health and Emergency Medicine Services in Colorado. Initially we offered $10 gift card for completing the survey. We raised it to $20 to increase participation.

A total of 225 surveys were initiated, out of which 167 answered all the questions (74%). 115 HCPs were female (69%), and the mean age was 39 years old, with a range from 23 to 70 years of age. The mean number of years in practice was 11.5 years, with a range from 0 to 43. The HCPs’ specialties included retail and clinical pharmacists (64%), physicians (13%), midwives (7%), physician assistants (6%), nurse practitioners (4%), and others (6%). The majority (63%) of pharmacists surveyed were specialty pharmacists who practice in medical settings and focus on therapy for patients with complex disease states.

**Results: Survey Findings**

When asked about their most recent incident where they sought teratogen information, the five most common inquiries were related to infectious (19%), psychoactive (14%), gastrointestinal (8.3%), pain (7.2%), and cold (5.3%) medication. To seek the information, the vast majority of the HCPs used online databases (86%), such as Epocrates®, Micromedex®, or UpToDate®. Others used textbooks (11%) and less frequently manufacturer’s website and package inserts (2%), and other clinicians (1%).

Almost half of the HCPs surveyed expressed dissatisfaction with their recent information searches (45%). The biggest problem noted was that the resources did not provide enough information. For example, “I wasn't very happy with the online databases that I have access to. They don't give much beyond the pregnancy category.” Relatedly, others noted being dissatisfied with having to access information that was spread across different sources. “There is no single, trustworthy, up to date resource for them to consult when it comes to drug use in pregnancy”. Usability and speed were also other issues noted by respondents. “Didn't like the layout in Briggs/Lexicomp - class effect data were emphasized over specific agent. Also - references had conflicting data.” And “info limited and not presented in easy format to understand. I think pregnancy categories should not be eliminated but refined.”

1. **Teratogenic Information Needs.** As part of the survey, HCPs were presented with a clinical scenario about a pregnant patient who is being treated with escitalopram and is concerned about its risks on her baby. HCPs were given the TERIS database output for escitalopram and were asked about its content. We found that participants also desire to have additional information on alternative drugs, breastfeeding, dosage, maternal disease and actionable recommendations. For our prototype, we incorporated this additional information into the mobile app.

2. **Usage of Mobile Apps for Drug Information.** In the survey, we also asked about the use of mobile devices to search for teratogen information. About 67% (112) of our respondents have used mobile apps to find teratogen information, with the most popular app being UpToDate® (53%), followed by Epocrates® (38%).

When asked about the major limitations of existing mobile apps, 106 responded. The issues reported were similar to what they had reported with their most recent teratogen information seeking experience. The main issues (52% of responses) were related to the amount and quality of information offered in existing apps. As one respondent wrote:

> Epocrates only gives an overall summary - no specific risks; Reprotox® can sometimes be hard to digest quickly if there's a lot of research; UpToDate® doesn't always list quality of evidence and is often the recommendation of the author based on studies, which, in my experience, don't always support the conclusions drawn.

Many simply desired a centralized database of information across pregnancy and lactation resources that contain concise summaries in addition to more in depth information and links to primary resources.

The second set of limitations was related to usability (22%). Many of these respondents noted challenges with finding and navigating information via a small screen, and a desire to have more intuitively organized content. Others pointed out that logging into the app and having it sync and update often takes too much time. The third set of limitations had to do with access and cost (18%). Some interesting points to note are: Mobile apps are not always supported by existing practices, so they are often out-of-pocket costs for HCPs; not all apps are available on all phones; a lack of access to the internet when the information is needed.

3. **Information Seeking in Front of Patients.** While we were initially concerned that HCPs would not be comfortable with using mobile apps in front of patients, we found that about 60% of participants were not concerned. In fact, more than a third of the HCPs (37%) reported that their most recent teratogen search was conducted in front of patients. When asked about specific concerns with using the app in front of patients, 65 HCPs responded. For them, the primary concerns are not appearing to be professional (40%) and being perceived as
incompetent (34%). A small number (9%) also mentioned that doing so may seem like they are doing something else, such as checking personal email and some (8%) are concerned that they are not sending the right message to the patients – “Patient might feel like it's something they can do as well.”

4. Survey Discussion

In general, our survey provided confirmation that an app dedicated to teratogen information would be valuable to providers. Both having a consolidated information source and disseminating this information in the form of a mobile app are useful. While there are some concerns about appearing to be unprofessional and unknowledgeable, many seem to be already incorporating the use of mobile apps into their clinical practices.

At the same time, these results offer insights on the types of information that should be included in an app, as well as indicating the need for effective information architecture and user interaction to support the often descriptive information about teratogens. Combining our survey findings with the new FDA guidelines that sought to minimize the oversimplification of teratogenic risks, we decided to focus on the following goals in design: (1) consolidate pregnancy and lactation drug information across multiple sources to create a single repository; (2) provide a concise summary and overview of teratogenic risk information without oversimplifying risks; (3) reference sources of information; (4) have an easy to use interface with navigation and search support to move between overview and detailed information; (5) provide author or editorial information to indicate the credibility and reliability of the information; and (6) provide patient education handouts.

Mobile App Prototype

After a wide exploration of ideas through sketching, followed by wireframes in increasing fidelity, we developed an interactive prototype design using Justinmind26, a prototyping platform.

The app’s homepage shows a list of drugs with an icon denoting the teratogenic risk (Figure 1a). Users can “search by drug” through an alphabetized list of all agents, or “search by condition” through a list of maternal conditions that will lead users to an alphabetized list of agents used to treat the selected condition. The drugs can also be filtered by their risk classification; “none,” “unlikely,” “minimal,” “small,” “moderate,” “high,” “undetermined,” and “variable.”

For each drug, we used the TERIS® database for the primary teratology content in our prototype. This includes brief information About the Drug, Risk Information and Comments, Research Findings, and References. To help HCPs fully explore the risks and the benefits of treating a pregnant patient, we added a section called “Clinical Considerations.” This section provided the following information (if available): Impact of disease on pregnancy; Dose adjustments in pregnancy; Drug-associated adverse maternal reactions unique to pregnancy; Fetal/neonatal adverse reactions; and Drug effects during labor and delivery. Further, using feedback from the survey, we incorporated information on breastfeeding, dosage, and a fact sheet for the patient. The individual sections use an expandable accordion design pattern to enable users to navigate to desired information quickly (see Figure 1b). To
help users assess the credibility and currency of information, we indicated when the drug information was updated right next to the “About the Drug” heading for each drug (the first line).

Another desired feature based on our surveys was for information about alternative medications that could be used to treat a particular medical condition. Thus, in our design, users can toggle between the summary or the alternative drugs screen, which features a full list of alternative agents to the current drug selected (Figure 1c).

One of the key challenges in our design is to effectively communicate the different teratogenic risk classifications used in TERIS®. The risk classifications for teratogenic effects in the children of women exposed to the agent during pregnancy range from “none,” “unlikely,” “minimal,” “small,” “moderate,” to “high,” and “undetermined” for agents that have an unidentified risk. For some drugs, the risk was considered to be somewhere between two ratings, e.g., drug may be assessed to have a “moderate to high” teratogenic risk if used during pregnancy.

To visually communicate these risks, we developed a color-coded system for the teratogenic risk classifications. Our final design utilizes a gradation of red circles. Red was chosen since it is commonly associated with danger. The higher the risk the more saturated the red is and the lower the risk the lighter the color. For the remaining risk classifications; “none” is represented with a white circle to symbolize no risk, “undetermined” is represented with a gray circle to symbolize unknown risk. (Figure 1e).

However, the risks for some drugs required more complex representations. For example, some of the drugs have different risk assessments depending on the nature and timing of the exposure during pregnancy, such as stage of pregnancy, dosage levels, or route of exposure. Other drugs had risks that fell between two gradations of risk (e.g., between “moderate to high”). For these, we developed a single additional symbol for “variable.” Our design for “variable” is represented with three overlapping gray circles to symbolize that some drugs may have more than one risk. We thought that this single classification would be sufficient to serve its main goal, which is to notify the HCPs that the risks for this drug may be complex and they need to read further to determine if the drug’s risk applies to their particular patient’s exposure (Figure 1d).

Methods: User Study

We conducted a user study to evaluate our app design. The study consisted of a 30-minute usability testing of the prototype, where we observed participants performing 4 tasks using our prototype. We then followed up the usability testing with a 30-minute interview. The interview enabled us to more broadly talk about the app and its potential for integration into their practice workflow.

For the usability testing, we asked the participants to complete four tasks using our prototype. These tasks were common clinical scenarios that we developed based on the survey results. The scenarios provided detailed information, and asked participants to (1) review five antibiotics and select one that might have less risk to the fetus, (2) review evidence-based risk information for escitalopram for a pregnant patient, (3) find a list of drugs that have a high teratogenic risk and should be avoided during pregnancy, and (4) evaluate the risk and benefits of using ondansetron or an alternative medication to treat hyperemesis gravidarum. Each of the tasks took about 5 minutes to complete. During the tasks, the participants were asked to vocalize their thoughts, feelings, and opinions while interacting with the prototype (think-aloud). After each task, they were asked a few questions about the task. Upon completion of the four tasks, participants were asked to fill out a questionnaire which contained the System Usability Scale (SUS), which is a ten-item attitude Likert scale often used to assess usability.27 The questionnaire also included questions about participants’ demographics.

Throughout the study, we audio recorded the participants think-aloud sessions, as well as screen-captured their interactions with the mobile prototype. For analyses, we first had the study sessions transcribed, then we used the similar procedure in analyzing the open-ended survey responses.

1. Participants

HCPs from our survey who were local and expressed interest in participating in the app testing were contacted for the study. In addition, we contacted HCPs through the Washington State Department of Health and by word-of-mouth through some of the authors’ colleagues.

Twenty-two HCPs who often worked with pregnant patients were recruited to participate in our usability study. Their ages ranged from 27-63 years. The number of years they have been in practice ranged from 1-35. Their specialties included: Family Medicine physicians (7), Naturopathic physicians/nurse practitioners/midwives (6), Medical geneticists/genetic counselors (3); Obstetricians (3); Pharmacists (2); Psychiatrist (1).
**Results: User Study Findings**

Overall, participants completed the tasks with ease. When asked “how easy or difficult was it to find the information you were looking for” after each task, all of the tasks had a median rating above 4 (1 is very difficult and 5 very easy). The most common reason participants gave for assigning a low score to a task was “unfamiliarity with the app”. Once participants became familiar with the app they found the subsequent tasks much easier to complete. The overall SUS score of 80.8 is considered in the A level (the top 10% of SUS scores). It is important to note that participants reported that the four tasks used in the study represented commonly encountered clinical scenarios.

In terms of content provided, participants appreciated the consolidated information. “I like this [app] because the information is consolidated, and there's less noise. You're not looking at other stuff. It's focused on pregnancy.” (P5). They specifically complimented us on the inclusion of lactation information, patient Q&A handout, and providing the alternative drug list. Many of them asked when the app will be available for download.

1. **Three Types of Risk Information Needs**

In terms of risk classification designs, participants thought the design from lighter to darker was fairly intuitive, and were able to describe what the different colors meant, after some usage:

*Having looked at it a few times, the dark red I know means high risk, the three little bubbles I know is variable. It makes intuitive sense to me lighter to darker. I think it would just take some [time] to [get used to] it.* (P3)

However, some participants noted that the different levels of red were not memorable and sometimes hard to distinguish. Some also thought the TERIS® risk classifications were unclear since they were unable to discern the subtleties in gradations of magnitude of teratogenic risk, e.g., between “minimal” or “small.” Many even specifically asked us to include the FDA Pregnancy Categories that have been discontinued by the FDA, not realizing the change in guidelines. One potential interpretation is that HCPs need more time to adjust to the TERIS® risk classifications and a clear legend or onboarding should be added to the app to help. However, we believe there is a deeper underlying issue. There is a mismatch in what we sought to design (an informational tool), and what the HCPs generally need (an easy to use decision aid). In fact, the HCPs indicated three types of risk information risks.

**To Understand.** One of the key goals of teratogen information seeking is to learn and understand the fetal risks associated with the use of a drug during pregnancy. Indeed, in our scenarios, some participants spent a lot of time reading through the detailed teratology information as they were completing the tasks. When asked about the amount of information presented and whether they were overwhelmed, one said: “If I’m looking it up, I want that much information” (P2).

This level of detailed understanding is often needed when HCPs are exploring drugs they have not used before or if the preliminary results from searching contradict their preconceptions or when they are counseling a pregnant patient about her chances of having an adverse pregnancy outcome.

*If I am trying to counter what I normally do, like what’s my custom and practice or If I am having a question about why I wouldn’t do the things I would normally do, then I want more information than I already have. That’s primarily how I would use something like this, for something that is not already in my head.* (P4)

**To Decide.** But to understand is not the primary use for the app. Most HCPs primarily perceived the app as a decision aid. This can be seen in how the HCPs approached our scenarios. When asked to prescribe one drug out of a list of five that poses less risk to the fetus, many participants simply started with a drug they know from experience that has a minimal risk, and stopped immediately when the app confirmed that drug’s risk is minimal. They tried to base their decisions simply on the risk ratings and risk comments when possible. As one participant said:

*As a practitioner or provider, not necessarily the pharmacist, but a doc will look at this and only want to know, is the risk information, general risk data, good. And honestly that’s the bottom line. Then they’ll read more if they had time. But if they’re the exam room with the patient, they just want to know what’s the risk, what’s the data... You know, is there data, and if there’s not very good data or something like that, then they’ll go ahead and read more... Right there it tells me, minimal risk, good data, and I’m sold. They would be, too.* (P1)

This decision-aid view of risk visualization also helps explain why some of the participants thought the eight different types of risks were excessive, and that varying the gradient of the red was not an optimal design. With the
8-level risk ratings as offered by TERIS®, HCPs may perhaps gain more nuanced understanding for the differences in teratogenic risk across drugs. However, for the purposes of deciding what to prescribe, HCPs tended to think in terms of three distinct tiers of risk – safe, not safe and maybe safe. In which case, having three distinctive types of colors might be more effective (e.g., green for safe, red for not safe, and yellow for maybe safe). One HCP said: “It’s almost 3 categories for me. I think of medications as ones that are safe and can be prescribed, ones that are not safe and ones that depend on the situation” (P15). Another: “In my mind, I lump minimal, unlikely, and none all together…I would clinically use them with the same frequency” (P3).

That is also how they used the outdated FDA Pregnancy Categories, which had five levels, A, B, C, D, & X. Some HCPs felt that any drug assigned an A or B category was safe to prescribe in pregnancy and others considered drugs in categories A, B, and C to be safe. For example, one HCP said “once you saw A and B, you were good to go and didn’t have to fuss much. (P6)” Whereas another said “we know in our minds X means teratogenic, and then pregnancy category D…might be some harm and so have to look at risk benefits, and then ABC we’ll all lump together and think it’s all fine. In our heads, we think it’s a quick way to separate out the drugs. (P3)”

To Explain. We also found that an important third usage of the teratogen information is to help HCPs explain their recommendations to the patients. Some of the HCPs would use the information in the app directly to corroborate what they are saying to the patients. “[Using it] demonstrates to the patients how I approach a scenario as a clinician and make lifestyle changes to benefit their health in general. It also helps to validate what I’m saying and not that I’m just saying stuff” (P14).

At the same time, HCPs also talked about the need to translate the information to terms that patients can understand. The detailed information provided can help the HCPs understand the teratogenic risks associated with the drugs themselves, but patients have a difficult time weighing the risks with the benefits when the risks are uncertain or the data are difficult to apply to their particular circumstances. For example, when HCPs saw “odds ratio” presented in the app, they wondered: “what’s a number that I can translate to a patient so they can understand” (P3). They also talked about the benefit of having clear descriptions of risk ratings as it “gives a little bit of language when you are explaining to a patient” (P4).

2. Benefits and Challenges of Mobile Information Apps in Clinical Settings

Another question we sought to answer in this work is whether a mobile app can provide additional value to providers over existing databases that are accessible through desktops. Through our study, we found a number of potential benefits to having teratogen information on an app.

Access. Prior research has found that the use of personal digital assistants (PDAs) can improve information access for HCPs. Similarly, when asked about potential uses, HCPs conveyed that having the information on the app enabled more flexibility in use. One example is using it during in-home visits. “I attend out of hospital births and do in-home visits. Which is another reason that [having] many of these tools not on a laptop is helpful” (P4). HCPs also talked about using the app as they moved between rooms at the hospital since it can easily fit in their pockets.

Another set of benefits related to access is the speed and efficiency of use. Many HCPs indicated preferences for using the app for information seeking even when other machines were within access. They argued that the app will be faster to use without having to move in and out of other applications already running on the other machines. It also helps keep the different machines and their tasks separate, e.g., keeping the desktop dedicated to EMR.

It all comes down to speed and efficiency. If a question comes up while in a room with a patient, I have to be able to quickly access [the information]. I am just such an app person. I am just much more inclined to use an app than a website. (P3)

I have my EMR, schedule, and my email going; a lot of time I’ll open a separate function on my phone so I don’t have my EMR shut down. Also, because I have my phone, apps are pretty easy to use on it. (P4)

Technology Savviness. Another potential benefit of using a mobile app for information seeking is that it can demonstrate technology-savviness. As one HCP said: “I used to worry that they are going to think I’m not smart enough. Now I think patients will think you are more tech savvy if you’re able to show them where your data sourcing is and [is] current” (P3). And as another pointed out, “Using an app looks better than having to get the textbook out” (P8). However, there are a couple of important caveats to note. One is that this perception of technology-savviness may depend on the patient population. As P3 also mentions, it may also be because in the area where she practices the patients are generally technology savvy and the patients have themselves adopted the use of
mobile devices and apps. Second, the perception of being technology savvy is likely to depend on the HCPs’ technology use skills. As another mentioned:

*I think my only objection to looking for stuff in front of the patient is not knowing whether I am going to have a hard time finding something. If I feel like it is going to be a challenge to find something, I am not going to do it in the room. I don’t want them to see me struggling looking for the information.* (P10)

**Opportunity to Teach.** Another potential benefit of using the mobile app for teratogen information is that it provides HCPs an additional opportunity to engage the patients and to teach them. As suggested in prior work, engaging patients in the information search process can be valuable and is being practiced.

*The process can also enable HCPs to provide insights about credibility of information and help improve literacy: “I like to show patients where to get reputable information. I like to show them ‘where I’m looking up the information.’ I show them how to navigate the site and find relevant information.”* (P13)

There are pros and cons, however, with the use of mobile devices for cooperative information search. The benefit is that it is easy to just turn the phone around or give it to the patients so they can look at it (“Yeah I just pick it up and show it to them,” P4). However, compared to the computer, the small screen size makes it harder for both to look at the information together.

**Demonstration of Care.** Based on our survey results, it seems that some of the HCPs are concerned about using mobile apps in front of patients because they may be perceived as not being competent. However, some HCPs think that doing so may actually help demonstrate that they care. That they would take the additional step and time to look up something:

*When you stop and when you are looking up something, the patients are very interested that their doctor cares enough. I don’t think it shows a weakness that you don’t know the answer to the newest drug. They look at it positively saying “the doctor is looking up something specific to me. He cares about me.”* (P6)

*I’m usually transparent. I would like to be sure I’m giving the right dose, so I am going to look it up. I haven’t gotten complaints where they thought “their provider is an idiot he doesn’t know anything.” I think it’s saying I care. I want to do it right; I want to provide the right dose. No one’s ever complained about that. Safety first.* (P7)

**Discussion**

In this work, we present a design of a mobile teratogen-related information app for HCPs. We sought to address several key challenges with disseminating the information. We designed our app to consolidate different information types that are currently sought for by HCPs but spread out across different resources, as identified through our initial survey. Further, we examined the feasibility of displaying this information on mobile devices, where screen real estate is limited. We organized the in-depth information into expandable sections, and provided meta-level information about when the information on the app was last updated, in addition to editorial information. Through our study, we found that HCPs were able to complete a number of common tasks using our app and did so with ease. They also found the information presented to be valuable. However, we also uncovered challenges and opportunities in designing an app to convey health risk information, and the use of the mobile apps in the clinical setting.

**I. The Three Different Needs for Risk Information and Implications for Design**

With our design, we focused on supporting HCPs’ need to understand a drug’s potential for teratogenicity, particularly in situations where a pregnant patient has already been exposed to a medication and wants to know the likelihood that her baby will be born with a birth defect. We consolidated as much information as possible into the app, and chose a systematic approach for assessing risk that is fine-grained; one that offers 8 gradations of risk in addition to providing information about the data quality. The risk assessment is followed by a succinct narrative that describes and interprets the scientific evidence. Our app did well to support this need to understand.

However, what we found was that HCPs primarily need the app to help them make decisions about prescribing a medication during pregnancy. Given their constrained time, they often just want enough information to decide: safe, unsafe, or maybe safe. In other words, how they want to use the app and the risk ratings, is exactly what the FDA hoped to move away from when they discontinued the Pregnancy Categories. Thus, one of the challenges in using mobile technology to assess potential teratogenicity of a medication is how to compress a large body of complex (and often conflicting) data for quick decision aid without sacrificing critical aspects of the risk-benefit discussion. In fact, we believe this is a critical design challenge that generalizes to risk communication in the health domain.
One possible solution is to prepare interpretative statements for those agents that have substantial and/or conflicting evidence. This executive summary would include the risk ratings, dominant research findings, the context (dose, stage of pregnancy, etc.) for these findings (if known), recommendations for use during pregnancy, and preferred alternative drugs, if any. Topic-specific links would enable HCPs to quickly select the content most closely-related to their patient’s situation. HCPs also discussed factors other than risk that they would like to include in the app to support decision making, such as the costs of drugs and whether the drug is available over the counter.

Finally, we cannot overlook the importance of designing the app to help HCPs better explain risk to patients. In our design, we have included handouts that HCPs can print out to patients and they all appreciated that. Additional features such as being able to directly email portions of the information on the app to patients, or printing it out are also desired. But we also found that designing the information presentation to help HCPs translate the information to patients is valuable and needs to be considered in apps like these.

2. Successful Point-of-Care Integration of Teratogen Information into Clinical Workflows in Healthcare

Another goal of this work is explore the use of mobile apps for teratogen information in the clinical context. Our findings suggest several ways that the mobile app can be utilized and benefit patient-doctor interaction. Its use can provide HCPs access to information when they are away from other technology access. But even when they are in proximity of other technologies, using the app for information search might be quicker and minimize interference with other tasks. Aside from access, the app can also be used to demonstrate to patients that they care and that they are aware and proficient with new technologies. Further, its use in front of patients also provides HCPs an opportunity to engage and teach patients. As information becomes more accessible to patients, using the apps in front of patients enables HCPs to teach effective information seeking practices.

However, as we have found in our survey, a large number of HCPs have been slow to adapt the use of mobile apps in their practices and expressed concerns about appearing to be distracted or unknowledgeable. We believe part of the reason for the difference in perceptions about mobile app usage in the clinical practice is that HCPs work with different patient populations. Some work with patients where the mobile apps are highly adopted. Patients may expect their providers to be technology proficient and adopt a multitude of mobile-based tools. In addition, patients may also be accustomed to the use of mobile apps for general information seeking in their daily experiences and are less likely to perceive it negatively. Another reason for underutilization of mobile apps by HCPs may be the lack of wireless capability in some clinical settings.

But like general Health IT usage, we believe there are general strategies that can be employed to make the integration of mobile information seeking by providers in a clinical setting to be more successful. If HCPs can clearly communicate what they are doing and why they are doing it, there is no reason why the app usage needs to be perceived as negative (or any more negative than if the HCPs were to use any other resources). Further, effective engagement of patients in the process will decrease misperceptions from patients that apps are being used for personal reasons in addition to providing additional opportunities for HCPs to educate the patients.

Conclusion

In this work, we present an exploration of a mobile app prototype to support teratogen information seeking. Aside from the prototype itself, this work also contributes to the ongoing question of how to effectively present pregnancy drug risk information. Our results suggest that part of the challenge stems from the complexity and uniqueness of teratogen risk information and the different information needs of the providers – need to understand, to decide, and to explain. We suggest different features to support these three types of information needs. In addition, our findings also advance our understanding of the potential role of mobile health information apps in HCPs’ practices. Access to this type of information through mobile devices enables flexible uses (e.g., on the go), is quick and limits dependency on desktops that usually already have EMR and other applications running. Further, using apps in front of the patients may lead to potential benefits such as signaling physician care and tech-savviness, in addition to having additional opportunities to engage and educate patients. These insights can help facilitate designing for mobile apps for HCPs during provider-patient interactions.

Acknowledgement

This study was supported through SBIR Grant 1R43DD001127-01 awarded by the Centers for Disease Control & Prevention in an effort to improve medication safety for pregnant women. The authors are grateful to the HCPs who generously gave their time to participate in our study. We thank Margaret Adam, Amy Bauer, Angela Chien, Debra Doyle, Ira Kantrowitz-Gordon, Theresa O’Young, Mary Puttmann-Kostecka, Bat-Sheva Stein and WWAMI for...
their help in recruiting HCPs for the study. We would also like to thank Jina Huh, Yunan Chen, Richard Boyce, and Wanda Pratt for their feedback on this work.

X Marks the Spot: Mapping Similarity Between Clinical Trial Cohorts and US Counties

Matthew C. Lenert, BA¹, Dara E. Mize, MD², Colin G. Walsh, MD MA (Primary Advisor)²

¹Vanderbilt University, Nashville, TN; ²Vanderbilt University Medical Center, Nashville, TN

Abstract

When patients and doctors collaborate to make healthcare decisions, they rely on clinical trial results to guide discussions. Trials are designed to recruit diverse participants. The question remains – how well do trial results apply to me or to people who live in our area? This study compared one complete clinical trial dataset (SPRINT) and one published study (ACCORD) to the Community Health Status Indicators dataset to assess the similarity of the trial populations to US county populations. Counties up to 495 miles to the closest SPRINT trial site and up to 712 miles to the closest ACCORD trial site had populations that were significantly more similar to the study cohort than counties farther away. The investigators detail a generalizable method for both assessing recruitment gaps in large multicenter trials and creating maps for clinicians to provide intuition on trial applicability in their area.

Background

The growing movement towards patient-centered care is an effort to improve the quality of health care delivery, thereby leading to a greater focus on shared decision making and evidence-based medicine¹. Under the shared decision-making model of patient care, it is the role of the clinician to present the best applicable clinical evidence. The role of the patient is to share their preferences and values. The physician then seeks to apply their clinical judgment to determine which therapies, diagnostic tests, and/or preventative services best fit their patient²,³. Randomized clinical trial (RCT) data often serve as the foundation of clinical evidence on which these decisions are made⁴,⁵.

The amount of data available for clinicians to digest continues to increase and integrating the latest study at the bedside or in clinic poses a challenge for practicing providers⁶,⁷. It is difficult to know – in practice and in real-time – how well a trial’s results apply to one’s patients. This task is further complicated with pervasive difficulties in determining the validity of study findings⁸. For example, the ratio of screened patients excluded from randomization has direct implications for the significance of trial results⁹. Studies may report surrogate outcomes that do not correlate with patient-valued outcomes (e.g. reporting changes in bone density for patients with postmenopausal osteoporosis is not the same as measuring rates of long-bone fractures)¹⁰. Treatment effects can be nonlinear across disease states, making the average effect deceptive¹¹. Providers often look to systemic reviews and meta-analyses as tools to consider these nuances.

Meta-analyses aggregate evidence by summarizing results to estimate an overall trend across many sample populations, but they have some stark limitations¹². It is difficult to produce a high quality meta-analysis, because one has to account for studies of varying external and internal validity in their designs. This heterogeneous mixture makes it difficult to focus on the scientific scale, and many analyses instead focus on the clinically removed statistical scale¹³. These limitations are the same limitations faced by providers, so it is not surprising that they are strong confounders.

Instead of pooling data from many small trials, there is a renewed push for building infrastructure to support large pragmatic-randomized-multicenter trials comparing an experimental treatment to the standard of care¹⁴. These trials recruit patients across the country and are carefully crafted to control for confounders. Despite accounting for population differences through the use of many sites, selection bias persists¹⁵. This bias affects the generalizability of trial results to the population at large, because the number of patients that participate in clinical trials may be a fraction of those seeking routine care¹⁶,¹⁷. Even in trials of tens of thousands of patients, trial samples may demonstrate differences from the population at large. Differences can manifest themselves in comparative functional status, age, and the number of comorbidities¹⁸. Trial results should hold for patients who are similar to trial participants, but there may be complex screening criteria or differences in subgroups that complicate comparisons¹⁹. Even at the highest level, measuring applicability of a study to the population at large remains a grand challenge.

A method to quantify similarity would help address the applicability gap. Researchers have used multiple definitions for patient similarity. The IBM TJ Watson group developed systems that combine supervised and
unsupervised approaches\textsuperscript{20,21}. Their system applies decentralized physician feedback to improve upon the base measure of similarity—in this case the Euclidean distance of a vector of clinical features for a pair of patients. The feature vector was made up of clinical variables such as International Classification of Disease (ICD) codes and objective clinical readings (e.g. blood pressure). Lee et al. took a similar approach, where they selected specific clinical features and put them into vector representation\textsuperscript{22}. This step enabled them to apply the cosine distance metric to quantify pairwise similarity, Zhang defined similarity as the Jaccard similarity over the set of ICD codes in the problem list between two patients\textsuperscript{23}. Panahiazar et al. used k-means clustering to quantify similarity as the Mahalanobis distance between a patient’s feature vector and the centroids of clustered training patients\textsuperscript{24}. There has been some exploration of making trial characteristic comparisons directly. In a small study, Cahan and Cimino devised a model that visualized where a patient would fall within the distribution of clinical and demographic features of an RCT cohort\textsuperscript{25}.

Most of these efforts focused on comparing a single patient to another patient or cluster of patients. A pairwise comparison is not ideally fitted for the problem at hand, since clinical trials tend to summarize characteristics of the cohort as well as the treatment effect. A clinical trial cohort has a distribution of clinical characteristics, while the individual patient has discrete characteristics. For example, the prevalence of smoking in the trial cohort might be 15%, but an individual currently smokes or does not. This suggests that it may be more tractable to compare the characteristics between two groups. Abstracting to the group level may lead to insights into how similar trial patients are to the local population. The investigators hypothesized that clinical trials record sufficient demographic, comorbidity, and adverse event data to readily produce a means of comparison with U.S. county-level health statistics. A quantifiable measure could then be mapped to give physicians an expedient intuition into how an RCT’s population compares to the people they see day to day. This measure may not sway a provider’s decision for a specific patient, but it may inform the (prior) probability they would recommend a specific therapy in the first place.

\textbf{Methods}

\textbf{Data Sources}

This study analyzed the complete dataset from the SPRINT Group’s blood pressure trial as well as the published data from the ACCORD Group’s type 2 diabetes trial\textsuperscript{26,27}. This study received IRB approval and completed a data use agreement to gain access to the SPRINT trial data. The SPRINT trial was a large pragmatic RCT that involved 9,361 patients across 96 clinical sites in the United States and 6 sites in Puerto Rico. This trial compared intensive blood pressure control to standard of care for patients with hypertension. The trial controlled for comorbidities such as chronic kidney disease, and several medication classes such as statins. The trial followed a clinically relevant primary outcome of myocardial infarction (MI), non-MI acute coronary syndrome, stroke, heart failure, or death attributable to cardiovascular disease. The SPRINT Group followed patients for a median of 3.26 years. The SPRINT trial planned demographic subgroups of: African-Americans, non-African Americans, ages less than 75, ages greater than or equal to 75, chronic kidney disease (CKD) present at the start of the trial, and CKD failure, or death attributable to cardiovascular disease. The SPRINT Group followed patients for a median of 3.26 years. The SPRINT trial planned demographic subgroups of: African-Americans, non-African Americans, ages less than 75, ages greater than or equal to 75, chronic kidney disease (CKD) present at the start of the trial, and CKD absent. The SPRINT trial is largely regarded as a model multi-site RCT for both its rigorous design and its methodical implementation.

The ACCORD group’s trial preceded the SPRINT trial by eight years and studied the effect of intensive control of glycated hemoglobin levels in patients with type 2 diabetes. The trial was a multi-site pragmatic trial that randomized 10,251 patients across 62 clinical sites in the United States and 15 sites in Canada. The ACCORD trial limited comorbidities and controlled for relevant demographic factors for cardiovascular and diabetic complications. The researchers also controlled for several medication classes such as beta-blockers and glucophages. The ACCORD trial measured the primary outcome of nonfatal myocardial infarction, nonfatal stroke, or death from cardiovascular causes. This trial planned for the following demographic subgroup analyses: age less than 65, age greater than or equal to 65, Caucasian, non-Caucasian, males, and females. The ACCORD group had an average follow-up period of 3.5 years. The ACCORD trial is another model exemplar of a pragmatic multi-site RCT.

The county health statistics came from the Community Health Status Indicators (CHSI) Dataset published by the Centers for Disease Control and Prevention (CDC). The CHSI dataset contains county-level social, environmental, and prevalence health data\textsuperscript{28}. This dataset is composed of a variety of CDC and Census Bureau studies from 2002 through 2014. It covers a wide array of disorders, diseases, and social behaviors. Its wide coverage of demographic and disease information at the county-level made it an ideal choice for this application. The investigators looked to map demographic and outcome data from the SPRINT and ACCORD trials to demographic and prevalence statistics from the counties based on the hypothesis that patients from a similar population should display similar features.

\textit{Mapping Between Data Sources}
Mapping variables from one data set to another requires input from clinical experts to ensure that nuances from the trial variables are accounted for and that the comparisons make clinical sense. The investigators established that a CHSI variable was comparable to a trial variable if and only if both physician authors agreed the comparison was reasonable. Demographic features such as obesity, smoking prevalence, and African-American race, mapped easily between the CHSI data and the SPRINT trial. The investigators assumed correlation between incidence rates of adverse events in the SPRINT control group and age-adjusted death rates in the CHSI county data. Outcomes of control patients were averaged to compare the prevalence of cardiac event and death, as well as stroke and death from the SPRINT control group to Coronary Heart Disease (CHD) death rates and stroke death rates in the CHSI data.

For the ACCORD trial the authors mapped the demographic features of African-American race, Hispanic race, and smoking status. The authors again used CHD death rates from CHSI and cardiac related deaths from the published data. The authors did not have access to the full ACCORD trial data; which prevented the inclusion of more features, such as the prevalence of obesity.

After selecting the variables for comparison the investigators needed to perform additional processing of the CHSI data set to ensure as fair a comparison was made as possible. Direct comparison between CHSI and trial variables is not advised, as trial participants are generally recruited conditional on the presence of some disease, disorder, or clinical state. For example, the SPRINT trial only recruited patients who had hypertension and the ACCORD trial only recruited patients who had type 2 diabetes. Patients with type 2 diabetes and patients with hypertension are subgroups of the general population, which may have markedly different characteristics.

**Missing Data**

The investigators did not find missing values in the CHSI data to be predictably missing (missing not at random). Therefore, the authors assumed that values in the data were missing at random. Predictably missing variables suggest bias in how the data were collected or how participants responded. Mean imputation was used to fill in values for variables with less than 3% (60 of 3,141 counties) of values missing. The authors used this threshold because the cost of computation time and complexity outweighed inferential benefits. The investigators used the mean of the state for mean imputation of missing county values.

Multiple imputation was used to fill in missing county values for variables with more than 3% of the feature missing. In multiple imputation, one uses a model to predict what the missing value would have been based on data one does have for that case. The investigators built one model per variable that had missing values. A bootstrapped elastic net (mixture of L1 and L2 penalty) penalized regression was used to select the features for each imputation model. Each model used all fully recorded demographic variables, features that were completed with mean imputation, quadratic, cubic, and log transforms of all features, and all interaction terms of first order features. The hyper-parameters (penalization for small regression coefficients and the ratio of L1 regularization to L2 regularization) of the elastic net regression were re-tuned for each bootstrapped sample over 200 bootstraps. The investigators optimized the hyper-parameters by minimizing the log loss of the model on the “out of bag” data. Once the most significant features were selected through the bootstrapped elastic net, the investigators needed to determine the effect or weights of those features before being able to predict the missing values. This required fitting the models over another 200 bootstraps where hyper-parameters were again retuned on each bootstrap. The resulting effects (coefficients) are the average of the coefficients for the 200 bootstrapped models. The variance of the imputed coefficients is the calculated variance from those 200 bootstrapped models.

**Conditioning on Disorders**

All CHSI variables required probabilistic conditioning on hypertension for the SPRINT trial and type 2 diabetes for the ACCORD trial. This step is crucial because all SPRINT trial participants have hypertension and all ACCORD trial participants have type 2 diabetes. The CHSI dataset is made up of multiple county averages over time along with the variance of that measure. The investigators used these moments to define a normal distribution for the county average of the various mapped variables (e.g. stroke deaths). The investigators needed to assume that each mapped variable was normally and identically distributed within a county for the years 2003-2014. This assumption means statistics over different years for the same county are independent and identically distributed. The investigators estimated the correlation parameter using a national average correlation of each variable and the conditioned variable (e.g. the correlation between obesity and hypertension).
Measuring Similarity

Similar to previous work, the investigators used feature vector representation to enable comparisons between a county and the trial population. Similarity was defined as the cosine similarity between a county feature vector and the average of the trial controls. For the SPRINT study, the feature vector was made up of the average rate of CHD death, stroke death, obesity, active smoking status, and African-American race. The investigators found the cosine similarity of each county vector to the SPRINT control group average. The same procedure was applied for the ACCORD trial control group. The cosine similarity measures were normalized and scaled to fall between 0-100, where larger values represented greater similarities.

Geographic Information System (GIS) Methods

CHSI data are keyed by state and county Federal Information Processing Standard (FIPS) codes. For example, Davidson County (county FIPS 037) in Tennessee (state FIPS 47) can then be mapped to other public data sources such as census data. The FIPS codes can be linked to GeoJSON data from the U.S. Census Bureau. The U.S. Census Bureau mappings allowed the conversion of FIPS codes to county border coordinates on GIS maps of the U.S. The investigators used SciPy and Folium (an open sourced package) for this process. The package allowed the investigators to illustrate the similarity of SPRINT/ACCORD participants to the people with hypertension or type 2 diabetes living in each county.

Statistical Analysis

The investigators sought to quantify if counties near trial sites were in fact more similar than those farther away. The investigators used latitude and longitude distances from the centroid of each county to the nearest trial site. The definition of “near” a trial site was increased one mile at a time starting at a radius of five miles. Figure 1 provides an illustration of the process of defining “near” and “far” sites. At each increment, a Wilcoxon Rank Sum test was used to examine if there was a difference in medians between the “near” sites and the “far” sites. The investigators repeated this procedure until no statistically significant difference, factoring in a Bonferroni-Holm correction, existed between counties “near” a trial site and those “far” away. The thought behind this procedure was that trial sites would mostly recruit patients within their geographic sphere of influence. However, as one expands the definition of “near”, differences should wash out as the average of the “near” group of counties becomes more like that of the “far” group of counties.

![Figure 1. Example of Near/Far County Definition From Vanderbilt University Medical Center (VUMC) Trial Site](image)

The investigators also analyzed if similarity had any correlation with differences in the rate of primary outcomes for the intervention group, essentially whether similarity was clinically meaningful. To begin this analysis, the investigators grouped the SPRINT participants by trial site. Next, the investigators calculated the similarity of the site-specific control group to the entire trial control group average, using the same feature vector of CHD death, stroke death, obesity, active smoking status, and African-American race. The investigators defined clinical significance as the absolute value of the site-specific difference in the primary outcome rate for the intervention group with the trial average primary outcome rate for the intervention group. Basically, does site similarity to the trial average (as measured by the control group) explain divergence in effectiveness of the intervention in the intervention group? Robust regression was applied to the measure of clinical significance with the following explanatory variables: similarity, number of participants at the site, and an interaction term. The investigators used the number of participants and the interaction term to address issues with discreteness. For example, a site with 3 participants can only observe rates of 0%, 33%, 67%, and 100%; such quintiles are far from a continuous measure.
Robust regression makes a Huber-White correction to the model variance, which often widens the confidence intervals for the model coefficients.

Results

The characteristics of the CHSI dataset are summarized in Table 1. All of the variables except for African-American race and Hispanic race appear to be symmetrically distributed. Symmetry is important for the rapid convergence of the sampling distribution (county measures over different years) to the normal distribution. The CHD variable was the only variable with missing values subjected to mean imputation (less than 3% missing). All other variables with missing values went through the multiple imputation pipeline. Table 1 and Table 2 are summarized to the national level for readability, but all the analysis was done at the county level.

After imputation, the CHSI variables were scaled to probabilities and transformed into conditional probabilities, e.g. the probability of smoking given hypertension (SPRINT) or type 2 diabetes (ACCORD). Table 2 reports the conditioned national averages at the 95% confidence level. Again, the analyses of this study took place at the county level, not the national level, making Table 2 a summarized view of the data.

The investigators compared each county data point to the average mapped characteristics of the trial control groups. The investigators used the trial control groups, because some of the features used were part of the primary outcome measured (CHD death and stroke death). These variables would likely be confounded by the intervention. Table 3 visualizes what the trial populations looked like for both the SPRINT trial and the ACCORD trial.

Figure 2 visualizes the similarity of all US counties to the SPRINT trial. The pins represent SPRINT Trial sites and were placed by latitude and longitude independent of the shading. The darker shading in the figure corresponds to greater similarity between that county and the SPRINT control group. One can see that the South Eastern United States has the greatest concentration of both trial sites and darkly shaded counties.

Figure 2. Applicability Map of SPRINT Trial to US Counties

The distribution of similarity scores is not symmetric across the similarity range. Similarity tends to cluster in two places, around a similarity of 60 and around a similarity of 95. The histogram does not describe an obvious distribution. Similarity also appears to have more significance in relative terms than in absolute terms.

Figure 3. Distribution of SPRINT Similarity Across U.S. Counties
Figure 4 shows the applicability scores of the ACCORD trial to each US county. One can see again that the South East and Eastern seaboard appear fairly well represented by the trial population. The western and central counties appear tend to be less similar.

The distribution of similarity for the ACCORD trial, shown in Figure 5, also appears to be bimodal and asymmetric. In this histogram, similarity is concentrated around 75 and around 98. Similarity also appears to be more concentrated and less differentiated than in the SPRINT trial.
The investigators tested if the similarity of counties near trial sites was greater than counties farther away from any one trial site. For the SPRINT trial the investigators observed a statistical difference in similarity between near counties and far counties up until the inflection point of 495 miles from the nearest trial site. Past this distance, similarities no longer differed between the two groups. In the ACCORD data, differences in control group similarity between counties near trial sites and counties far from trial sites were significant up until 712 miles. Note that these distances are measured from a trial site to the geometric center of a county.

When assessing if similarity had any correlation with differences in intervention outcomes the investigators wanted to get a sense about the distribution of differences across sites. Figure 6 presents a box plot of differences in the rate of primary outcomes (in the intervention group) by SPRINT trial site. Note that in the SPRINT trial, the primary outcome was a negative (MI, non-MI acute coronary syndrome, stroke, heart failure, or death attributable to cardiovascular disease). The distribution is centered at zero, but deviances are skewed toward higher rates of the primary outcome than the average.

![Figure 6. SPRINT Intervention Group Difference in Primary Outcome Rates Grouped by Site](image)

The next part of the analysis took the absolute value of all the site intervention group differences and regressed them on site control group similarity, total number of patients recruited at the site, and an interaction term. Table 4 shows the confidence intervals of all the regressors for this model. Both similarity and the number of site participants were statistically significant predictors. The interaction term was not significant, but was left in the model because it had a significant contribution to the model $R^2$. This simplistic robust regression was able to explain 36% of the variance of site-specific intervention group differences in the rate of primary outcomes. The similarity coefficient is negative meaning that greater similarity leads to smaller differences in intervention group outcomes. More site participants also corresponded to smaller intervention group differences in outcomes.

Discussion

The primary findings of this work demonstrate that the geographic similarity of trial cohorts to population data can be estimated using publicly available health indicators. Proximity to study sites correlated with increased similarity from trial controls to county data. This result is intuitive and face valid, yet had not been demonstrated using this kind of approach, to the investigators’ knowledge. In the SPRINT trial most of the country, geographically speaking, is lightly shaded, meaning the trial cohort does not represent them as well. A possible rationale for this result is that the SPRINT trial population generally has more African Americans, fewer smokers, and more people with high Body Mass Indices (BMI) than what the authors found the national hypertensive population to be. Both trials performed various subgroup analyses on different demographic and clinical criteria. While neither publication mentioned oversampling explicitly, both research groups had predefined subgroups in mind during study design. The predefined subgroup analyses may have influenced the demographics of recruiting with regard to racial features, nevertheless the overall results the researchers reported reflect the mixture of who they recruited.

This study demonstrated weak correlation between cohort similarity and outcome similarity. This result offers further face validity to the method, because one might expect results to hold in a population that looks similar to the population used for testing. The regression results also demonstrate the dangers of over generalizing results; intervention outcomes can differ significantly from the trial reported average. Further study is needed to better establish the link between population similarity metrics and differences in intervention outcomes.

The investigators conjecture that comparing variables that are more contextually similar will increase the power of this method. For example, many studies report the mean BMI and its standard deviation; this cannot be mapped to the CHSI data set easily. Instead, it would be of greater value for this method to know the percentage of trial participants considered obese. The investigators were able to use the prevalence of obesity in the case of SPRINT trial because they had received the data as part of a New England Journal of Medicine (NEJM) Challenge. Generally, the full trial data set is kept privately as the hard-earned spoils of the trial authors’ large and taxing effort to design, fund, and execute the trial. The decision to share SPRINT trial data in rapid fashion by the NEJM was not without controversy, but reflects a cultural trend toward open data.

The strengths of this work include the application of publicly available data to generate a generalizable method for assessing similarity of trial controls to county population health data. The CHSI data cover many of the most impactful and prevalent diseases and demographic behaviors in the population. The investigators’ method is scalable to other trials, because very little trial specific data are needed. The data needed by this method can be aggregated, lessening the risk of health privacy issues. Mapping fields between CHSI and a trial can largely be done with control population summary statistics and tables of adverse outcomes. These two sources of information are often published as part of the trial results. Open source software was used to generate all results to encourage generalizability. While this method does require some clinical expertise for variable mapping and some work is required for each trial, the results can be served across the country, hinting that this approach has economy of scale returns. Another strength of the approach is its use of the normal distribution to condition general health statistics onto sub populations. The properties of the normal distribution allow one to condition on an infinite number of conditions using similar methods.

A major limitation of this approach is the lack of joint probabilities in CHSI data with respect to outcomes such as stroke death and risk factors such as hypertension. Having joint and marginal probabilities would allow for flexible conditioning and would not require the assumptions made here. This approach may benefit from better assumptions on distribution (e.g. Gamma or Poisson). These bivariate distributions are challenging to find conditional expectations for analytically. Altering the distributional assumptions represents future work. This method may also benefit from using a likelihood-based approach to compare the likelihood function of one population to another. Another assumption was the use of equal weights for all population features. It is likely that some population characteristics affect study applicability more than others. Future work should include replicative efforts with other trial data and assessment of whether the applicability differences actually manifest.

Conclusions

Large public data sets with a broad coverage of demographics, lifestyle variables, and clinical states empower researchers to think at a national level. The rapid assessment of an interactive map comparing trial cohorts to county populations, such as the one presented, may help inform shared decision-making between providers and patients. Specifically, this work would help providers set a prior probability of study applicability to their local population. This may also help providers quickly prioritize which trial results to integrate into their practice. Furthermore, trial administrators could use this method to assess geographic recruitment gaps in rapid fashion.

Abstract

The transmission of hospital-acquired Carbapenem-resistant Enterobacteriaceae (CRE) is a serious and growing concern in hospitals worldwide. Previous research of CRE found that traditional patient-to-patient transmission of the bacteria does not fully account for all cases of transmission. Recent efforts to further understand modes of transmission found identical genomes of CRE in patient sinks as was found in cultures collected from patients, indicating that environmental reservoirs could be playing a larger role in transmission than was first realized. This study evaluated imputation methods for linking multiscale clinical and environmental microbiological data. We then utilized the imputed data set to model the risk of CRE presence in sinks between culture dates. We demonstrated that imputation based on expert knowledge of the unique factors of the physical hospital layout and patterns of occurrence throughout hospital sinks provided the best representation of sink positivity and also identified several significant risk factors for explaining environmental contamination. This work helps to more clearly define the mechanism and risk of transmission from a wastewater source to hospitalized patients in a world with increasingly antibiotic-resistant bacteria which can thrive in wastewater environments and cause infections in vulnerable patients.

Introduction

The spread of hospital-acquired antibiotic-resistant bacteria is a serious and growing problem. The Center for Disease Control and Prevention (CDC) estimates that more than two million people are sickened each year with antibiotic-resistant infections resulting in at least 23,000 deaths [1]. Of the many bacteria that are growing in drug resistance, there is particular concern with gram-negative pathogens as they are becoming increasingly resistant to nearly all drugs, including Carbapenems. Carbapenems are widely considered to be the strongest class of antibiotic in use today and are typically administered as a last resort in treating gram-negative infections [1]. Because of their resistance to the strongest antibiotics available, infections caused by Carbapenem-resistant Enterobacteriaceae (CRE), most commonly found in a patient’s gastrointestinal tract, are difficult to treat and can result in death [2].

Traditionally, understanding and tracking of hospital acquired infections has focused on direct contact transmission where infected and colonized patients act as reservoirs of transmission between uncolonized patients and hospital workers [3]. A large healthcare facility in the United States has been tracking a low-level spread of a nosocomial CRE pathogen between August 2007 and September 2015 with approximately 450 patient colonizations. Since the discovery of CRE transmission, active surveillance of all patients has been instituted and strict contact precautions have been in place for patients who revealed a positive culture for the bacteria. Additionally, large-scale cleaning, disinfecting, sterilization, replacement, and limited-use interventions have been conducted, but these methods have produced only temporary successes in reducing the spread of the bacteria. Recent efforts to further understand transmission of the waterborne bacteria led hospital epidemiologists to begin sampling wet surfaces including patient sinks, toilets, and hoppers for the CRE pathogen. As a result, it has become increasingly recognized that non-patient reservoirs within the hospital setting may play a larger role in the transmission of drug resistant pathogens than was first realized [4] [5].

Beginning in September of 2013, nearly 3500 samples of sink drains, sink p-traps, toilets, hoppers, and other wet surfaces have been collected periodically throughout the hospital looking for the presence of CRE. Sampling found identical genomes in samples of patients as was found in the sinks, indicating that sinks, or other environmental factors, could be acting as reservoirs for transmission [6]. However, manpower and financial constraints limited the frequency and volume of samples taken over time leaving a large gap in knowledge of the lifecycle of the bacteria in sinks and
resulting in a sparse data set with samples at irregularly spaced intervals. In order to understand the sink positivity between sample dates and to utilize the environmental microbiological sample results for further modeling, the data must be at equally spaced intervals, and thus missing data must be cleaned by removal or imputation.

Missing data are often unavoidable in epidemiological and clinical research. They can bias study results distorting statistical parameter estimates and decreasing the statistical power of a study. Numerous methodologies have been proposed to handle missing data [7]. We hypothesized that using standard methods of imputation would not provide the best representation of the environmental samples in this study because the study data include all three types of missing data, and the percentage of missing observations is significantly larger than the number of non-missing data when translated to daily measurements for modeling.

To determine which imputation method provides better representation of the presence of CRE in patient sinks over the study period, we examined two non-standard imputation methods as well as two regularly practiced methods. After determining the imputation method that resulted in the most accurate representation of the environmental sample results, we used the imputed data set for further modeling to understand the significant risk factors in predicting the presence of CRE in patient sinks.

The objectives of this study are twofold: 1) to evaluate imputation strategies for continuous representation of irregular sampled environmental microbiological data and 2) to use the selected imputation approach for modeling of the environmental reservoir positivity as a function of other significant risk factors including colonized patients, environmental interventions, and characteristics of patient room sinks.

1 Related Work

1.1 Patient Infection Risk Factors

The transmission of CRE infection occurs when a non-colonized person comes into direct contact with an infected or colonized patient, through intermediate carriers such as healthcare workers, or through contact with contaminated environmental reservoirs such as sinks and toilets, among others. Previous studies [8, 9] from the US and Israel have shown that the primary risk factors for patient acquisition include ICU stays, long-term hospitalization, transplantation and antibiotics. Another outbreak of CRE at the Tisch Hospital at New York Medical Center included 24 infected patients in intensive care units (ICUs) over the course of a year. Similar to other outbreaks, risk factors for infection during this outbreak included prolonged hospital stay, a stay in the ICU, and ventilator usage [10].

1.2 Environmental Risk Factors

Risk factors from the studies conducted in the US and Israel did not completely explain infection transmission. Previous studies [4, 11, 12] provide evidence that environmental reservoirs are a source of infection and transmission. Additionally, a study from Spain [4] described an outbreak due to multidrug-resistant *Klebsiella oxytoca* in an ICU where damp environmental reservoirs were linked to bacterial transmission. In that study samples collected from sinks, drainpipes, and traps showed that only one storage sink, which had its drainpipes connected to two other sinks, was found to be positive. The connecting drainpipes were also found to be positive. Furthermore, this study showed that the outbreak was completely eradicated after replacing the horizontal drainage system that connected the two impacted sinks. In conclusion, this study stated that wet environmental reservoirs should be considered when strictly applied traditional control measures are not efficacious.

A study from France [12] found that sinks were frequently contaminated in ICUs as a result of their use in disposing of patient bodily fluids and were a potential source of extended-spectrum beta lactamase-producing *Enterobacteriaceae* (ESBLE), thus increasing risk in the environment of patients as a consequence of the splash-back effect. Recent research from Wolf et al. [11] demonstrated that sinks acted as a source of infection by verifying that the ESBLEs recovered from patients were identical to those that had been previously recovered from sinks. The outbreak described in a Colombian [13] study found that the likely cause of the infections was the improper design of sinks; in particular, the joints of the sinks to the walls were not sealed, leading to facilitation of colonization.
1.3 Modeling Infection Transmission

Methods including logistic regression have been used in previous studies to identify risk factors associated with nosocomial transmission. A study [14] conducted at Roosevelt hospital in New York City used logistic regression models to evaluate efficacy of infection control measures in preventing the transmission of multidrug-resistant tuberculosis. The study found that distance from infected patient room is a significant predictor of nosocomial transmission.

The logistic regression approach has also been used in some studies [15, 16] to identify patient risk factors for CRE transmission in hospital settings. Research by Papadimitriou-Olivgeris et al. [15] focused on patient characteristics, diagnosis, and procedures to determine that prior ICU stay, duration of previous hospitalization, diagnosis of chronic obstructive pulmonary disease, carbapenem administration, and beta-lactamase administration were significant risk factors. Similarly, Tuon et al. [16] considered procedures such as mechanical ventilation and found that urinary catheter devices and central venous catheter devices were significant risk factors, along with advanced age and antibiotic exposure to ciprofloxin.

Work by [17] focused on modeling the nosocomial transmission of carbapenem-resistant bacteria using logistic regression and random forest models to determine important risk factors for CRE transmission. Both models showed that distance to the infected room was one of the significant predictors. One of the models showed that the proximity to sinks is important in predicting patient infection. This study also found that the cumulative presence of positive patients in the same room as a sink, distance from the bed to sink, and sink design are significant predictors of sink positivity. However, the model was constructed using limited data and a restricted time range, which leaves many questions about the role of sinks in the spread of infections.

Studies [4, 11–13] have demonstrated that sinks play a role in infection transmission but did not highlight additional environmental risk factors responsible for sink contamination. This study improves on the understanding of sink contamination by highlighting important variables. This study is similar to [17] in terms of the modeling approach used, but it differs in the level of spatiotemporal variables from environmental data. In addition to examining the presence of positive patients in the same room over time, this study also considers the status of neighboring rooms and sinks as potential risk factors.

1.4 Imputation in Healthcare Studies

Missing data is a frequent issue in epidemiological and health sciences research. While most modeling techniques would simply call for the removal of incomplete cases, doing so can cause bias and loss of information [18]. Imputation methodologies can be used to replace missing data with substituted values in order to create a complete data set. Standard methods for imputation such as k-nearest neighbor, last observation carried forward, and mean value can lead to bias and are not effective in handling categorical variables [19]. These methods are also typically used to address only one of the three types of missing data - missing completely at random, missing at random, and missing not a random.

Missing data in health care settings is a result of many complex sources of information and their incompatibility between each other and also due to the personal nature of care given that varies among patients [20]. A recent study of outcomes of trauma cases found that using a combination of existing imputation methods, specific to each individual data set in the analysis significantly improved the accuracy of predicted mortality after trauma over the more common method of handing missing data by simply removing all unknown cases [20]. Additionally, a study on classification of respiratory patterns involving imputation of missing data found that self-organizing maps (SOM) machine learning techniques were more effective in predicting patterns than other more commonly used statistical methods such as mean/mode imputation and multiple linear regression [21].

2 Methods
2.1 Data

This Institutional Review Board (IRB) approved study used clinical and environmental data from a major U.S. hospital. Clinical data included culture dates of approximately 130 patients who tested positive for CRE and their room movement information from September 2013 to September 2015. Environmental data included 967 positive and negative swab and liquid samples from 166 sink drains and sink p-traps from floor 3-8 in the hospital over the same 740 day period. Twenty six attributes describing the physical characteristics of the sink were manually collected. The attributes include surrounding countertop area, faucet, exposed piping, and the presence of other wet areas such as showers, hoppers, and toilets. Lastly, dates and units of any clinical interventions that were performed during the period in question were collected.

For this analysis, our environmental microbiological sample dataset was transformed into to a sink-day format that includes a record for each sink and each day during the study period. We defined positive (“1”) population as the set of sink-days for which a known positive culture was found, negative (“0”) population as the set of sink-days for which a known negative culture was found, and unknown (“U”) population as the set of sink-days for which there was missing sample data or no environment sample taken. Of our data set with approximately 81,000 cases, only about 1,000 (1.2%) had known culture values.

Table 1 describes the variables used in this study. Variables Lag0, Lag1, Lag2, and Lag3 indicate whether on the given day, a positive patient stayed for any length of time in the given room. The lag number corresponds to the time with Lag0 indicating the current day, Lag1 indicating one day prior, and Lag2 indicating two days prior. If a positive patient moved through the room, a binary response of “1” was indicated at the appropriate lag value. Similarly, CumSum7 and CumSum14 were created to demonstrate the cumulative number of days in the past 7 or 14 days respectively that a positive patient was in the given room with the given sink. Variables Intervention0, Intervention1, Intervention2, and Intervention3 were used to indicate whether an intervention was performed on the current day or one of the prior three days. The timing of different interventions was considered since infection control leadership hypothesized that these interventions influenced environmental positivity. SinkDesign represents 25 unique sink characteristics throughout the 166 sampled sinks. SinkBedDis represents the distance of the patient bed to the sink.
2.2 Imputation of Environmental Sample Data

We evaluated four imputation methods, two non-standard methods based on expert guidance (Linear and Midpoint methods) and two traditional imputation methods that are frequently used in health care studies (Logistic Regression and Multivariate Imputation by Chained Equations). In the linear imputation method, a positive sample is carried forward to the next negative sample while linearly imputing the probability of the sink being positive between negative and positive observations. The midpoint method carries the first observation forward to the midpoint between two observations and carries the next observation backward to the midpoint. The logistic regression method trains a set of data on the given samples and predictor variables and predicts on the missing samples. The mutivariate imputation by chained equations (MICE) method uses the statistical package MICE in R to perform multiple imputation over 10 iterations of known variables to predict a binary response [22] [23].

For the purpose of imputation, we consider each sink as a univariate time series. Each imputation method was implemented on each sink over the period of 740 days resulting in a value for each sink-day that will be used in modeling. Predicted values are replaced by any known values. Figure 1 shows visual depiction of the sample data and each of the four methods on one sink over the first 350 days.

![Figure 1: Example plot of Imputation Methods for Patient Sink](image)

2.3 Modeling and Feature Selection

We employed two modeling techniques to identify risk factors that affect sink positivity. First, Bayesian model averaging (BMA) [24] was used to explore all possible subsets of variables from Table 2 and identify the most significant predictors. Based on each subset model’s posterior probability, which can be estimated using Bayesian information criterion (BIC), the models that were at least 20 times less likely than the best model were removed. Among the rest of the models, any model which was less probable than its nested subset model was also excluded. The remaining models were averaged to estimate variable importance as well as mean and standard deviation of the coefficients. Secondly, a random forest model using an ensemble technique was developed to examine variable importance and to predict sink positivity. The random forest model was trained with 10-fold cross validation, using 500 trees with a maximum node size of 5.

3 Results

3.1 Imputation Methods

We evaluated the four imputation methods using the data that consists of 967 known positive samples. We began by evaluating a simple generalized linear model (logistic regression) of the given samples as a response to the extracted and selected features in Table 1 where $g_t$ annotates the probability of a positive sink given the selected set of predictor variables.

\[
g_t = \beta_0 + \beta_1(\text{Unit}) + \beta_2(\text{CumSum14}) \\
+ \beta_3(\text{SinkDesign}) + \beta_4(\text{Intervention2})
\] (1)

Next, we sequentially add in an imputed value from each method at t-3 (3 days prior to sink-day), t-7 (7 days prior to sink-day), and t-15 (15 days prior to sink-day) to determine which imputation method provided the most increase in the prediction accuracy of the sink based on 10-fold cross validation.

\[
g_t = \beta_0 + \beta_1(\text{Unit}) + \beta_2(\text{CumSum14}) \\
+ \beta_3(\text{SinkDesign}) + \beta_4(\text{Intervention2}) \\
+ \beta_5(\text{Imputed Value})
\] (2)

Our baseline data set consisted of the original 967 sink-days while the imputed data sets provides us the ability to use over 80,000 completed sink-days. Table 3 shows the performance of the four imputation methods. It indicates that

regardless of time interval, the Midpoint imputation method provides the highest accuracy of prediction of positive sink compared to the baseline (without any imputed values).

3.2 Logistic Regression Model

Based on the results of BMA, we selected the variables whose importance was higher than 10 percent for the final logistic regression model. Table 4 shows the odds ratios and confidence intervals of the variables included in the final model. The odds ratio denotes the increase in probability of a sink becoming positive given the presence of any variable. The confidence interval of odds ratio was calculated using a bootstrap method.

The results showed that the odds of a sink becoming positive increases by almost 13-fold (95% CI: 12.39-14.18) when the status of the sink was positive in the last 30 days. Intervention has a negative effect on sink positivity. This is consistent with the general understanding that interventions would reduce the odds of sink contamination for a short duration. The odds ratio reduces by 50% if an intervention is performed within the last 7 days. Instances of positive sinks in adjacent room\(_1\) which share common plumbing increase the chances of a sink becoming positive by 80% (95% CI:1.68-1.93). Instances of positive sinks in adjacent room\(_2\) that do not share common plumbing increase the chances of a sink becoming positive by only 13% (95% C.I: 1.03-1.24).

The presence of a positive patient in the same room increases the odds of a sink becoming positive by 1.92-fold (95% CI: 1.46-2.53), whereas the presence of any positive patient within the past 14 days increases the odds by 1.78-fold (95% CI: 1.52-2.08). Furthermore, the presence of a positive patient in an adjacent room\(_1\) which shares common plumbing increases the odds of sink positivity by 1.13-fold (95% CI: 0.92-1.40), while the presence of a patient in adjacent room that do not share common plumbing increases the odds by 1.70-fold (95% CI: 1.37-2.09). The overall significance of the model was evaluated using the likelihood ratio test, and the result indicates the model is significant at \(\alpha=0.05\) level.

3.2.1 Random Forest Models

The results for Random Forest are shown in Figure 2, which summarizes the importance of variables by mean decrease accuracy (MDA). MDA can be used as a feature selection method because it shows the impact of each variable on the
model accuracy. The results show that 7 of the 9 variables included in the logistic regression were also included in the random forest model, while the accuracy slightly increased (81%) compared to Logistic regression (80%). Both models show identical true positive rate, which is important in our case since the cost associated with misclassification of a positive sink as negative is higher than falsely classifying negative sink as positive. Additionally, we see a higher specificity based on random forest model compared to logistic regression. Table 5 summarizes the results from both models.

### 4 Conclusions

The modeling results indicate that variables such as presence of positive sink in adjacent rooms that share common plumbing, status of the patient in the same room, status of sink in the past 30 days, presence of a positive patient in last 14 days, presence of a positive patient in the adjacent room and interventions performed in the past 7 days are significant risk factors in explaining sink contamination. The findings on the presence of a positive patient in last 14 days, status of sink in the last 30 days and interventions implemented in the last 7 days are consistent with the understanding shared by infection control practitioners we consulted with.

Previous research [25] has shown that biofilms found in sinks were linked to outbreaks. Some research [26,27] has also shown that these biofilms are resistant to traditional disinfectant methods. Our results indicating the significance of adjacent rooms that share common plumbing can be explained by the probable presence of biofilms in sink drain walls, traps or drainpipes connecting the two room sinks. Despite the timely implementation of intervention strategies, it could be likely that the presence of biofilms contributed to the adjacent sinks becoming positive.

Another spatial factor that we found to be significant in the model is the presence of a positive patient in the adjacent room. The model results show that the odds of sink positivity increase by 1.13-1.70 fold when the adjacent rooms have a positive patient. We would expect this to be true given that positive patients in the adjacent room would use the sink (adjacent room sink). Thus, it is likely that they would contaminate the sink of the room that they are staying in.

Developing an imputation method for bacterial presence between known samples provided valuable insight into the growth and movement of the bacteria throughout sinks in the hospital. Additionally, the ability to complete a data set of environmental testing allows for the capability for it to be included in other models, such as patient risk modeling,
that will provide a more comprehensive predictive capability. In modeling the presence of CRE in sinks, this research aimed to understand what factors contribute to sink positivity. Knowledge gain in both capacities can lead to better understanding the role of environmental reservoirs in the spread of the bacteria and could be used to support changes to hospital policy and procedures that ultimately aid in the containment or eradication of the bacteria from the hospital.

Abstract

Atrial fibrillation (AF) is a common cardiac arrhythmias, which increases the risk and severity of ischemic stroke. For predicting ischemic stroke in AF patients, a risk prediction model that can achieve both good model discrimination (e.g., AUC) and statistical significance of predictors is required in real clinical practices. In this paper, we propose a new bootstrap-based wrapper (Boots-wrapper) method of feature selection, and apply this method on Chinese Atrial Fibrillation Registry data to develop 1-year stroke prediction models in AF. The proposed method can heuristically search a subset of features to maximize the discrimination of the prediction model and minimize the penalty for the non-significant features. To achieve robust feature selection, we perform bootstrap sampling to get a more reliable estimate of the variation and significance statistics. The experimental results show that Boots-wrapper can balance model discrimination and statistical significance of features for developing AF stroke prediction models.

Introduction

Atrial fibrillation (AF) is a common cardiac arrhythmias, affecting over 2.7 million Americans¹ and approximately 10 million adults in China². AF significantly increases the risk and severity of ischemic stroke³. Though warfarin and radiofrequency ablation (RFA) are both effective therapies in preventing ischemic stroke for AF patients⁴, these therapies are normally recommended to high-risk AF patients⁵ because warfarin may have side effect of bleeding and RFA is expensive. Therefore, it is critical to accurately identify the truly high-risk AF patients that have high probability to develop ischemic stroke within relative short-term periods (e.g., 1 year). For this purpose, in our previous AF studies⁶⁷⁸, we identified potential predictors for ischemic stroke and built prediction models using different feature engineering and machine learning methods, based on Chinese Atrial Fibrillation Registry (CAFR) data⁹, which can achieve significantly better model discrimination in terms of the area under the ROC curve (AUC) than the widely-used risk models such as CHADS², CHA²DS²-VASC¹⁰ and Framingham Score¹¹.

However, there is a factor we did not take into account in our previous studies – the statistical significance of predictors, which is as important as discrimination for a risk model to be adopted in many clinical scenarios. Actually, because the purpose of stroke prediction is to help clinicians identify high-risk AF patients and then decide to whom warfarin and/or RFA should be used, only those who have not been treated with warfarin or RFA at baseline are of interest for developing stroke prediction model. This criteria greatly decreases the number of patients that can be used in modeling. Furthermore, compared to long-term risk prediction (e.g., 5-year stroke risk prediction by Framingham score¹¹), relative short-term prediction (e.g., 1-year) is more practical for clinical decision-making. However, a 1-year stroke prediction model had to be built on a highly imbalanced dataset, because there was not enough cases of ischemic stroke onset within 1 year after baseline. For this dataset with limited patient numbers and rare positive cases, the statistical significance test of predictors in the multivariate risk model is even more important. Therefore, the objective of this study is to identify potential predictors for developing 1-year prediction models for AF patients, by balancing model discrimination and statistical significance of predictors.

Feature selection methods in machine learning¹² can be used to automatically test and select predictors from a large number of candidate features. There are three main supervised feature selection strategies: filter, wrapper and embedded optimization. Filter methods calculate a score to represent the relevancy of a feature against the outcome and filters the features based on the score. Though the p-value from chi-squared or other tests can be used as the relevancy score to filter the features that have significant univariate correlation with the outcome, it can neither ensure
the statistical significance of features in a multivariate model, nor the discrimination of the model. Wrapper methods utilizes a specific learning model (e.g., logistic regression) to select the subset of features that provides the best performance for a specific metric using a heuristic search strategy. The current wrapper subset selection method can optimize the model discrimination (e.g., AUC) of a subset of features by cross-validation, but cannot ensure the statistical significance of selected features. The traditional stepwise selection method for generalized linear model (GLM, including logistic regression and Cox regression) is also an example of wrapper method, which uses the Score statistics to evaluate the goodness-of-fit and constrains the statistical significance of selected features in the model using a hard constraint (e.g., p-value of an entered feature must be less than 0.05). However, the hard constraint of p-value may result in under-fitting for a small imbalanced dataset. Finally, embedded optimization methods incorporate feature selection directly into the learning process of a model. For example, the Lasso method introduces L1-norm regularization to GLM, which can achieve feature selection by shrinking the coefficients of low relevant features to zero during model training. However, it is difficult to constrain statistical significance of features in the objective function of model optimization.

In this paper, we propose a new bootstrap-based wrapper (Boots-wrapper) method of feature selection, and use this method to build stroke prediction models for AF patients. The proposed method can select a subset of features to balance the discrimination (e.g., AUC) of the GLM model built on the selected features and the statistical significance of features, by maximizing the model discrimination and minimizing a soft penalty for the non-significant selected features. To achieve robust feature selection, we perform bootstrap sampling instead of cross-validation to get a more reliable estimate of the variation in feature coefficients, and also use the p-value from bootstrap test to get more reliable significance statistics. We applied Boots-wrapper on a training dataset derived from CAFR data to develop 1-year prediction models of ischemic stroke for AF patients, and compared its performance on a separate testing dataset with that of existing feature selection methods. The experimental results show that Boots-wrapper can balance model discrimination and statistical significance of features for developing AF stroke prediction models.

Methods

Cohort

The objective of this study is to build 1-year ischemic stroke prediction models for AF based on the Chinese Atrial Fibrillation Registry (CAFR) data'. The CAFR study started from the year of 2011 to 2015, and has enrolled more than 17,000 AF patients from 32 hospitals in Beijing, China. The study collected the patients’ demographics and clinical information at baseline, and followed up the patients every 6 months. At every follow-up visit, the clinical events such as ischemic stroke were collected. In this study the patients of interest are those who had not been treated with warfarin or RFA at baseline. From the CAFR data, we identified 3738 AF patients who meet this criteria, where 143 patients (3.83%) are cases who had ischemic stroke within 1 year after baseline, and 3593 patients are control instances who completed 1-year follow-ups and did not have ischemic stroke within 1 year. To make the result models more interpretable, the clinician selected 51 features as candidate features, including demographics, medical histories, vital signs, laboratory test results and treatments.

In this study, we used the data of patients registered in 2011 and 2012 as the training set (2872 patients, where the proportion of positive cases is 4.04%) to develop the risk prediction models, and the data of patients registered after 2013 as the testing set (866 patients, where the proportion of positive cases is 3.12%) to evaluate the performance of the models.

Method Framework

The goal of our method is to select a feature set that can maximize the discrimination of the GLM model (e.g., logistic regression) built on the selected feature set, and minimize the penalty for the non-significant selected features:

$$L = \text{discrimination (features)} - \text{penalty (non-significant features)},$$

where discrimination can be measured using the metrics such as accuracy, sensitivity, specificity, or AUC. However, it is very difficult to optimize this objective using an embedded feature selection method that is built in the process of model learning. Therefore, we propose a wrapper method of feature selection to heuristically optimize the objective. Figure 1 shows the pipeline of our proposed approach Boots-wrapper, which follows the general framework for wrapper methods of feature selection. Given the training dataset and the testing dataset, the approach will perform the following main steps:
• **Feature Set Search**: searching a subset of features from all possible feature subsets. Some existing heuristic search strategies, such as hill-climbing, best-first, and genetic algorithms\(^{11}\) can be used to search the feature set.

• **Bootstrap-based Feature Set Evaluation**: evaluating the performance of the GLM models that are trained on the above subset of features. In this step, our feature set evaluation method, which uses the bootstrap-based algorithm to evaluate model discrimination and statistical significance of features, is different from the previous wrapper method and can achieve more reliable estimation. We will give more details about the evaluation method in the following sub-section.

• **Feature Set Search** and **Feature Set Evaluation** are repeated until the performance is optimized and the final predictor set is found.

• **Final Model Training**: developing the final GLM model using the selected set of predictors.

• **Final Model Evaluation**: evaluating the performance of the final GLM model on a separate testing dataset.

---

**Figure 1.** Pipeline of Boots-wrapper approach

**Bootstrap-based Feature Set Evaluation**

Given a set of features, the feature set evaluation method include the following steps:

(1) **Bootstrap sampling**: As shown in Figure 2, given a training dataset with \( N \) instances, the dataset is randomly sampled with replacement \( N \) times to obtain a set of data samples, which is referred to as bootstrap-sampled dataset. Accordingly, the remainder validation set includes all the data samples that are in the whole training dataset but not in the bootstrap-sampled dataset.

(2) **Model training**: As shown in Figure 3, the bootstrap sampled dataset is used to train a prediction model (GLM) from the Bootstrap-sampled dataset

(3) **Model validation**: The discrimination of the prediction model (e.g., AUC) is evaluated on the remainder validation dataset.

Step (1)–(3) are repeated \( M \) times.

Model discrimination (e.g., AUC)

\[ D^{(1)} = 0.70 \]

\[ D^{(2)} = 0.68 \]

\[ D^{(3)} = 0.66 \]

(4) **Significance statistics of features**: As shown in Figure 4, the coefficients of features from all repetitions are used to compute the p-values of features. For the coefficient \( \beta_i \) of each feature \( i \), we first compute its mean \( \bar{\beta}_i \) and standard error \( \sigma_i \) of all repetitions. Then we compute the p-values by performing z-test: \( p_i = Prob(z \geq \bar{\beta}_i / \sigma_i) \)

(5) **Discrimination Statistics**: The average discrimination statistics (e.g., AUC) of all repetitions \( \bar{D} \) is calculated.

(6) **Performance Evaluation**: The discrimination statistics and the p-values of features are combined to estimate the performance of the feature set:

\[ L = \bar{D} - \alpha \cdot \sum_{i=1}^{k} (I(p_i \geq \theta) \cdot p_i) \]

where \( k \) is the number of risk factors. If \( p_i \geq \theta \) then \( I(p_i \geq \theta) = 1 \), else \( I(p_i \geq \theta) = 0 \). \( \alpha \in [0,1] \) is the parameter to balance the importance of prediction performance and statistical significance. \( \theta \) is the pre-defined threshold for p-value (e.g., 0.1, 0.05, 0.01).
Results

We evaluated the performance of Boots-wrapper in building 1-year ischemic stroke prediction models for AF patients from CAFR dataset. As our dataset is highly imbalanced and has very rare positive instances (3.12% in the testing set), AUC and the area under the precision recall curve (AUPR) were used to evaluate the prediction performance of models, because AUC and AUPR can provide a more informative assessment than accuracy, sensitivity and specificity for imbalanced data. Note that the baseline of AUPR for our testing dataset is the average precision of randomly predicting the risk, which equals the 1-year stroke occurrence rate (i.e., 0.031 for the testing set).

In the experiments, we used AUC as the discrimination metric of the Boots-wrapper method, and set the parameters $M = 100$ and $\theta = 0.05$. Different values of parameter $\alpha$ were tried in our experiments. We use logistic regression, which is a GLM with a logit link function and a binomial distribution, to build prediction models based on the selected features. The proposed Boots-wrapper method was compared with the state-of-the-art feature selection methods, including:

- **Filter.** The p-value from two standard statistical tests, which are the Chi-square test for categorical features and the ANOVA F test for numeric features, were used as the relevancy score to select the features whose p-value is less than a predefined threshold.
- **Lasso.** We used Lasso\textsuperscript{14} to introduce L1-norm regularization to logistic regression for embedded feature selection.
- **Stepwise.** The stepwise selection method for logistic regression was applied to maximize the Score statistics using the whole training dataset and rigidly constrain p-values of selected features to be less than a predefined threshold.
- **Cross-validation (CV) based wrapper.** We applied the cross-validation based wrapper subset selection method\textsuperscript{14} to search the subset of features that can achieve optimized performance (AUC) by cross validation.

1135
In the first experiment, the initial predictor set was set to empty (i.e., no predictor was forced in the models). Then each feature selection method was performed on the original candidate feature set to select predictive features. The wrapper methods (Boots-wrapper, Stepwise and CV wrapper) were performed using a forward hill-climbing search strategy. The performance of the models built on the selected features were also compared with that of the existing risk scores: CHADS², CHA²DS²-VASc, as well as the model built on the whole feature set. As shown in Table 1, Boots-wrapper achieved better AUC and AUPR than the other feature selection methods on the testing dataset, while selecting a small set of features. The prediction performance of our models also outweigh the CHADS² and CHA²DS²-VASc scores.

Table 2 gives the details of some models built on the selected features. As the Stepwise method with the entered p-value < 0.05 rigidly constrains the p-values of selected features, it only selected 5 predictors into the model. In our experiment, we also changed the threshold of entered p-value to 0.2 and selected 12 predictors, but the prediction performance of the model built on the testing set obviously decreased due to over-fitting (AUC = 0.661, AUPR = 0.055). Without constraining the statistical significance of the selected features, the CV-based wrapper method identified 12 features, where 8 of them are not statistical significant, and it also resulted in over-fitting (AUC = 0.681). The proposed Boots-wrapper method selected 8 predictors when setting α = 0.001, where 5 features are not statistical significant, and achieved the best AUC and AUPR on the testing set. When setting α = 0.1, Boots-wrapper selected 6 predictors, where only 1 features are not statistical significant, and also achieved decent testing performance. The results show that Boots-wrapper can balance the model discrimination and statistical significance of predictors, as well as reduce over-fitting.

In the second experiment, we introduced prior knowledge to the models to make the models more interpretable, by adding some known predictors (age, prior thromboembolism, congestive heart failure, hypertension and diabetes) into the initial predictor set (i.e., these predictors were forced in the models). Then each wrapper feature selection method was performed on the remainder candidate feature set to select additional predictive features. As shown in Table 3, Boots-wrapper also achieved better AUC and AUPR than Stepwise and CV based wrapper methods on the testing dataset with prior knowledge. Table 4 gives the details of some models built on the combination of knowledge-based predictors and selected predictors. We can find that some of the knowledge-based predictors are actually not statistical significant in the model built on CAFR dataset. In addition to these known predictors, Boots-wrapper also discovered other features that can improve model discrimination, where some of the selected features are statistical significant. Finally, the prediction performance and predictor number of some models in the above experiments are also compared in Figure 5.

Figure 5. AUC and AUPR of different models, evaluated on the testing set
Discussion

In this study, we compared several feature selection methods in developing 1-year prediction models of ischemic stroke for AF patients. The logistic regression method did not work well on the whole feature set due to severe overfitting (training AUC = 0.747, testing AUC = 0.667), but the prediction performance can be improved by appropriate feature selection. However, the Filter and Lasso methods did not achieve obvious performance improvement. That is probably because Filter is a univariate feature selection method and the selected feature set still have high redundancy, while Lasso tends to remain high variance features, such as numeric values of laboratory tests, but some predictive features are binary features with relatively low variance.

We also compared three wrapper methods of feature selection: CV-based wrapper, Stepwise and our proposed Boots-wrapper. The CV-based wrapper method uses cross-validation to evaluate the performance of a subset of features, and does not constrain statistical significance of features. The Stepwise method can constrain the p-value of statistics test (e.g., Wald test) for each feature in a GLM model using hard p-value thresholds. Our proposed method uses a soft penalty to non-significant features to balance the model discrimination and significance of selected features, making the result prediction models more flexible and practical for small and imbalanced dataset. The identified risk predictors, odds ratios and p-values in logistic regression were verified by clinicians, concluding that the selected predictors are interpretable and reasonable to clinicians.

Bootstrap approaches has been widely used in model validation. A filter feature selection method based on bootstrapping was also proposed. In this study, we developed a novel wrapper feature selection method based on bootstrapping, which uses bootstrap sampling to validate model discrimination while evaluating the significance of features by calculating the p-values of bootstrap test. Compared with cross-validation, bootstrap can get a more reliable estimate of the variation in feature coefficients and p-values. Both k-fold cross-validation and leave-one-out cross-validation cannot obtain reliable estimate of the variations. For k-fold cross-validation (e.g. k = 5 or 10), the sample size in the training data could be very different from the whole dataset, therefore the variation could be over-estimated. On the other hand, leave-one-out cross-validation tends to under-estimate the variations since the training sample set at each fold is almost identical. Bootstrap uses the "sample with replacement" approach to overcome the aforementioned issues: 1) the training sample size is the same as the whole dataset; 2) the training sample set at each Bootstrap iteration has reasonable amount of variation. With a reliable estimate of the variations, the selected feature set is more robust. Secondly, conventional statistical tests such as Wald test usually impose distributional assumptions on the data, and are based on asymptotic theories. Distribution of the real-world data may not always fit the distributional assumptions. In addition, the behavior of a test statistic under finite sample could be different from the theoretical results based on asymptotic assumptions (sample size goes to infinity). Bootstrap is a non-parametric approach to estimate the variations and to perform hypothesis testing. No distributional assumption is imposed on the real-world data. Also, by "sampling with replacement", we ensure that the sample size in each bootstrap sample is the same as the real data. Therefore, the test statistic from bootstrap can be more reliable than the ones from conventional methods.

The major disadvantage of the proposed Boots-wrapper method is the high time complexity. As the wrapper framework is very computationally expensive, the method is not practicable for large datasets. Fortunately, it is very easy to parallelize the bootstrap sampling algorithm because each repetition of sampling is independently of each other. Therefore, the method could be run in a distributed system to speed up the computation.

Conclusion

AF is a common cardiac arrhythmias, which increases the risk and severity of ischemic stroke. For predicting ischemic stroke in AF patients, a risk prediction model that can achieve both good model discrimination (e.g., AUC) and statistical significance of predictors is required in real clinical practices. In this paper, we propose a new bootstrap-based wrapper (Boots-wrapper) method of feature selection, and use this method on CAFR data to develop 1-year stroke prediction models in AF. The proposed method can heuristically search a subset of features to maximize the discrimination of the prediction model and minimize the penalty for the non-significant features. To achieve robust feature selection, we perform bootstrap sampling to get a more reliable estimate of the variation and significance statistics. The experimental results show that Boots-wrapper can balance model discrimination and statistical significance of features for developing AF stroke prediction models.

Abstract

Gleason grading of histological images is important in risk assessment and treatment planning for prostate cancer patients. Much research has been done in classifying small homogeneous cancer regions within histological images. However, semi-supervised methods published to date depend on pre-selected regions and cannot be easily extended to an image of heterogeneous tissue composition. In this paper, we propose a multi-scale U-Net model to classify images at the pixel-level using 224 histological image tiles from radical prostatectomies of 20 patients. Our model was evaluated by a patient-based 10-fold cross validation, and achieved a mean Jaccard index of 65.8% across 4 classes (stroma, Gleason 3, Gleason 4 and benign glands), and 75.5% for 3 classes (stroma, benign glands, prostate cancer), outperforming other methods.

Introduction

Prostate cancer is the most common and second most deadly cancer in men in the United States [1]. A key component of prostate cancer staging and treatment selection is the Gleason grading system, in which histopathological slides of prostate tissue are assigned grades that represent the aggressiveness of the cancer. The Gleason scale ranges from Gleason 1 (G1) - Gleason 5 (G5), with a score of G1 indicating cancer that closely resembles normal prostate glands and a score of G5 indicating the most abnormal histopathology, which is associated with the highest mortality risk. Final Gleason scores are generated by summing the first- and second-most prevalent patterns in the tissue sections. Currently, Gleason score is the best biomarker in predicting long term outcome of prostate cancer [2–4]. Yet, a recent clinical trial found no significant difference in mortality at 10 years between patients on active surveillance and immediate surgery [5], underscoring the need for more effective risk stratification tools to improve the outcomes of treatment deferral. Studies have also demonstrated the prognostic value of quantitative pathology features, such as the percent of Gleason 4, for diagnosis and treatment planning [3,6,7]. In addition, Gleason scores are assigned manually through pathologist review, a process that has been shown to have low inter-observer agreement across pathologists, especially when differentiating Gleason 3 (G3) vs Gleason 4 (G4), a distinction that may have substantial impact on further care [8–10].

A computer aided diagnosis (CAD) tool for performing Gleason scoring would provide a repeatable method for grading cancers and may be used as a pre-step for quantitative pathology feature extraction, thus providing a more precise assessment of cancer stage and treatment planning. In this paper, we propose a multi-scale U-Net CNN model for pixel-wise Gleason score prediction. We also compare the performance of several machine learning approaches to Gleason score assignment, including a pixel-wise deep convolutional neural network (CNN), a standard U-Net, the proposed multi-scale U-Net, and the previous work by Gertych, et.al.[11] on 224 histological image tiles from radical prostatectomies of 20 patients.

Previous Work

Previous work has been done in developing an automatic Gleason grading system to help improve diagnosis accuracy and achieve quantitative histological image analysis. A commonly used approach is to extract tissue features and apply classifiers on pre-selected small image tiles, each of which only contains one tissue class. Farjam, et.al. [12] developed a method to segment prostate glands with texture-based features, and then used the size and shape features of glands to classify image tiles into benign or malignant glands. Nguyen, et.al. [13] used structural features of prostate glands
to classify pre-extracted regions of interest (ROIs) into benign, G3, and G4, achieving an overall accuracy of 85.6%.

In the work by Gorelick, et.al. [14], a two stage Adaboost model was applied to classify around 991 sub-images extracted from 50 whole-mount sections of 15 patients. They achieved 85% accuracy for distinguishing high-grade (G4) cancer from low-grade cancer (G3).

However, the above algorithms require a set of pre-extracted image tiles with homogeneous tissue content, which may not be generalizable to larger and more heterogeneous images. Moreover, accurate localization of such small image tiles is a non-trivial problem [15]. Rather than attempting to classify the entire image tile, some efforts focus on segmenting and classifying glands with glandular features such as lumen shape and nuclear density [16,17], but these efforts require well-defined gland boundaries, and may not be applicable for high-grade prostate cancer with few recognizable glands.

Instead of using features from segmented glands, Gertych, et.al. [11] used intensity and texture features from joint histograms of local binary patterns and local variance to segment stroma (ST), prostate cancer (PCa), and benign glands (BN). In their two-stage classifier, a support vector machine (SVM) was trained with local intensity histogram to separate ST and epithelium (EP) areas, and then a random forest (RF) classifier was trained to segment BN and PCa. They obtained an average Jaccard index ($J$) of 59.5% for segmenting ST and EP areas. For separating BN and PCa, they achieved a $J_{\text{BN}}$ of 35.2% ± 24.9%, and a $J_{\text{PCa}}$ of 49.5% ± 18.5% in the test set. Although their model was able to do pixel-wise classification on heterogeneous image tiles, they did not address the problem of differentiating high-grade (G4) versus low-grade cancer (G3).

Additional previous work has explored the use of neural network models to learn features directly, rather than using handcrafted features. Deep convolutional neural network (CNN) models have demonstrated high performance in a variety of natural image analysis tasks [18–21]. Litjens, et.al. [22] implemented a deep convolutional neural network (CNN) to detect cancerous areas on prostate biopsy slide images at 5x magnification. They achieved around 0.90 AUC, but did not address the challenge of distinguishing high-grade versus low-grade cancer.

Pixel-wise deep convolutional networks are difficult to apply to pathology image analysis due to the high resolution of digital pathology slides [23,24], direct analysis of which would generally require more memory than is available on a graphics processing unit (GPU). Two approaches to handling this challenge are resolution downsampling and patch extraction. In down-sampling, high resolution images are scaled down to more manageable sizes, at the cost of the loss of potentially discriminative fine details. In patch extraction, images are divided into (possibly overlapping) sub-patches that are then treated as independent training samples. This approach allows for the analysis of full resolution data, but may lead to an intractable number of potential patches, requiring subsampling of the dataset. In both of these methods, an overall prediction is created for the image or the patch.

Shelhamer and Long, et.al. [24,25] proposed a fully convolutional network (FCN) that can be trained from end to end to output pixel-wise predictions for an entire input image patch (rather than a single prediction for the patch). In order to get dense predictions for each pixel, they used up-sampling operations, and replaced the final fully connected layer with an N×1×1 convolution layer, which output probabilities for N classes. Shallow layer features were fused with deep layer features to mitigate the challenge that intensive up-sampling can lead to coarse segmentation results. The model obtained a mean $J$ of 67.5% and showed 30% improvement on PASCAL VOC 2011 test datasets.

The U-Net architecture proposed by Ronneberger, et.al.[26] extended the FCN by adding a relative symmetric up-sampling path to down-sampling path, creating a U-shaped network architecture. Another important modification of U-Net was the use of an overlap-tile strategy for large image segmentation, in which a slightly larger tile is used as input and predictions are produced for the centered small tile. This method achieved an average $J$ of 77% on a cell segmentation task [26].

While much work has been done in histological image analysis of prostate cancer, few addressed the problem of differentiating high-grade versus low-grade cancer. In this paper, we developed a multi-scale U-Net to predict four tissue classes at once (ST, BN, G3, and G4). We compared the proposed method with a pixel-wise CNN, a standard U-Net and a previously developed model by Gertych et.al.[11] that uses a combined SVM and RF classifier. Our multi-scale U-Net outperformed all other models and achieved the highest mean $J$ of 65.8% across four classes.

Methods

Dataset

Radical prostatectomy specimens from 20 patients with a diagnosis of G3 or G4 prostate cancer according to the contemporary grading criteria [27,28] were retrieved from archives in the Pathology Department at Cedars-Sinai.
imbalance of the dataset, in this methodology, individual potential patches from different classes would have unequal probability of being sampled. Because of the class probability of being sampled. Training was performed using an RMSProp (LR = 0.001, optimizer using Keras [32] with Tensorflow [33] on two NVIDIA Titan X GPUs with synchronous gradient updates and a batch size per GPU of 50 patches. In order to saturate the GPUs during training, patch sampling was run in threads with separate state; one sampler thread was used per GPU. Training was performed over 25 “epochs” of 100,000 patches.

For evaluation, every possible patch was extracted from tiles in the testing set, and any patches that would have extended outside of the bounds of the original tile were discarded. Class predictions were obtained for these patches from the network, and each pixel was assigned a class based on the maximum prediction probability for that pixel.

Semantic Image Segmentation with U-Nets

Convnets produce dense predictions by extracting patches around every pixel, which can be inefficient even for images with moderate size. The FCN proposed by Shelhamer and Long, et.al. [24,25] uses up-sampling and fully convolutional layers to generate pixel-wise predictions efficiently in a single pass. The pooling operation makes CNNs relatively invariant to spatial transformations and also reduces spatial resolution of feature maps. To enable making local predictions with global context, the U-Net [26] extends an FCN with a U-shape architecture, which allows features from shallower layers to combine with those from deeper layers [24,26].

One intuitive way of performing semantic segmentation with FCN is to use the entire image as the input. However, training FCN with large images may require a huge number of samples and also can cause high GPU memory requirement. To solve these problems, large images are divided into several relatively smaller patches, and the overlap-tile strategy is used for seamless segmentation [26]. This requires the size of the patch to be carefully chosen so that the patch can be segmented with sufficient contextual information. Yet, the size of cellular structures such as glands may vary greatly as shown in (Figure 1). To better segment tissue structures with variable size, we propose a multi-scale U-Net architecture that incorporates patches (subtiles) of three different sizes: 400x400, 200x200, and 100x100 to explicitly provide contextual information at multiple scales [34]. To handle border patches that cause one of these patch sizes to extend past the boundary of a given image tile, the tile is padded with reflection of the border [26]. A detailed overview of our multi-scale U-Net architecture is shown in (Figure 2). Instead of taking the whole 1200 x1200 image tile as input, we divided images into 100x100 subtiles and extracted the three patches of varying size around each of these image subtiles. Features from different sizes of patches were then concatenated together and used as...
inputs for the multi-scale U-Net model. The commonly used fully connected layer was replaced by a 4x1x1 convolutional layer that output pixel-wise probabilities for four classes (G3, G3, ST, and BN).

Figure 1. Variations in gland size. (a) shows a tile with heterogeneous Gleason grades (G3, G4 and benign glands). Pathologist annotation mask is shown in (b). The high-grade cancer (G4) areas are shown in red, low-grade cancer (G3) areas are denoted as pink, benign glands are indicated by green, and stroma areas are represented by blue. These images demonstrate the heterogeneity of glands both between grades (e.g. glands A and C) and within the same grade (e.g. glands A and B).

Figure 2. Architecture of the multi-scale patch-based U-Net. The whole image was divided into multiple non-overlapping 100x100 subtiles. To capture contextual information, a 200x200 patch (framed in yellow) and a 400x400 patch (framed in black) were extracted around each centered 100x100 patch (framed in red). Features of different sizes were either down-sampled or up-sampled to 200x200, and concatenated into 64x200x200 feature maps that were input to a U-Net model. The final layer output a 4x100x100 probability map, each channel of which corresponded to a probability map of one class.
In this experiment, we trained two FCN models. The first was the baseline U-Net model that followed an existing work [26]. The other is the multi-scale U-Net. Both models were trained with batch gradient descent (batch size: 25) and backpropagation. A momentum of 0.9 and a learning rate of 0.05 were used. A heuristic was followed to improve the learning of deep neural network model [19], where the learning rate was decreased by 10x when validation errors stopped decreasing. Models were implemented in Torch7 [35], and the training was done on two NVIDIA Titan X GPUs. The dataset of 20 patients was divided into 10 folds resulting in two patients in each fold. This patient-based cross validation ensured independence of training and testing data.

**Evaluation Metrics**

Overall pixel accuracy, mean accuracy for each class, and Jaccard index are three commonly used evaluation metrics for multi-class semantic image segmentation. Overall pixel accuracy measures the proportion of correctly classified pixels, however, it can be biased by imbalanced datasets. Mean single-class accuracy calculates the average proportion of correctly classified pixels in each class, which can also be biased by imbalanced datasets and overestimates the true accuracy due to combining multiple negative classes into one inference class [36–38]. Jaccard index, also known as intersection-over-union, overcomes the limitations of overall pixel accuracy and mean accuracy since it considers both false positives and negatives.

Here, we report Jaccard index and overall pixel-wise accuracy for our models, which can be obtained from a pixel-wise confusion matrix $C$. $C_{ij}$ is the number of pixels labeled as $i$ and predicted as $j$. The total number of pixels with label $i$ is denoted as $T_i = \sum_{j=1}^{N} C_{ij}$, where $N$ is the number of classes. The number of pixels predicted as $j$ is represented as $P_j = \sum_i C_{ij}$ [36]. The Jaccard index for class $i$ is then defined as follows:

$$J_i = \frac{C_{ii}}{T_i + P_i - C_{ii}}$$  

(1)

The overall pixel-wise accuracy (OP) is defined as

$$OP = \frac{\sum_i C_{ii}}{\sum_i \sum_j C_{ij}}$$  

(2)

**Results and Discussion**

**Model Comparison**

For the pixel-wise deep CNN model, class predictions were produced for a testing set comprising 30,170,133 pixels in 37 tiles across 3 patients. For the standard and multi-scale U-Net models, pixel-wise confusion matrices were summed across all 10 folds. In the first evaluation, true positive, true negative, false positive, and false negative rates for each class were calculated for all pixels in the dataset. Gleason 3 and Gleason 4 predictions were summed into a single inference class (PCa) for evaluation. For comparison, results from a baseline SVM + RF model by Gertych et.al. [11] are also included. The Jaccard index and overall pixel accuracy of each model are reported in (Table 1). The analysis was also performed without combining Gleason 3 and Gleason 4 into a single class, with performance shown in (Table 2). In both cases, the same network (trained on separate classes) was used for prediction. The multi-scale U-Net architecture achieved the highest Jaccard index in both segmentation tasks: mean $J = 75.5\%$ for 3 class segmentation and mean $J = 65.8\%$ for 4 class segmentation. Both the U-Net and multi-scale U-Net models outperformed the pixel-wise CNN and the SVM-RF model by Gertych et.al. [11].

The approximated inference time for each model is also measured. It took about 2 hours for pixel-wise deep CNN model, around 3 seconds for U-Net model, and 9 seconds for multi-scale U-Net to generate predictions for a 1200x1200 tile on one NVIDIA Titan X GPU. Dense predictions can be much more efficiently produced by FCN.

^a The previous model (SVM+RF) by Gertych, et.al. only addressed three class segmentation by combining G3 and G4 to PCa.

Segmentation results generated by U-Net and multi-scale U-Net for two representative image tiles are shown in (Figure 3). Our models performed well in segmenting different tissue types on image tiles with heterogeneous content, but both models struggled with some border areas due to a lack of contextual information. The small high-grade gland marked by a white arrow in the second row in (Figure 3), for example, was segmented as low-grade gland by both models.

In cases in which global information may be more important for class prediction, the multi-scale U-Net showed superior performance. As shown in (Figure 4), the single input U-Net misclassified areas with dense nuclei on a large benign gland. However, the multi-scale U-Net was able to segment this area correctly. Though both models could segment large irregular high-grade glands very well (Figure 3), they had limited power in segmenting poorly-formed high-grade areas, as shown in the first row of (Figure 5). Models could detect the approximate location of high-grade glands.
cancer, but failed to segment the exact areas. Segmentation performance of both models decreased on tiles with a mixture of small high-grade glands and small low-grade glands. The highest Jaccard indices for G3 and G4 achieved by the multi-scale U-Net were 49.8% and 61.5%, respectively. This reflects the reality that differentiating G3 and G4 is a challenging task, even for pathologists. The inter-observer agreement of clinical pathologists for distinguishing G3 from G4 is between 25% to 47% [11,39]. A larger training dataset that represents more of the natural variance of these cancer grades could allow for improving the models’ ability to discriminate between these classes.

**Conclusion**

In this paper, we addressed the challenge of segmenting different tissue types on heterogeneous histological image tiles by using deep learning techniques. The performance of three different deep learning models (pixel-wise CNN, U-Net, multi-scale U-Net) were evaluated and compared using the Jaccard index and overall pixel accuracy. All three models outperformed a reference algorithm on three-class (ST, BN, PCa) segmentation. Both the U-Net and multi-scale U-Net models achieved a higher Jaccard index than the pixel-wise model. The multi-scale model with three types of inputs (400x400, 200x200, 100x100) showed superior performance as compared with the original U-Net, likely due to its ability to explicitly make use of more global information without overly increasing memory requirements during model training.
There are some limitations in our work. Models were only trained on image tiles, rather than whole histological images. Though our method can be extended to whole image segmentation by splitting these images into non-overlapping tiles, the prediction accuracy for boundary patches could be influenced by lack of contextual information and changes in class balance. Also, our model did not perform as well in segmenting G4 cancer with less differentiated glands. Exploring other approaches, such as the use of two separated models with two scales of inputs [40], could improve performance in the future. We also plan to investigate the influence of global versus local features on predicting dense labels, and will perform further evaluations of our models with whole histological images and extend our algorithm to a computerized tool which can be used to extract reliable and reproducible quantitative features from histological images.

Abstract

In this paper, we propose a novel neural network architecture for clinical text mining. We formulate this hybrid neural network model (HNN), composed of recurrent neural network and deep residual network, to jointly predict the presence and period assertion values associated with medical events in clinical texts. We evaluate the effectiveness of our model on a corpus of expert-annotated longitudinal Electronic Health Records (EHR) notes from Cancer patients. Our experiments show that HNN improves the joint assertion classification accuracy as compared to conventional baselines.

Introduction

In recent years natural language processing techniques have demonstrated increasing effectiveness in clinical text mining. Electronic health record (EHR) narratives, e.g., discharge summaries and progress notes contain a wealth of medically relevant information like diagnosis information, adverse drug events etc. Automatic extraction of such information and representation of clinical knowledge in standardized formats could be used for a variety of purposes like clinical event surveillance and decision support, pharmacovigilance and drug efficacy studies etc. Extracting information from EHR narratives presents challenges unique to this domain. Unlike open-domain data, clinical text normally contain a substantial amount of in-domain terminology and domain-specific knowledge. Therefore, accurately recognizing and understanding the medical entities in clinical text become essential for useful information extraction.
