The findings of our study are a building block toward the development of an approach to improve the specification of eligibility criteria. An understanding of the pragmatics of interfacing with actual clinical data in repositories can inform previous work on the semantics and interoperability of criteria. A set of questions, such as those listed above, guided by knowledge of criteria semantics, will help to establish a dialogue between the investigator and the data analyst (or provide an opportunity for introspection if the investigator is accessing a repository in self-service mode). Further study can lead to refinements in the categories and further strategies and tools for prioritizing criteria. Improving self-service queries will likely require an iterative process of extensions, corrections and refinements.

**Conclusion**

The findings of this study support the hypothesis that clinical research eligibility criteria fall into stereotypical categories with respect to ease of querying data available in EHR repositories. Describing these categories explicitly supports the potential development of a structured process using a data entry form or interactive “wizard.” Such an application may encourage researchers to express their criteria in ways that promote realistic expectations for the recruitment process and improve data retrieval by analysts and researchers.

Abstract

Documentation processes have changed substantially with EHR adoption. User satisfaction studies have focused on usability or cognitive analysis perspectives. Few studies have provided useful information to developers to improve designs. The purpose of this study is to report a 3-pronged approach to deepen understanding of the documentation process, with the intent to provide useful information for future design. This study was conducted in two phases, beginning with cognitive task interviews and observations, followed by post-observation interviews. Twenty-five constructs were identified across the phases, and we observed several patterns of note writing. Participants provided useful information to potentially inform future design. Our study illustrates how electronic documentation serves many clinical processes and is at the core of the medical record. Providers need multiple kinds of notes and ways to display notes. In order to meet provider goals, we must completely re-think the way electronic documentation is composed and displayed.

Introduction

Adoption of electronic health records (EHRs) has resulted in large-scale use of computerized documentation. An emerging tension has resulted between provider’s traditional documentation practices as a component of clinical care, communication and record keeping versus the drive to use computerization to support structured data, in order to feed automated decision support, billing and general quality tracking.

This tension plays out in the complaints of clinicians regarding the usefulness and quality of current electronic notes. These complaints range from a widespread concern with increased time burden, inefficiencies as well as patient safety issues associated with copy and paste tools.(1-9) In addition, the notes themselves have become longer and perhaps less informative. (8-12) In fact, electronic documentation is one of the main areas of clinician’s complaints about the burden of computers and is often thought to be wholly inadequate. Yet, clinicians spend on average 60% of their time in notes.

To address these complaints, vendors and EHR designers have incorporated many time saving features in the documentation software, including templates that automatically insert text, labs, problem lists and other information in addition to copy and paste tools. Although these features have improved efficiency, they have resulted in increasing concerns for patient safety as well as for the overall quality of clinical progress note documentation. In one qualitative study using focus groups of experienced VA users, Weir, et al. identified emergent issues including unreadable notes, template-created errors, lower quality information, and inability to track the patient’s story.(13) Embi, et al’s work found similar results with house staff in another institution.(2) Roosenbloom found that although users noted increased accessibility and improved communication, they also complained that electronic documentation was less professional and informative.(6) The source of this dissatisfaction remains unclear, but likely goes beyond time saving documentation features. Note writing is not serving all of the goals in clinical documentation. Prior research may not be digging deep enough to understand user’s goals at the level that could really be used to improve design.(14-16)

In addition, the use of electronic documentation has changed the way clinicians do work, suggesting that new action identities or goals may be emerging out of a transformation process that has emerged with the adoption of the EMR. Such a transformation is highly likely, because of all of the clinical workflow processes, electronic documentation has been the most disruptive. When paper was used, notes were short, to the point and unreadable. With electronic documentation, notes can be as long as 5 pages, full of unnecessary information that is hard to read and integrate. Note writing can take hours or more.(17, 18) Given this transformation, we need to understand the current practice patterns and workflows and model the purpose of electronic documentation in the new world. The workflow of documentation has changed as electronic notes are used to support handovers, serve as event logs, and as tools to organize thinking.
The purpose of this paper is to report a qualitative study to clarify user’s action identities or goals associated with computerized clinical documentation. Hopefully, these results will contribute to the dialogue about how we can rethink the role of progress notes in an EHR.

**Action Identities or Task Goals**

Action representations are the complex mental representations or schemas that support the full action cycle. These mental representations are hierarchically organized and include the meaning of the task, the contextual cues that will trigger the action, the physical actions learned to support the task, and the overall purpose or goal that is trying to be achieved. When these complex schemas are activated, perception becomes more goal oriented, related memory becomes more available and many behavioral tendencies are automatic. Because many different actions can support the same high level goal, understanding goals and their associated action identities may be one of the most important steps in designing systems that will in the end change behavior.(19-21)

Measuring goals is complex because experts are often not aware of their actions (but may be aware of their goals) and action identification (how people label about what they are doing) varies as a function of expertise, difficulty and role. For example, novices often describe their behavior in terms of the actions involved and rarely refer to purpose or goal. Similarly, those in charge will describe their work in terms of meaning or big-picture goals, whereas subordinates are much more likely to describe their tasks in more concrete terms. Everybody will report their goals in terms of the context in which the question is asked.(20, 22) In this study, we approached the measurement of goals from several directions in order to more fully understand the mental representation of clinicians regarding computerized documentation. We focused this study mostly on inpatient physicians, but our future plans will extend to other disciplines and settings.

**Methods**

The study was conducted in two phases. In phase I we conducted cognitive task interviews in order to initially explore users’ perception of the documentation process. In phase II, we engaged in observations of clinicians across diverse clinical settings writing notes and completing documentation (with very little interruption) in order to capture the context of documentation and workflow patterns. We also conducted short post-observation interviews.

**Setting and Sample**

The University of Utah Institutional Review Board approved this study. Data collection was conducted at a large, >500 bed academic hospital located in Salt Lake City, Utah. Participants were physician interns, residents, attendings, hospitalists, and consultants, and were selected by convenience sampling methods. Sample size for each phase is listed in Table 1. Phase I was conducted in May 2014, phase II/observation interview participant data was collected from October 2014-February 2015. All phases included participants across a diversity of inpatient clinical domains (Table 1).

Procedures

Phase I. Phase I of this study consisted of cognitive task interviews conducted with participants during the week prior to the implementation of a new Epic EMR system replacing a previously used Cerner EMR. A list of potential participants were selected by first identifying the desired clinical domains, then creating a list of current residents in each domain as well as at least 1 attending and/or hospitalists. Potential participants were approached in their clinical units and asked to participate in a brief, recorded interview (average 15”). Questions were open-ended (and loosely based on the procedures for eliciting a Critical Incident(23): 1) Please recall a typical recent documentation episode in last 24 hours; 2) Describe the context (when, where, type of note, how did you start/finish, how do you fit it into workflow); 3) What was your main purpose in writing the note (e.g. what were you trying to achieve, definition of success, goals); and 4) What prevents you from reaching those goals/purposes. These questions were adaptations from the Action Identification methods of Vallacher and Wegner (1984),(20) whose approach to identifying action identities starts with an initial question “What are you doing”, followed by “You are doing X in order to do what?” followed by “You accomplish Y, but doing what?” (thereby mapping out the whole value to action mental representation). We used similar questions as sub-probes. Prior work suggested that note writing included cognitive activities of synthesizing and organizing their own thoughts, communicating to other team members in a way that they would understand, creating summaries of the hospital progress, and following rules for billing. Three investigators independently coded the transcribed data looking explicitly for statements related to goals, purpose, and action statements. Because goals and task descriptions are often imbedded, assumed, or nuanced, we took time to look for emergent concepts in vivo and through consensus in an iterative process. We used @Atlas.ti qualitative analysis software for coding, then organized into a Microsoft Excel spreadsheet for discussion.

Phase II. Phase II consisted of observations and very short interviews with participants in the clinical setting during targeted time periods of high rates of documentation activities. Data collection forms (using I pads) were iteratively pilot tested and refined using the goals and action tasks derived from the codes identified in phase 1. Six investigators approached potential participants in their clinical units and explained the purpose and procedures of the study. We identified important times, so that about 50% of the times sampled were in the morning, before and after rounds, afternoons in order to capture handovers, and early evening in order to capture admission from the Emergency Room. For every time period, we entered a physician group area and asked if someone would be interested in volunteering. Always somebody did, and anybody we directly asked (such as a hospitalist or outside Attending) never refused. The institution is a teaching organization, meaning that in every clinical setting there are house staff teams, attendings, and fellows. Our goal was to enroll a representative sampling of each role. Occasionally, an outside consultant would appear.

The procedures consisted of entering a setting with several physicians working on computers and ask if anyone would volunteer to be observed writing a note. Nobody refused when asked directly. Those agreeing to participate were observed during a documentation session wherein a participant created one of several types of notes in the Epic EMR (2016) including: rounds preparation, daily progress note, history and physical exam, consultation note, transfer note, or a discharge summary. We measured the time to complete the notes, where else they went in the chart in order to complete the note, their use of templates, copy and paste, and what determined when they could complete the note (turns out to be more complicated in that they would be waiting for more data, waiting to get input from their Attending, or waiting to get more lab results). If they offered their evaluations (such as this is a pain to do in EPIC), we would probe to ask why. The brief interview (< 3 minutes) simply asked their goals, barriers to achieving their goals, perceived efficacy, and any suggestions they had for the Epic system implementation.

Observations and interview responses were captured in written notes by each investigator and entered into a secure REDCap database (@Vanderbuilt, 2015). No audio recording was done. Interview responses were aggregated and extracted from the data set and uploaded into Atlas ti@. Three researchers independently reviewed and then iteratively discussed the selected data and associated codes until consensus was reached in order to identify mid-level action identities regarding the documentation process.

Results

Interviews

We identified 20 actions identities in the phase I cognitive task interviews (Table 2). The goal of supporting ‘billing’ was the most prominent goal identified in Phase 1 (n=17) and in additional 9 in Phae 2 (total = 26). ‘Demonstrating rationale for care provided’ followed as the next most frequently occurring goal for documentation (n=7), with
‘understanding rationale for care provided,’ ‘provider information exchange,’ and ‘educational tool’ following in frequency (n=5 each). The remaining constructs occurred <4 times.

There were a total of 22 action identities that emerged from the interviews in phase II (Table 2). The most frequently occurring was ‘creating and monitoring plans’ (n=15), followed by ‘provider information exchange’ (n=13), ‘summarize patient status’ (n=12), ‘information repository and resource’ as well as ‘to be accurate’ (each n=11), ‘demonstrating rationale for care provided’ (n=10), ‘billing’ and ‘to be comprehensive’ (each n=9), ‘rules & regulations compliance’ (n=8), ‘providing “gist”’ (n=7), and ‘providing clear and informative information’ (n=3). The remaining constructs all occurred with a frequency <4.

Twenty-five unique action identities were identified in total across both initial phases. Specific constructs, their descriptions, and example excerpts are listed below in Table 2.

**Observations**

During our observations, we observed 3 patterns of note writing: 1) preparing notes (sometimes began and left to be completed, or used for rounds); 2) writing daily progress notes (sometimes attached to rounds) containing a detailed log; and 3) brief, 24-hour summaries of what happened in the day. Each clinical setting varied significantly in note length and content.

**Suggestions to Improve Design**

In phase II, participants were asked if they had any suggestions to improve the documentation process. The participants provided useful information regarding data display, customizability, searching for information, and training. Suggestions for data display improvements were highly concentrated around “note bloat,” with the great deal of excessive information in the display being the greatest source of frustration, inefficiency, and potential risk to patient safety. Many features of the EHR could be greatly improved by limiting the amount of information displayed and eliminating redundancies. A common documentation goal was to write concise, informative notes that could communicate easily the “gist” of the patient’s situation. (Communicate to Team or Assist with Thinking). For example, several residents talked about the need for a better discharge summary process so that they could easily see the course of the hospitalization. Because each team has unique clinical information needs and diverse role responsibilities, more customizability is needed across specialties and providers. Apparently, communication to nurses and other allied health is subsumed in the documentation process as well as part of workflow, but not supported in current functionality (Care Coordination).

Participants also suggested that searching and tracking of information could be improved. All residents had to go to other parts of the chart while writing notes. (Assist with Thinking) Sophisticated search engines within the note writing environment would be useful and are now widely used across information technology industries. Finally, the easiest way to improve existing design was the simple request to provide additional training. Many participants knew that some of the features they wanted already exist within the system; however, the early training they received did not adequately prepare them for the optimal level of mastery. Several participants asked for brief “YouTube” type videos that addressed certain topics that they could search for as needed, or having periodic, on-unit re-trainings at 6-month intervals.

**Discussion**

Identification of clinician’s documentation goals provided insight into current usage patterns of electronic documentation. As experience with EMRs has increased, users have impacted the design of the technology and the technology has impacted the users. This co-evolution is continuing and demonstrates the transformative nature of health information technology. Assessing this change is challenging and this work helps put forward an approach that could be used over time to clarify the change.

**Measuring Satisfaction**
This work can support a conceptual model of documentation satisfaction that can be used across systems and time. Because the constructs were derived empirically from clinicians who have been working and using two EMRs for many years, the results capture the current transformational changes in workflow created by electronic documentation. Developing a model that can be generalizable across systems as well as across time will allow for future development impact to be measured effectively.

**Clinical Implications**

Our study illustrates how electronic documentation serves many clinical processes and is at the core of the medical record. Providers must be able to successfully write notes and use documentation as a communication tool as they provide patient care and fulfill institutional responsibilities. It is the area where clinicians spend most of their time. EHR interfaces that are designed with complicated, confusing, or superfluous data display and/or entry mechanisms may interfere with workflow by at best frustrating and dissatisfying providers, or at worst by hindering patient care.(24) Specific areas where documentation processes were impactful were handoffs, rounds and transitions. The tension between structured data and narrative data is most visible in regards to billing requirements.(18) Clinicians were very aware of the need to support billing requirements, but often expressed an attitude that it was more an institutional requirement than a clinical one. They also requested more decision support in meeting those billing requirements. This has additional implications for physician workflow, as the link between clinically relevant data representation and billing requirements is confusing in many EHRs.(25). To support the goals of communication and planning, EHRs should provide explicit, standardized terminology and data elements in order to optimize and support clinical workflow.(26)

As billing was the most prominent issue for providers in phase I of the study, the data suggest that streamlining the documentation processes in a way that makes billing easier while concurrently making documentation of care more seamless would be beneficial. A space for rationale of care and/or communication space outside of an actual note might be beneficial too. More intuitive clinical decision support (CDS) with best practice alerts (BPAs) may also prove effective in guiding documentation.

**Design Implications**

The health care domain provides one of the best use cases for user-centered design (UCD). While billing, administration, and secondary use of patient information are important, electronic documentation in this high demand/high risk sphere must be responsive to user needs so they can spend more time providing care and less time in front of a computer. These goals might be mutually exclusive and it might be time to rethink the medical record design. Information display literature focuses largely on what content is displayed rather than how it appears, however UCD insists on the opposite. Improving data display by reducing “note bloat,” adding customizability features, organizing information into clinical patterns and improve information searching would workflow. A streaming feed of most recent orders could appear alongside a patient's chart, which includes labs and vitals automatically uploaded from instruments that would serve as communication and information and have hyperlinks to longer reports in the patient chart.

In addition, providers need to have more than one kind of note and more than one way to display notes. There is a wide range of preferences for how providers prefer to do their documentation, also varying by service, which must be considered. As not all services are the same, providers cannot and should not be expected to document the same way. For example, in psychiatry, interactions with patients are more conversation and observation-based, which lends itself more to text narratives than drop-down lists or smart phrases. Providing a note writing area for thoughts, being able to tag information, or run summary reports with exactly the information a user wants (and nothing they don’t) from that contains the whole story of the patient, or just the “gist,” or choose tagged info with plans or assessments, etc. would greatly improve the safety, efficiency, and satisfaction of physicians. The variation across clinical settings suggests that documentation is evolving differently in different domains. To support this diversity, system designers must create more documentation options.

**Limitations**

This study was done at one site only, with one system only, and using volunteer and available participants. In addition, the focus was narrow, with observations of only physicians in the inpatient setting with an emphasis on internal medicine areas. The methods were qualitative, not experimental. However, every effort was made to get as close as possible to the clinical work process. Collecting Phase 1 interviews during a transition may be a limitation.
Conclusion

In this study, we evaluated workflow and documentation goals across a spectrum of clinical services and provider levels. The current formulation and mechanisms for documentation may not be able to meet all those goals. A transformation in the way progress notes are composed and displayed might be essential. Separating out functionality to support expressivity in documentation (telling the patient’s story), complying with billing regulations, communicating to other providers, and support for higher-level thinking may be necessary.

As medical organizations increasingly adopt the use of electronic health records (EHRs), large volumes of clinical data are being captured on a daily basis. These data provide comprehensive information about patients and have the potential to improve a wide range of application domains in healthcare. Physicians and clinical researchers are interested in finding effective ways to understand this abundance of data. Use of visual analytics to explore healthcare data is one such research direction. Here, we present a visualization and analysis environment to understand patient progression over time. Through the use of optimized data structures and progressive visualization techniques, we allow users to interactively explore how patients and their progression change over time. Compared to existing techniques, our work provides additional flexibility in analyzing patient data and has the potential to be used in a real-time hospital setting. Finally, we demonstrate the utility of our approach using a publicly available intensive care unit (ICU) database.

1 Introduction

The US healthcare system is producing hundreds of thousands of patient records detailing a wide range of information from admission times and dates, to symptoms and outcomes. Until recently, this data has been difficult to access, especially in bulk, often lacked a useful organization, and thus has been generally underutilized for clinical research. With the increasing use of EHRs, this paradigm changes, allowing researchers easy access to a large collection of information. If used effectively, this data may lead to better predictions of patient outcomes, personalized medication, and more targeted interventions. However, to realize this potential requires the ability to understand the clinical data in detail. Given the massive amounts of available data, for example, ICUs may collect real-time data streams of all patients\textsuperscript{1}, which implies automatic or semiautomatic techniques to identify and explore interesting patterns and underlying trends. In this context, visualizing and exploring patient progression over time can provide valuable insights and facilitate the decision-making of physicians and clinical researchers.

Several factors need to be taken into consideration when analyzing this type of data: First, given the large number of patients, an individual, per-patient analysis is time-consuming and does not lend itself to finding commonalities and trends. Instead, patients should be grouped according to various criteria, such as symptoms, outcomes, etc. Second, to compare groups of patients who arrive at different times, their records must be aligned, for example, by their time of admission, time of major procedures or other common factors. Third, patient progression over time needs to be presented in a concise manner to allow simultaneous exploration of large numbers of patients. Finally, to utilize such a system in a hospital setting, the analysis must be interactive, allowing users to quickly explore different hypotheses.

The ideal system described above presents a number of practical challenges, especially for the large databases of interest. First, there exist a number of potentially interesting metrics by which to group patients and thus any analysis must be flexible and efficient enough to change the metric on-the-fly. Furthermore, whereas some metrics are easy to apply and absolute (e.g., splits by gender), others depend on specifying a similarity threshold that determines when two patients are considered to be in the same group. However, in practice this threshold is typically not known a priori, and in fact understanding how patient distributions and progression change with different thresholds may provide important insights. Most existing approaches focus on a single metric and a preselected threshold\textsuperscript{2,3}; we present a system that allows users to freely explore patient grouping metrics and thresholds in an interactive setting.

Another challenge is the size and complexity of the data. Given a large number of patients and high temporal resolution, it is often difficult to grasp the progression of certain groups, let alone identify salient ones. Therefore, presenting data in a concise manner and providing support for various parameter selections and simplifications is crucial to provide the necessary insights.
From an analysis perspective, providing an effective exploration of patient progression requires three abilities: first, grouping patients within a time step at different similarity thresholds; second, correlating patient groups over time; and third, interactively visualizing and exploring patient progression to understand how different similarities affect their behavior. In this paper, we extract patient groups across multiple patient similarities and explore their progression with the aid of tracking graphs, where a concise representation of feature evolution is captured as a collection of feature tracks, see Figure 1. We provide clinical researchers with a visualization and analysis environment that is developed based on our earlier research in the scientific domain\textsuperscript{4,5}. This prior system couples feature grouping and correlation components with visualization techniques to explore the temporal evolution of features in combustion data sets.

Our system process data in several steps. First, we use the patient similarity metric introduced by Lee et al.\textsuperscript{6} to group patients across multiple similarity thresholds. Here, it is important to note that any other patient similarity metric can be used within this system as well. Second, patient groups are correlated over time by tracking the individual patients within a group. In order to allow interactive extraction of data, our system uses optimized data structures to store these patient group and correlation details. Within the system, tracking graphs are used to present a global concise view of patient progression, and progressive visualization techniques are employed to enable interactive exploration of data. Finally, in collaboration with clinical researchers, we apply our visualization and analysis environment to a publicly available ICU database, the clinical database of Multiparameter Intelligent Monitoring in Intensive Care (MIMIC II) databases\textsuperscript{7}, and explore the temporal progression of patients for varying similarity thresholds.

2 Related Work

A subset of the relevant related work is presented here to provide context and background for our research work. Analyzing time-varying data sets usually involves feature extraction and tracking steps. For healthcare data, tracking the progression of patient groups, i.e., the features-of-interest, is relevant to clinical researchers. Among the many feature definitions and their computation techniques found in the literature, techniques that extract feature information for all or a large range of values in a single pass are particularly useful. These techniques often result in hierarchical representations. For instance, hierarchical clustering\textsuperscript{8,9} and various other topological techniques\textsuperscript{10–12} have been used to effectively capture flexible feature hierarchies.

Hierarchical clustering is considered to be one of the most popular methods for creating a feature hierarchy. It partitions data into homogeneous groups based on a measure of similarity through the use of clustering. Depending on the similarity measure used, the results can lead to very different hierarchies. Moreover, many sequential and parallel algorithms for hierarchical clustering are available in the literature\textsuperscript{8,9}. This type of clustering imposes a hierarchical structure on the underlying data irrespective of whether such a structure is appropriate. However, due to its simplicity, many applications have used this method to explore the clustering hierarchy of features. In this work, we also make use of hierarchical clustering to group patients within a time step at different similarity thresholds. In topological analysis, techniques exist that are able to efficiently extract and encode entire feature families in a single analysis pass. Reeb graphs\textsuperscript{13}, contour trees\textsuperscript{10}, merge trees\textsuperscript{12}, and Morse-Smale complexes\textsuperscript{11} are several such techniques. Among them, Reeb graph, contour tree, and merge tree are contour-based and the Morse-Smale complex is gradient-based. As a result, the Morse-Smale complex captures very different structural information.

Visualizing the temporal evolution of features has long been a problem of interest within the visualization community. Depending on the subject area, many different techniques have been developed to address this problem. Traditionally, abstraction, illustration, morphing or animation-based techniques have been used to visualize temporal evolution of features\textsuperscript{14,15}. Tracking graphs that show the feature evolution as a collection of feature tracks that split or merge over time are considered to be an effective representation for visualizing feature evolution\textsuperscript{4}. These graphs provide concise...
global views of feature evolution and are more amenable to filtering and simplifications. As clinical researchers are particularly interested in concise representations, we make use of tracking graphs to visualize patient progression over time.

Rind et al.\(^{16}\) present a comprehensive survey of information visualization systems used to visualize, explore, and query EHRs. These approaches related to EHRs can be broadly categorized into two categories: those that focus on a single patient record\(^ {17}\) and those concerned with a collection of patient records\(^ {2}\). Approaches in the first category focus on providing comprehensive information about a single patient (e.g., patient history, significant events, medication, and treatment), and the second category aims at presenting an overview from multiple patients. The latter provides less detail on each individual patient and focuses more on recognizing patterns and outliers within patient groups. Among these approaches that fall in the second category, LifeFlow\(^ {3}\) and OutFlow\(^ {2}\) are particularly interesting as they visualize event sequences in EHRs. LifeFlow uses color for a compact view and OutFlow uses a graph-based representation. In contrast, we do not visualize the progression of patient groups as an event. At a particular time step, the current event of a patient is one of the parameters considered within the patient similarity metric used. Also, within our system any similarity metric can be used to define patient similarities, providing more flexibility.

3 System Components

An interactive visualization and analysis environment is essential to gain an in-depth understanding of patient progression. In this paper, we refine a prior system that relies on dynamically constructed tracking graphs to enable feature extraction, tracking, and simplification\(^ {4,5}\). This system is designed to study general time-varying features. However, so far it has only been applied to analyze features in scientific simulations. Here, we extend its functionality to effectively visualize patient progression in healthcare data. This section describes our system partitioned into several subsections dealing with: patient grouping, patient correlation, visualization, exploration, and implementation.

3.1 Grouping Patients Within a Time Step

The first step towards understanding clinical data is defining its features and a time step size based on which subsequent analysis is to be conducted. For our intended research, the feature-of-interest is a patient group (i.e., similar set of patients), and a day is considered to be the appropriate time step size. Next, for each time step in the data set, these patient groups need to be extracted and aligned. In this work, to ensure all patients’ hospital stays start at the same time, we align data based on a patient’s admission time.

Once features are extracted and aligned, they should be grouped based on an appropriate grouping method. By maintaining a notion of scale, this feature grouping naturally approximates a meaningful hierarchy. The naive approach of creating this hierarchy is by exhaustively precomputing all possible features at all possible scales. Many popular grouping algorithms also produce nested sets of features for varying scale, which in turn create feature hierarchies (e.g., hierarchical clustering techniques progressively merge elements\(^ {8}\) and threshold-based segmentation creates increasingly larger regions\(^ {11}\)). In this case, we use hierarchical clustering. Patient groups in each time step are clustered based on their similarity to generate a hierarchical representation in the form of a tree. During clustering, we use the similarity metric by Lee et al.\(^ {6}\) to define patient similarities but any other similarity metric could be used as well.

Figure 2(a) shows an example where such a hierarchy is constructed by progressively merging individual patients, with the most similar ones clustered first. Each leaf in the hierarchy represents a patient and each branch a patient group. Along with the hierarchy, various patient group-based attributes such as patient count, mean age and mean heart rate are computed and stored on a per-branch basis. For a given data set, an offline preprocessing step is used to compute these patient hierarchies, and the results are stored in a look-up structure to allow interactive exploration of patient groups. Within this look-up structure, for each patient group, its parent details and patient group-based attributes are stored. To determine correspondences across patients later, each patient is marked with a unique ID. This hierarchy is computed for each time step in the data, and is stored in a separate file to allow interactive exploration of patient groups. Once the hierarchy is computed, patient groups and their attributes can be quickly and easily extracted for any similarity threshold within its range, see Figure 2(b). Given a similarity threshold \(s\) within the full range of \(r\), the corresponding patient groups can be extracted by “cutting” the hierarchy at \(s\). This creates a forest of subtrees, where each subtree represents a patient group existing at \(s\).
3.2 Correlating Groups of Patients Over Time

Once patient groups are identified, the next step is to correlate them over time by tracking individual patients within a group. Two patient groups in consecutive time steps are considered to be correlated if they share at least one patient. All such correlations are extracted for each time step. To efficiently store and interactively extract these patient group correlations, we utilize the meta-graph structure of Widanagamaachchi et al.4. Similar to the patient hierarchy, this meta-graph structure is able to encode patient group correlations and their attributes for a range of similarity thresholds.

The meta-graph is generated in two steps. First, per-patient correlations are computed using the patient IDs computed above. For example, two patients in consecutive time steps are considered to be correlated if they have the same ID. As individual patients are represented by leaf branches in the patient hierarchy, this step results in correlations across leaf branches in consecutive time steps. If a correlation exists, we assign an edge with the weight of 1 across the two corresponding leaf branches, \((s_j', s_j'^{t+1}, 1)\). Second, these per-patient correlations are accumulated along the patient hierarchy to compute the per-patient group correlations. At the accumulation time, if a correspondence already exists, we accumulate only the edge weights.

Just as in the patient hierarchy, various correlation-based attributes such as the amount of patient overlap are computed and stored within the meta-graph structure. Again, once the meta-graph is computed, patient group correlations and their attributes can be quickly extracted for any similarity threshold within the full parameter range. For a selected similarity threshold \(s\), first, patient groups existing at \(s\) for each time step in the data set are obtained using the precomputed patient hierarchies. Then, correlations that exist across those extracted patient groups are obtained from the meta-graph structure. Together, these extracted patient groups and their correlations form the tracking graph at \(f\), see Figure 3. This meta-graph structure is also created in an offline preprocessing step and the resulting structure is stored in multiple files (i.e., one file per time step), each containing a set of edges representing its correlations to patient groups in the next time step.

3.3 Visualizing and Exploring Patient Progression

Our system for exploring patient progression over time contains three views: patient grouping view, patient progression view, and patient view, see Figure 4. Within each view, various progressive visualization techniques are employed to achieve interactivity. For instance, data is always presented with respect to a focus time step that is processed first.
Data for the neighboring time steps is then extracted and presented in order of increasing distance. All views designed for only a single time step (i.e., patient grouping view and patient view), use the focus to determine their time step. The parameters such as hierarchy parameters and other filter parameters are coordinated across all views to provide a fully linked analysis environment.

3.3.1 Patient Grouping View

To enable researchers to gain a quick visual understanding of how patients group together for varying similarity thresholds, the patient hierarchy of the focus time step is visualized within this view. As the similarity threshold is changed, active patient groups within the hierarchy are also highlighted. In Figure 4(b), the selected similarity threshold within the hierarchy is displayed in a brown vertical line, and the active patient groups are highlighted in prominent colors.

3.3.2 Patient Progression View

This view visualizes the temporal progression of patients using tracking graphs. Starting from the user-defined focus time step, nodes and edges are iteratively added both forward and backward in time up to the user-defined time window to create the tracking graph, see Figure 4(c). Each node in the graph represents a patient group. A set of nodes in the same x coordinate indicates groups in one time step and edges across them indicate their correlations. For visual clarity, nodes in the focus time step are always displayed in prominent colors. Progressive techniques as in, specifically, a fast initial graph layout and a slower greedy one, are used to visualize these tracking graphs.

3.3.3 Patient View

Several visualization techniques are combined here to present a specialized view of patients. Specifically, we integrate word cloud, textual, geometric embeddings, and geospatial visualizations, see Figure 4(a).

The word cloud visualization is dedicated to providing a quick overview of textual information regarding patients. For a selected patient group, a word cloud is constructed from the patient group-based attributes stored within the patient hierarchy, see Figure 4(d). Here, to obtain more intuitive overviews, the numerical attributes are converted into ranges. This visualization displays high-frequency words using bigger fonts and brighter colors, and others in faded and smaller fonts. As the name suggests, textual visualization presents textual details of patients in their native domain (i.e., as text), see Figure 4(e). For a selected patient group, this component displays its attributes such as hospital admission ID, patient ID, care unit and age.

Regardless of the data type, visualizing geometric embedding reveals interesting details and trends about data. The geometric embedding visualization displays the geometric embedding of patients in either 2D or 3D, see Figure 4(f). As geometric embedding details are not very obvious for the clinical data, for each time step, the GraphViz's ‘neato’
layout algorithm together with patient similarity details is used to compute the 2D embedding of patients. In the geospatial visualization, when relevant information is available, we allow data exploration to be augmented with geospatial visualizations, see Figure 4(g). For instance, if a patient has his physical location details available for each moment in time (both during and/or prior to his hospital stay), this information will be visualized within this view. In addition to visualizing patient geospatial locations, their trajectories can also be displayed to easily identify data trends related to geographic locations.

3.3.4 Interactive Exploration

As tracking graphs can easily become complex and difficult to understand, various simplifications have to be performed on them to successfully understand their underlying trends. Specifically, we enable several simplification options. Through the linked-view interface, researchers are allowed to explore data sets by changing the focus time step and time window. They can select a particular day within a patient’s hospital stay, expand and contract its neighboring days to view progression both forward and backward in time. Within our system, the similarity threshold within the patient hierarchy, correlation amount within the meta-graph and other attribute values available (i.e., patient group-based and correlation-based), can all be explored. We also allow tracking graphs to be filtered by the length of stay of a patient group, which enables small patient stays to be eliminated from the analysis. Valence two and zero nodes of a tracking graph can be hidden to prevent visual clutter, nodes can be scaled based on their size, and progressions of certain patient groups can be highlighted. To help researchers maintain context across systems’ views, we also make use of correlated color maps and allow nodes to be colored using various patient group-based attributes. All these options combined enable researchers to interactively simplify tracking graphs, isolate interesting patient progressions and explore their parameter space.

3.4 Dataflow

Our system is implemented using the ViSUS framework\textsuperscript{19}, which provides the basic building blocks for designing a streaming, asynchronous dataflow. Figure 5 shows the dataflow utilized within our system. The Data Reader module is dedicated to reading data into the system. It checks whether all data required for the current tracking graph has been loaded. If needed, it loads the required data and passes it to the Filter module. This module filters the received patient group and correlation details for the current parameter and attributes values. This filtered information is then simultaneously sent to layout and view modules.

Each of the two layout modules computes a graph layout and sends those layout details to the relevant view modules for rendering. The Hierarchy Graph Layout module computes the initial layout for the tracking graph and sends this information to the Patient Grouping View and Patient Progression View modules. This hierarchy graph layout is computed only once for each time step as the data is read for the first time. The second layout module, Greedy Graph Layout, computes a greedy layout for the tracking graph each time its parameters change and passes them to the Patient Progression View module. This greedy layout minimizes the edge crossings within the tracking graph.

Our dataflow contains three view modules. The first view module, Patient Grouping View, visualizes the patient hierarchy of the focus time step. Once the module receives
the necessary node and hierarchy details from Filter module and the layout details from Hierarchy Graph Layout module, it renders the patient hierarchy. The Patient Progression View module initially renders the tracking graph using the hierarchy graph layout. Then, as the greedy layout becomes available, it is integrated with the current graph. The third view module, Patient View, provides more specific views of patients (geometric embedding, geospatial, word cloud, and textual visualizations). Once this module receives the required data, depending on which visualization mode is selected, the corresponding computations and renderings are triggered. Each time parameters and/or selections are changed, the current processing within the dataflow is interrupted and restarted. However, rendering within the views maintains the current state for visual continuity.

4 Results

We enable clinical researchers to study the progression of patients via interactive exploration of dynamically constructed tracking graphs. The effectiveness of our framework is demonstrated with the use of a publicly available ICU database. The clinical database of Multiparameter Intelligent Monitoring in Intensive Care (MIMIC II) databases\(^7\) contains comprehensive EHR data collected from hospital medical information systems (both patient bedside workstations and hospital archives). This data is obtained from a set of ICUs including medical, surgical, coronary care, and neonatal in a single tertiary teaching hospital in the 2001 to 2008 time period. It includes patient information that falls into various categories such as general, physiological, medications, fluid balance, notes, and reports, see Table 1. The entire database totals to about $\approx 27\,\text{GB}$ and contains information about tens of thousands of ICU patients.

In order to visualize MIMIC II clinical data within our framework, the relevant patient hierarchies and meta-graph structures need to be computed and stored. This is done in an offline preprocessing step. First, for each day in a patient’s hospital stay, patient details available in the database (e.g., admission ID, age, gender, race, ICD-9 code, drug code, hospital stay length, mean heart rate, mean temperature, and max urine output) are extracted, which results in 38291 patient admissions from 32536 patients. These details are then aligned to make sure all admissions fall on the first time step of the resultant data set. The resulting data set after aligning contains 174 time steps (i.e., 174 days).

Patients in each time step are then clustered together using the metric by Lee et al.\(^6\). This patient similarity metric was previously applied to the same MIMIC II clinical database to identify patient similarities within the first day of the ICU stay. In order to apply the metric to our research, the required clinical, administrative, and categorical variables are extracted from the database for each day within a patient’s hospital stay. Next, correlations across patient groups are computed by tracking individual patients within the groups. Once the patient groups and their correlation details are stored in our data format, the total data size is reduced to $\approx 680\,\text{MB}$. By precomputing the patient hierarchies and meta-graph structures and storing them using optimized data structures, we allow interactive exploration of patient progression over time for several gigabytes of data.

Researchers are provided with the flexibility to vary the patient similarity thresholds and explore the entire parameter space interactively. Such interaction provides an understanding of how patients group together for varying similarity thresholds within a particular day in their hospital stay. In a hospital setting, such interaction provides the flexibility to explore patient progression details to better predict patient outcomes for a specific patient. For example, as new patients come in, for each day in their hospital stay, a patient’s outcome for the next day can be predicted based on

<table>

</tr>
</tbody>
</table>

Table 1: An overview of the data categories within MIMIC II clinical database
their similarity to the existing patient groups. Figure 6 shows several examples of patient groups and their progression for 30, 34, 35 and 38 similarity thresholds. As the similarity thresholds decrease, more patients are grouped together, reducing the complexity of the tracking graph. For a specific similarity metric, exploring the full range of similarities enables researchers to gain insights on that metric’s range of values. In our case, upon exploration we realized that for this particular patient similarity metric, the appropriate similarity threshold range is 30-38. Any similarity threshold below or above that range either grouped all patients into one group or divided each patient to be in a separate group.

Figure 6: Effects of varying the similarity threshold to explore the temporal progression of patients. Here, patient groups and a portion of their corresponding tracking graphs are shown at 30, 34, 35, and 38 similarity thresholds. The focus time step of the tracking graphs is indicated with a black arrow, and the nodes are scaled based on the patient group’s size. In each graph, patient progression for 10 time steps both forward and backward in time from the focus time step is displayed.

Our system presents a global concise view of patient progression over time using tracking graphs. The full tracking graph showing the patient progression over time at 36 similarity threshold is displayed in Figure 7. By observing these tracking graphs, specifically feature track length indicating the hospital length of stay of patients, it is clear that although many of the patient stays are less than 90 days (i.e., 3 months), our data set also contains several longer patient stays. Of 32536 patients, we found 6 patients with hospital lengths of stay greater than 90 days.

Figure 7: The entire tracking graph showing the complete patient progression for the MIMIC II clinical database. The graph contains 1110 nodes and 1288 edges for a total of 174 time steps. Here, 36 similarity threshold is used.

More importantly, various simplification options available in our system allow researchers to further simplify the tracking graphs. For example, filtering the tracking graph by correlation amount allows removal of the least frequent patient progression paths from the tracking graph, making frequent patterns more prominent. If an analysis is to be conducted only on longer hospital stays of patients, filtering options available within our system, specifically filtering tracking graphs by the length of a feature track, are useful. Furthermore, various patient group based attributes stored along with the patient hierarchy such as mean age and mean heart rate can also be used to filter patient groups. Figure 8 illustrates several such simplification results.

Additionally, the patient view of our system is useful for obtaining an overview of patient groups. As the user selects a certain patient group, this view displays the details of its patients. The word cloud visualization provides a quick visual overview of the information within a selected patient group, see Figure 4(d). The numerical attributes such as age and hospital length of stay are converted to ranges to obtain more intuitive results. The exact patient details are also presented in the textual visualization within the system, see Figure 4(e).

Due to the generality of its design, this proposed framework provides new avenues for exploring healthcare data. Depending on the domain question we wish to answer, different options can be used within the visual analysis process. Instead of the patient similarity metric used, any other patient similarity based metric (e.g. age based, symptom based) can be used to group patients within time steps. Different patient attributes can be stored along with the patient
hierarchies. For example, say we wish to study whether patients with diabetes stay longer in the ICU than other patients. We can use a patient similarity metric based on diabetes-specific symptoms to group patients for each time step. It then allows the users to explore the length of stay of patient groups where the patients are grouped based on their diabetes-specific symptoms.

5 Conclusion and Future Work

In this work, we present a visualization and analysis environment for understanding patient progression over time. The system’s interactive abilities to explore patient progression for different similarity metrics and for varying similarities are a distinct advantage over existing techniques used in healthcare. Using our system, researchers are able to explore how patients group together and progress over time, identify frequent progression paths, and also refer back to the native space of data for a visual understanding. By combining optimized data structures and progressive visualization techniques, we enable interactive exploration of terabytes size data, which provides the platform to use this type of analysis in a hospital setting. Within this work, an existing patient similarity metric is utilized for defining patient similarities. At each moment in time, patient similarities are computed by looking at a patient’s current clinical, administrative, and categorical information. A better similarity metric would be one that considers both the current information of the patient and the entire history starting from the hospital admission time. In order to obtain better results, we hope to utilize such a similarity metric in the future. In this work, we demonstrate the applicability of our approach using a publicly available ICU database. We are looking into obtaining additional healthcare databases to use within our system, specifically, databases with geospatial information for which the patient view within our system would prove to be more beneficial. Finally, we aspire to use our visualization and analysis environment in a real-time setting to assist the decision-making process of our collaborating physicians and clinical researchers.

Abstract

Social determinants of health (SDOH) have an important role in diagnosis, prevention, health outcomes, and quality of life. Currently, SDOH information in electronic health record (EHR) systems is often contained in unstructured text. The objective of this study is to examine an important subset of SDOH documentation for Residence, Living Situation and Living Conditions in an enterprise EHR informed by previous model representations. In addition to two publicly available clinical note sources, notes created by Social Work, Physical Therapy, and Occupational Therapy, along with free text Social Documentation entries were reviewed. Sentences were classified, annotated, and evaluated once mapped to element entities and attributes. Overall, 2,491 total notes yielded 616, 813, and 30 sentences related to Residence, Living Situation, and Living Conditions. This study demonstrated the need for additional elements in the model representation, more representative values and content culminating in a more comprehensive model representation for these key SDOH.

Introduction and Background

Social and individual behavioral factors play an important role in diagnosis, prevention, health outcomes, and quality of life.1, 2 As defined by the World Health Organization, “social determinants of health are the conditions in which people are born, grow, live, work and age”.3 Social determinants of health (SDOH) can cause illness, exacerbate or contribute to chronic illness, and conversely can also improve health.

Previous studies have demonstrated the deleterious effect of behaviors such as alcohol and tobacco use on health outcomes.4-7 Housing has also been relatively well studied, especially the impact of homelessness on various conditions.8-14 Other housing conditions have been correlated with health outcomes. Residential status, specifically housing instability, has been studied in relation to outcomes in certain disease or treatment groups, and found to be a risk for poor outcomes.8-10 It overall appears that there is a complex interconnectedness between poor housing and poor health.15 Costa-Font found that owning a home, or housing equity overrides the effect of income as a determinant of health and (absences) of disability in old age.12 In contrast, permanent supportive housing can addresses homelessness and health disparities.16 This is also some evidence that improving housing can contribute to improved health.17 For example, Jacobs et al. found evidence that specific housing interventions can improve certain health outcomes.18

However, other aspects of social determinants related to Residence, Living Situation, and Living Conditions have not been investigated as thoroughly. For example, the impact of housing type (Residence) such as single family home, assisted living, group living situations, has not been investigated. Studies have also shown that certain housing models can be beneficial to specific patient groups.14, 19 In addition, significant exposures risks have been associated with indoor environments.20, 21 For example, with multi-unit dwellings there is risk of exposure to hazards such as second-hand smoke as smoke can seep into neighboring units resulting in involuntary exposure.22 Knowledge of a patient’s physical living space, type of dwelling, stairs, safety mechanisms, etc. could be of benefit to the clinician or therapist in providing care to that patient and obtaining the proper support in further promoting their wellness.

With whom a patient lives (Living Situation) as well as the conditions (Living Conditions) under which they live also have heath implications. While living with others creates a support network for the patient, housing density increases exposure to communicable diseases, causes stress in adults and poor long-term health in both children and adults.23

The increase in the use of EHRs provides unprecedented opportunity to collect and analyze SDOH information in conjunction with clinical data in secondary use for research and process improvement. SDOH information can be
used in a myriad of ways from health outcomes evaluations to predictive modeling for prevention. The National Academy of Medicine has completed a consensus study on social determinants in the EHR.\textsuperscript{24, 25} The Committee on Recommended Social and Behavioral Domains and Measures for Electronic Health Records has identified domains and measures that capture the social determinants of health to inform the development of recommendations for Stage 3 meaningful use of electronic health records (EHRs). The NAM final report recommended documentation of race and ethnicity, education, financial resource strain, stress, depression, physical activity, tobacco use and exposure, alcohol use, social connections and social isolation, exposure to violence (intimate partner violence), and neighborhood and community compositional characteristics. The final recommendations unfortunately did not include \textit{Residence, Living Situation, or Living Conditions}.

Currently, comprehensive documentation standards for many SDOH do not exist.\textsuperscript{26} As a result, EHR systems and their associated user interfaces are not optimized for the consistent collection of discrete social history information leaving this important information often buried in free text notes or as unstructured text fields in the social history sections of the EHR. Natural language processing techniques are being developed that allow us to extract social history information from the notes and into discrete datasets but primarily only around substance use information which has more developed and robust information models providing a “target” for discrete representation.\textsuperscript{27, 28}

The overall goal of this study is to evaluate documentation of three SDOH topic areas (\textit{Residence, Living Situation, and Living Conditions}) using publically available note sources and Enterprise EHR free text documentation. This work also builds from work of Chen et al. and Melton et al. to model social history from progress notes and public health surveys, including living situation, residence, social support, and occupation.\textsuperscript{29} Other previous work to harmonize interface terminologies, standards, specifications, coding terminologies, vocabularies, documentation guidelines, measures, and surveys provides a model representation of our three topic areas.\textsuperscript{26} This study also further refines the model representation of \textit{Residence, Living Situation, and Living Conditions} informed by additional interdisciplinary EHR system content.

\textbf{Methods}

This study is focused on the three topic areas \textit{Residence, Living Situation, and Living Conditions}. Clinical notes from three sources were evaluated. Individual sentences related to the topic areas were identified and were classified, into one or more of the target topic areas. Lastly, statement-level annotation was performed, with a 10\% secondary review for Kappa, and elements were mapped to generate a model representation (Figure 1).

\textit{Topic areas}: Using definitions developed from previous work, \textit{Residence} describes dwelling types, physical residence, and geographic location and includes safety considerations such as railings or number of floors and steps.\textsuperscript{26} \textit{Living Situation} describes with whom the patient lives such as roommates, family members, multi-resident dwelling as well as how many others they live with. Lastly, \textit{Living Conditions} describes environmental cleanliness and precautions against infection and disease and includes such things as animals, and presence of mold or an unclean living space.

\begin{figure}[h]
\centering
\includegraphics[width=\linewidth]{methods.png}
\caption{Overview of Methods.}
\end{figure}
Data Sources: The data sources utilized for this work were: 1) MTSamples.com (MTS), a publicly accessible clinical note data source; 2) University of Pittsburgh Medical Center (UPMC) NLP Repository with de-identified clinical notes (following execution of a data use agreement for research); and 3) multiple sources of data from the University of Minnesota-affiliated Fairview Health Services (FHS) electronic health record system. Overall, there were 491 history and physical and consult notes from MTS and 200 history and physical and consult notes from the UPMC included. The majority of clinical data for the study otherwise originated from the FHS EHR system through the University of Minnesota Academic Health Center Information Exchange (AHC-IE) data repository. We included only patients who had consented for their medical records to be used in research with inpatient encounters in 2013. For the purposes of this study to also obtain a broader understanding of documentation of this information by non-provider clinicians including several inter-disciplinary fields, we randomly selected 200 random progress notes authored by social workers, 200 progress notes authored by physical therapists, and 200 progress notes authored by occupational therapists, as well as 1,200 social documentation notes. Social Documentation is a portion of the Social History section in the EHR composed of a single free text field that can be documented on by any EHR clinical user.

Annotation Guidelines Development: Guidelines for sentence-level annotation were developed through literature review and included 28 classifications covering most social determinants of health. Related to this work, of those 28, 7 classifications were further analyzed for this study which included: Residence, Residence Exposure, Residence Other, Living Condition, Living Situation, Living Situation Exposure, and Living Situation Other.

Guidelines for statement-level annotations were developed through previous work reviewing existing standards and terminologies. Separate schemas were developed for each of the three topic areas (Tables 1, 2 and 3).

Sentence-level Annotation

All notes were initially reviewed and sentence-level annotation was performed by a single reviewer using General Architecture for Text Engineering (GATE) to identify and classify sentences related to the three topic areas of Residence, Living Situation, and Living Conditions. Sentences containing information related to more than one of the three topic areas were classified into each appropriate topic for statement-level annotation. For example, the sentence “He lives in <city name> with his mother and step-father” was classified as both Residence (“lives in <city name>”) and Living Situation (“lives...with his mother and step-father). Table 4 shows example statements for each topic area.

Table 4. Example sentences classified into each topic area.

</tbody>
</table>

Statement-level Annotations

Statement-level annotation was performed on the classified sentences using the brat rapid annotation tool (brat) to identify elements, attributes and relationships. The schema was modified iteratively to accommodate newly found elements and attributes for three sustentative iterations to include subject and temporal entities not previously encountered to ensure a stabilized schema. The original Residence annotation schema was amended to include “Subject”, “Time Point”, and “Time Frame”. The Living Situation schema was amended to include one new element “Current Age” that refers to the age of the persons with whom the patient lives. And the Living Conditions schema was amended to include the element “Living Conditions Detail Subtype” which refers to the subcategory of type.

The statement-level brat annotations was performed by a single reviewer and a subset of 10% of sentences were annotated by a second reviewer to ensure internal consistency and to assess inter-rater reliability. Values sets were compiled from the annotations for each entity found in the data sources as were schema amendments. The model representations from previous work were then amended with additional elements from this analysis to create and enhanced model representation of Residence, Living Situation, and Living Conditions (Tables 6A, B, C).

Results

In total, 2,491 notes were reviewed by two reviewers, resulting in 1,459 sentences classified into the three topic areas of Residence, Living Situation, and Living Conditions. The initial classification analysis resulted in 616 sentences categorized as Residence, 813 sentences categorized as Living Situation, and 30 sentences categorized as Living Conditions (Table 5). MTSamples, FHS Physical Therapy, and FHS Occupational Therapy notes did not have any sentences that could be classified under the Living Conditions topic.

</tr>
</tbody>
</table>

The statement-level annotation yielded an inter-rater reliability of $K = 0.84\%$ and proportion agreement of 0.98%. Overall the FHS set of notes were the most comprehensive and this had the highest contribution to this work. In totality, the 616 sentences or statements for Residence yielded significant contributions to the overall model. Of these sentences, Status was documented in 60.1% (416) of sentences, Residence Type 51.8% (359), and Geographic Location Detail (i.e., specific city, state country locations) in 38.4% (302) (Table 6A). Temporal elements were present but to a much lower degree.

For Living Situation, a total of 813 sentences were analyzed and, as with Residence, Status was highly prevalent being present 823 times and in total there were 1303 references to Subject other than patient or family member (Table 6B).
For *Living Conditions* in the 30 sentences were annotated, Living Condition Type was the most prevalent entity found with 39 instances with many sentences referencing more than one Living Condition Type per sentence, followed by subject being found 16 times (Table 6C).

**Tables 6A, B, C. Elements, counts, and example values/patterns Residence, Living Situation, and Living Conditions.** For each source n= the total number of unique sentences that we eventually annotated for distinct elements. Percent of unique sentences that contained the element (Total number of instances of that element). Example values and patterns in bold are newly added to the existing model as a result of this work. Bolded Example Values represent items added to the existing model through this study.

Discussion

While social determinants of health (SDOH) play an important role in the provision of patient care, they also play an important role in secondary use of data for research and quality improvement. Unfortunately, SDOH information is not well documented as discrete data in the EHR. By leveraging a diverse collection of notes including general social history documentation notes and notes authored by different types of clinical authors our evaluation helps information about the three topic areas of Living Situation, Residence, and Living Conditions. By far, Living Situation was the most common topic found of the three topic areas followed by Residence with much less information around Living Conditions in our dataset. The prevalence of documentation related to Living Situation appears to be an effort by clinicians to indicate the relative amount of potential social support for patients.

Many sentences included elements that crossed topic areas. For example, “She lives in <CITY NAME> with her parents and 2 older sisters.”, which includes Residence and Living Situation. Another example: “Lives at home with mom and two pets.”, crosses all three topic areas. Not surprisingly, physical therapist and social worker authored notes had a higher proportion of sentences related to Residence. The Social Documentation notes, which could have been authored by any clinician type, had the highest number of sentences related to Living Situation and Living Conditions.

Further analysis and mapping of the Residence sentences to the element axes showed persistent use of status, residence type and geographic location. Temporal entities and attributes were less prevalent with most documentation describing current state with some references to past situations. For Living Situation there was again significant presence of status as we as subject specifically family member. Living conditions was much less represented in these data sources and most references were related to type of water available.

The enhanced model representations (Tables 6A, B, C), built upon the foundation of previous standards evaluation work, now represent the analysis of 27 data sources including existing standards, terminologies, guidelines, and measures and Surveys as well as the analysis of 2491 notes. The analysis of the notes added more elements. For
Residence and Living Situation the temporality elements “Duration Since Time Point”, “Time Point”, and “Time Frame” were added as was the element “Residence Type Subtype” and “Living Situation Detail Subtype”. For Living Conditions the temporal elements “Duration Since Time Point” and “Time Point” were added. Overall, the EHR unstructured text significantly contributed to enhance and strengthen the model representation. Value lists are much more complete for each of the elements.

Although we obtained an inter-rater reliability of $K = 0.84$ and proportion agreement of 0.98, we observed some inconsistency between reviewers regarding the difference between Geographic Location as opposed to Location Detail. This inconsistency was resolved and the annotation schema was amended accordingly. Another challenge area was around statements regarding safety concepts. In some cases safety items such as railings and stairs were annotated as Residence Detail and in other they were annotated as Living Conditions Detail. More work will be needed to sort out where these concepts logically fit the best. Lastly, while it is expected that not every sentence would have every element, in examination of these results it was noted that in the Residence annotations the number of sentences that had a “status” documented was lower than expected. After further manual review the issue was traced back to several of the question answer type “Living Arrangements” could be considered a section header and, in past work, section headers have been identified separately from text. For this work these sentences were left as is and will be considered in future work and iterations of the annotation schema.

In summary, this work has demonstrated that the SDOH topic areas of Residence, Living Situation, and Living Conditions are being documented in the EHR within unstructured text, specifically general progress notes, Social Documentation notes, and notes authored by Social Workers, Physical Therapists, and Occupational Therapists. This analysis contributes to overall representation models for these three topic areas. Next steps will include an evaluation of flow sheet documentation related to these three topic areas and further enhancement of the model representation that can be used to extract information from EHR text, to design discrete data collection tools for the EHR, and to contribute to the development of ontology for the social history topics of Residence, Living Situation, and Living Conditions.

Towards precision informatics of pharmacovigilance: OAE-CTCAE mapping and OAE-based representation and analysis of adverse events in patients treated with cancer drugs

Abstract
A critical issue in the usage of cancer drugs is its association with various adverse events (AEs) in some, but not all, patients. The National Cancer Institute (NCI) Common Terminology Criteria for Adverse Events (CTCAE) is a controlled terminology for AE classification and analysis in cancer clinical trials. The Ontology of Adverse Events (OAE) is a community-based ontology in the domain of AEs. In this study, OAE was first updated by including AE severity grading and OAE-CTCAE mapping. An OAE subset containing CTCAE-related terms and their associated OAE terms was generated to facilitate term usage. A use case study based on a published cancer drug clinical trial demonstrates that OAE provides better hierarchical representation, includes semantic relations, and supports automated reasoning. Demonstrated with a single patient analysis, the OAE framework supports precision informatics for representing AEs and related genetic and clinical conditions in individual patients treated with cancer drugs.

Introduction
While cancer drugs play a critical role in treating cancer patients, the adverse events (AEs) associated with cancer drugs can be very detrimental. As a result, the surveillance and analysis of cancer drug AEs are important to improve public health. To support such surveillance and analysis, it is critical to maintain proper terminology and documentation. A foundation of AE reporting and analysis is the controlled terminology of various AEs. MedDRA [1], WHO-ART [2], and the Common Terminology Criteria for Adverse Events (CTCAE) [3] are commonly used AE controlled terminology systems. These controlled terminologies tend to have drawbacks, such as missing term definitions, poorly defined hierarchies, and lack of semantic relations among terms across hierarchies [4]. Ontologies have been proposed and developed to address these drawbacks [4-6].

As a product of the US National Cancer Institute (NCI), CTCAE is a specialized controlled terminology that provides the standardized classification of AEs of drugs used in cancer therapy. CTCAE has substantially evolved since its inception in 1983. Initially published in 2009, CTCAE v4.0 lists 790 AE terms, and each of these AE terms may be associated with a range of severity grades [7]. Most US and UK cancer drug trials encode their observations based on CTCAE.

The Ontology of Adverse Events (OAE) is a community-based open source ontology that logically represents various AEs [6]. OAE represents various AEs based on patient anatomic regions and clinical outcomes, including symptoms, signs, and abnormal processes. In OAE, an AE is defined as a pathological bodily process that occurs after a medical intervention (e.g., drug treatment). By logically linking the medical intervention, patient, patient conditions, and AE outcomes, OAE provides a robust framework that supports systematic analysis of AE case classification and analysis. With over 5,000 terms, OAE has been used in many scenarios [6, 8-10]. Figure 1 shows the general OAE model of an adverse event of a human patient treated with a drug. Specifically, a human patient is administered a drug in order to treat a specific disease (e.g., cancer). The drug has its active chemical ingredient, dose, and it is administered through a specific route (e.g., oral). After an incubation time, the patient will experience a specific adverse event(s) that occur in a specific anatomic location. The patient conditions (e.g., age, gender, and disease) may affect the drug treatment effectiveness as well as AE outcomes. Even for the same type of AE, there exist different severity grades (as detailed later in this paper).

To support ontology interoperability, in addition to its own terms, OAE imports many terms from existing ontologies such as Basic Formal Ontology (BFO) [11], Ontology for Biomedical Investigations (OBI) [12], and Ontology for General Medical Science (OGMS) [13] (Figure 1). For example, OAE imports many terms from the
upper level BFO [11] and aligns with BFO [6]. Both administration and drug AE are classified as BFO: ‘process’. On the other hand, the drug administration is subclass type of OBI: ‘planned process’ (i.e., a process intentionally planned by human), and an AE is a subclass of OGMS: ‘pathological bodily process’ (Figure 1). The disease, drug, quality, and anatomical entity can be represented by Disease Ontology (DOID) [14], Drug Ontology (DrON) [15], Phenotypic Quality Ontology (PATO) [16], UBERON [17], and NCBITaxon [18], respectively (Figure 1). Terms from these ontologies are semantically linked to provide a comprehensive picture of a drug AE and its associated drug, drug administration, anatomical location where the AE occurs, and detailed patient conditions (e.g., gender, age, and health condition).

Figure 1. OAE modeling of drug AE and related terms in a systematic framework. The terms inside boxes are ontology classes, and terms in the middle of arrows are relations (i.e., object properties). The boxes with blue text indicate patient information, and the boxes with red text represent AE-related terms. See more explanation in the text.

In the Figure 1 modeling, the relation ‘preceded by’ is used to link drug administration and drug AE. This relation is simply a temporal relation that indicates the drug AE occurs after the drug administration. The usage of this relation is aligned with the FDA definition that a drug AE does not have to be causal. It means that the drug administration does not have to be the cause of the AE. An AE may be just part of a disease process that started with the patient treated with the drug. For example, a patient who has gastric cancer and is treated with a drug has gastrointestinal bleeding. The bleeding AE may be caused by the gastric cancer or the drug usage. If we do not know the cause, we can use the relation ‘preceded by’. To represent a defined causal relation, OAE uses the relation ‘induced by’, which is a special subclass of the ‘preceded by’ relation [6]. If we know a causal relation between the drug administration and the bleeding, the relation ‘induced by’ can be used.

In addition, OAE and CTCAE may assign term hierarchies differently. For example, In CTCAE, ‘Rash pustular’ (CTCAE code E11545) is asserted as a subclass of ‘Infections and infestations’ in CTCAE (Figure 2A). This assertion is questionable since not every rash pustular is associated with an infection. CTCAE includes three other types of rash where ‘Rash acniform’ and ‘Rash maculo-papular’ are under ‘Skin and subcutaneous tissue disorders’, and ‘Papulopustular rash’ is under ‘Infections and infestations’. However, CTCAE does not have a class called ‘rash’ (Figure 2A). In contrast, OAE has ‘rash AE’ (OAE_0000528) and over ten specific subclasses of ‘rash AE’ (Figure 2B). Such comparisons suggest possible issues with CTCAE classifications and broader coverage of OAE.

Since CTCAE is commonly used in cancer drug AE reporting, we hypothesized that the CTCAE-OAE mapping followed by OAE-based analysis would improve cancer drug AE classification and analysis and support personalized pharmacovigilance investigation. Not all drug-treated patients will experience AEs. For patients under different conditions, the AE patterns may vary greatly, and should be investigated by considering different variables including personal conditions and drug usage. To address this hypothesis, we updated OAE with a systematic CTCAE-OAE mapping strategy and applied the updated OAE to two different use cases to demonstrate how OAE supports better cancer drug AE classifications and personalized drug-AE case representation.
Figure 2. CTCAE and OAE term hierarchy comparison. This comparison uses the Grade 2 pustular rash AE as the example. (A) CTCAE hierarchy. Rash pustular is under ‘Infection and infestation’. (B) OAE hierarchy. OAE includes the term ‘rash AE’ while CTCAE does not have a matching term.

Methods

**OAE ontology visualization and editing.** The Protégé OWL editor ([http://protege.stanford.edu/](http://protege.stanford.edu/)) was used for ontology visualization and editing.

**OAE modeling of AE severity and semi-automatic OAE-CTCAE mapping.** We first generated an OAE design pattern that represents AE severity. Our OAE severity representation strategy is similar to the CTCAE severity grading in terms of severity definitions, but also differs in terms of their classification and usage. The CTCAE source studied in this project primarily comes from the CTCAE 4.0.3, which is the version available in NCBO Biportal ([http://biportal.bioontology.org/ontologies/CTCAE](http://biportal.bioontology.org/ontologies/CTCAE)). To ensure high quality of the OAE-CTCAE mapping, manual curation was applied to annotate individual CTCAE records and map the records to OAE. The annotations, such as, definition, definition source, MedDRA ID, etc., were manually obtained from either CTCAE or online resources, and the mapped results along with the annotated information were initially represented in a pre-defined Excel template. After second review, the Excel data were then automatically converted to an OWL file using the Ontotator software program [19], and merged to OAE. A Java-based program was developed to automatically assign severity axioms to OAE terms to indicate possible grades for specific OAE AE terms.

An important feature of CTCAE is its classification of AE severity. Specifically, the CTCAE v4.0 includes Grades 0 through 5 with unique clinical descriptions of severity for each AE based on the general guideline: Grade 0 – signs and symptoms within normal limits; Grade 1 - Mild AE; Grade 2 - Moderate AE; Grade 3 - Severe AE; Grade 4: life-threatening or disabling AE; and Grade 5 - Death related to AE [7].

Corresponding to the six grades of severity in CTCAE, OAE also has 6 grades of ‘AE severity’. However, OAE and CTCAE implement the severity grades differently. The OAE ‘AE severity’ is a subclass under the term ‘process quality’ (PATO_0001236). The term ‘process quality’, imported from the PATO, represents a quality which inheres in a process. For example, ‘skin ulceration’ includes five grades (Figure 3A).

To represent a specific AE severity, OAE uses two approaches. First, for an AE with a defined severity range, OAE uses an axiom with the relation term ‘has participant quality’ to link the AE and a severity grade of the participant undergoing the AE process. For example, OAE defines an axiom of ‘skin ulceration AE’:

’ve participant quality’ some (‘AE severity G1’ or ‘AE severity G2’ or ‘AE severity G3’ or ‘AE severity G4’ or ‘AE severity G5’)

1778
The second approach in OAE for severity representation is to generate specific subclasses with severity specifically defined. For example, OAE represents 4 different subclasses of ‘skin ulceration AE’ corresponding to the Grade 1-4 of this AE (Figure 3B).

Figure 3. Comparison of AE severity definitions in CTCAE and OAE. (A) CTCAE term ‘Skin ulceration’ and its five grades. (B) OAE term ‘Skin ulceration’, all its child terms, and related axioms. Ontofox was used to extract all children under ‘skin ulceration AE’ and all their related terms and axioms from OAE. The Ontofox output was displayed in Protege OWL editor, and the screenshot was taken from the display. The OAE annotation includes its mapping to CTCAE ontology term ID. The linkage of the OAE term to the AE severity grade is logically defined using the new relation ‘has participant quality’. The ulcer diameter is included in another axiom to specify the Grade 2 severity. OAE does not include ‘Grade 5 skin ulceration AE’ as explained in the text.

Note that we did not generate a class ‘Grade 5 skin ulceration AE’ because Grade 5 always means death. Since our ‘skin ulceration AE’ axiom has shown Grade 5 is possible, we do not need to generate a specific term for Grade 5. However, OAE represents Grade 1-4 individually (Figure 3B) since each of the grades has its specific criterion other than the general grade definitions. For example, according to CTCAE definition, Grade 2 skin ulceration AE shows a combined area of ulcers <1 cm and nonblanchable erythema of intact skin with associated warmth or edema. In align with the CTCAE definition, we represent such a case in OAE with a specific class “Grade 2 skin ulceration AE” (OAE_0002618) (Figure 3B). In addition, OAE includes an ontological axiom to logically represent the ulcer size criterion of “Grade 2 skin ulceration AE”:

’reresults in formation of’ some (ulcer and ‘has diameter in cm’ some decimal[>0, <1])

With the above axiom, when the ulcer diameter is measured, an OAE-based grading system will be able to automatically classify the ulceration with a Grade 2 severity. The CTCAE does not include such an axiom definition, and its usage requires manual interpretation.

Generation, deposition, and query of CTCAE-related OAE subset view (CTCAE-OAEview). Ontofox [20] was used to generate an OAE subset view that contained all CTCAE-matched OAE terms and their associated OAE terms. The CTCAE-OAEview was then deposited to the Ontobee linked ontology server [21] at http://www.ontobee.org/ontology/CTCAE-OAEview. Ontobee SPARQL (http://www.ontobee.org/sparql) was used to query CTCAE-OAEview for addressing various questions.

OAE application use case studies. Two use cases were analyzed. First, a randomized, multicenter, placebo-controlled phase 2 study of a cancer drug clinical trial was used for testing the application of the newly updated OAE in cancer clinical trial AE analysis [22]. This case study demonstrated how OAE could be used to support AE and AE grading hierarchical classification from a cancer clinical trial. The second use case reported a single patient treated with selumetinib [23] and illustrated the application of the OAE framework for a single patient, personalized pharmacovigilance study.
Results

**OAE-CTCAE mapping and annotation results**

Using our semi-automatic annotation methods, we have established in OAE the OAE-CTCAE mapping for all the CTCAE terms. Many CTCAE terms like “Blood and lymphatic system disorders, Other, specify” are not included in OAE because this term is not specific and does not meet the requirement of generating a new ontology class term. According to our OAE modeling design of AE severity as described earlier, only those grade-specific terms with details more than the general grade definitions were mapped and included in OAE as OAE classes. Those grade-specific CTCAE terms that do not contain additional information than the common Grade definitions (e.g., those terms with Grade 5) were not included in OAE. Overall, we added 1,140 grade level terms to OAE.

We also generated a CTCAE-related OAE subset view (CTCAE-OAEview) that includes all CTCAE-related OAE terms and the OAE terms associated with these CTCAE-related terms. The generation of such OAE subset (or “view”) supports easy usage of the CTCAE-mapped OAE system for cancer drug clinical trials and cancer drug AE case reporting and analysis. In addition, we can better study the CTCAE-related OAE subset to clarify the coverage of the CTCAE system. The CTCAE-OAEview has been deposited on Ontobee ([http://www.onotbee.org/ontology/CTCAE-OAEview](http://www.onotbee.org/ontology/CTCAE-OAEview)). CTCAE-OAEview includes 3,267 CTCAE-associated OAE terms. Among these terms, there are 2,169 terms with “OAE_” prefix, 854 terms with “UBERON_” prefix (for anatomic location), and other terms from different ontologies (Figure 4A).

*Figure 4.* CTCAE-OAEview information and its SPARQL query demonstration. (A) CTCAE-OAEview statistics page information on its Ontobee website ([http://www.onotbee.org/ontology/CTCAE-OAEview](http://www.onotbee.org/ontology/CTCAE-OAEview)). (B) SPARQL query of the CTCAE-OAEview using Ontobee SPARQL website ([http://www.onotbee.org/sparql](http://www.onotbee.org/sparql)). This query identified all the terms directly under ‘rash AE’ in CTCAE-OAEview.

**Use case demonstrating the advantages of OAE-based hierarchical classification**

We applied our OAE-CTCAE mapping method to study the AEs reported in a paper published in *The Lancet Oncology* [22]. Since there was no targeted therapy for KRAS-mutant non-small-cell lung cancer (NSCLC), this clinical study tested whether selumetinib plus docetaxel had a good effect on KRAS-mutant NSCLC. KRAS, encoding for the protein K-Ras that regulates cell division, is the most frequently mutated oncogene in NSCLC. Both selumetinib and docetaxel are antineoplastic drugs. Selumetinib is a potent, selective, orally available, ATP-independent inhibitor of mitogen-activated protein kinase kinase 1 and 2 (MEK1/MEK2), two essential mediators in the activation of the RAS/RAF/MEK/ERK pathway [24]. Inhibition of both MEK1 and 2 by selumetinib prevents cellular proliferation in various cancers. Docetaxel binds to and stabilizes tubulin, thereby inhibiting microtubule disassembly and resulting in cell death. This study found that selumetinib plus docetaxel had promising efficacy but was associated with a higher number of AEs compared to docetaxel alone. Overall, 26 AEs associated with two groups of cancer treatments: selumetinib plus docetaxel, and placebo + docetaxel [22].
**Figure 5.** OAE-based classification of adverse events shown in a cancer drug clinical trial. The 26 CTCAE-defined AEs came from Table 8 of the paper [22] were classified using CTCAE or OAE. (A) CTCAE hierarchy of 20 AEs reported in the paper. Note that 6 out of 26 terms in the paper could not be found from CTCAE. (B) Asserted hierarchy of the 26 terms and their associated terms in OAE. (C) Inferred hierarchy using a reasoner in the Protégé OWL editor. See the text for detailed explanation. Note that for (B) and (C), the Ontofox tool (http://ontofox.hgroup.org/) was then used to generate the hierarchical structure of the subset of OAE that contains all the 26 AE terms and the other OAE terms related to these 26 AE terms.

After the OAE-CTCAE mapping, we could use the CTCAE and OAE hierarchical structures to classify the 26 AEs and their top-level AEs (Figure 5). Interestingly, CTCAE4 only includes 20 of the 26 terms reported in the paper (Figure 5A) [22], while OAE includes all these 26 AE terms. In addition, our OAE-based AE analysis system demonstrated that OAE at least has the following advantages compared to the CTCAE alone:

First, OAE provides additional intermediate layers in the AE hierarchy that supports enhanced AE classification. For example, OAE includes an additional layer ‘abnormal defecation AE’ that covers two subclasses - constipation and diarrhea AEs. The combination of these two subclasses in the treatment group makes up to (32% + 73% =) 105% of AE occurrence rates (Figure 5B), suggesting the high susceptibility of this treatment to the abnormal defecation AE. The 105% AE occurrence rate was likely because some patients might have these two AEs simultaneously or at different points in time during the trial. To handle the temporal occurrence of AEs, OAE provides a mechanism to record the time and time period during which an AE occurs (Figure 1) [6].

Second, unlike CTCAE, OAE supports inferred hierarchy generation based on semantic axiom definitions. For example, although OAE does not assert the term ‘hematology investigation result abnormal AE’ as a subclass of ‘hematopoietic system AE’ (Figure 5A), such a subclass relation is inferred using a semantic reasoner (Figure 4C). Note that this term ‘hematology investigation result abnormal AE’ is not an AE term reported in Table 8 of the paper. However, its usage allows the clear classification of this term in OAE.

Third, unlike CTCAE, OAE includes many semantic relations that logically link different AE terms. For example, OAE provides the following axiom: ‘neutrophil count decreased AE’: ‘is evidence of’ some ‘neutropenia AE’. This relation closely links the laboratory count to the neutropenia AE.

In addition, the updated OAE ontology represents different grades of severity. While the contents of defining different grades of severity are the same between OAE and CTCAE, OAE uses its own strategy in representing different grades of severity as detailed earlier in this article. The use case paper summarizes the numbers of cases in Grade 3-4 of 26 different AEs [22]. Such grading results could have been done easily using the OAE grading strategy. As exemplified earlier, one advantage of the OAE grading system is that by measuring some parameter values (e.g., ulcer diameter), OAE will be able to automatically identify the grading level of an AE (e.g., ulceration).
Personal informatics use case demonstrating OAE-based modeling of patient AE after cancer drug treatment

As shown in Figure 1, OAE provides a logical framework that semantically links different variables (e.g., drug features, drug treatment detail, and patient conditions) with the AE outcomes. Each of these variables may affect the final AE outcome. For example, the drug ingredient, the usage of drug, the human quality (e.g., age, gender, concurrent disease, and disease severity) may all affect the outcome of the adverse event.

To show how the OAE-based framework supports practical use case, we used OAE to model a use case of selumetinib treatment on a patient with recurrent low-grade serous ovarian carcinoma (LGSOC) with KRAS mutation [23]. After treatment with selumetinib for more than 7 years, this patient’s tumor has not progressed and the patient has maintained a good general condition without severe toxicities. A next-generation sequencing study showed that her tumor included a G12V mutation in KRAS [23]. Overall, the patient’s LGSOC carcinoma had not progressed, and the patient experienced several mild AEs over the many years of therapy. The most notable AEs were intermittent rashes (grade 2 at the maximum) at anatomically disparate areas including the trunk, chest, and eyelids. She also intermittently experienced grade 1 stomatitis. Figure 6 demonstrates the OAE modeling of the AE process of this LGSOC patient treated with selumetinib.

Figure 6. OAE-based instance level modeling of a drug AE from a selumetinib-treated patient. The boxes with red text represent AE-related terms.

In this use case, the patient’s drug AEs were linked with the patient’s background, health condition, drug treatment details, and treatment efficiency (Figure 6). This comprehensive view under the OAE framework provides a systematic understanding of the patient treatment outcomes and possible variable associations. Note that in this model, the “intermittent” in the Grade 2 intermittent rash AE case is not modelled in detail here. This paper does not provide such detail either. For better representation of “intermittent” rash AE, we will need to specify when the rash occurred and then stopped over the course of drug exposure and over the course of the disease process.

Discussion

The major contributions of this study are multiple. First, OAE was updated to include terms representing different grades of AE severity. While such severity definition references the CTCAE definitions, the two definition strategies and their usage still differ in many aspects. Second, we achieved the task of OAE-CTCAE mapping by primarily using manual curation to obtain high accuracy and also using software tools such as Ontotator to facilitate ontology editing process. Note that it is possible to use a natural language processing (NLP) method to achieve part of the manual curation work. However, given the relatively small number of CTCAE terms, we did not perform such a strategy. Third, an OAE view of the CTCAE-related terms (CTCAE-OAEview) was generated, which provides a simplified OAE version to support CTCAE-related cancer drug AE data analysis. Finally, two use cases were applied to demonstrate how the updated OAE system can support AE hierarchical classification and personalized pharmacovigilance research. Future directions of the OAE-CTCAE mapping project include the completion of an OAE-based automatic AE grading classification system.
Since a large number of cancer drug AEs are represented using CTCAE, the CTCAE-OAE mapping allows easy conversion of the CTCAE-reported AE terms to OAE terms, which can then be utilized to support AE hierarchical classification (Figure 5). Based on the first use case study, we demonstrate the advantages of applying OAE to study CTCAE-annotated cancer clinical trial results. Our case study shows that after OAE-CTCAE mapping, OAE can be used to better support AE classification and analysis for cancer clinical trials. Furthermore, since OAE covers more terms than CTCAE, it is possible to apply OAE to leverage the coverage of AEs in cancer clinical trials. In the future, we will investigate more use cases, and provide solutions on best usage of both CTCAE and OAE to support cancer clinical trials.

A major difference between CTCAE and OAE is that CTCAE is a controlled terminology and OAE is an AE-specific ontology. As a controlled terminology, CTCAE includes only simple and loose ‘is a’ hierarchies. In comparison, as an ontology, OAE not only includes ‘is a’ hierarchies, but it also allows the generation of robust axioms that link different terms under different hierarchies [4]. Therefore, unlike CTCAE, OAE provides a platform to support automatic reasoning. As exemplified by the size-based grading ulcerations, Grade 1 ulceration means that the formed ulcer diameter is greater than 0 cm but less than 1 cm. The inclusion of this knowledge as a logical axiom in OAE makes it possible for computers to utilize this and other axioms to automatically reason the Grade 1 ulceration. A reasoning engine can also be developed based on such an ontological system. In the future, we will generate more axioms and based on them to develop an automatic AE grading classification system and semantic reasoning engine.

Personalized informatics, which includes systematic individual data analysis, is critical to personalized medicine. The second use case provided in this report demonstrates that the OAE modeling offers a logic linkage of different variables of this cancer patient. Such a modeling provides the ability to integrate various types of data, such as general patient information (sex, gender), medical condition (e.g., concurrent disease, and disease severity), drug name, drug dose, treatment route, time of drug treatment, or AE symptom occurrence, into a single comprehensive picture. Such personalized information illustration is different from the traditional method of summarizing results from pooled patient records. When many patients’ records are available, it is possible to conduct such personalized record organization for each patient, and develop new statistical methods to better analyze the relations among variables in different patients. Such a strategy would promote personalized medicine and public health.

Conclusion

The OAE ontology was updated to ontologically represent different AE severity grades and mapped to CTCAE. An OAE view of the CTCAE-related terms (CTCAE-OAEview) was generated to support better usage of the mapped information in OAE. Two use cases were applied to demonstrate that the OAE ontology can support cancer drug AE hierarchical classification and provide a semantic framework for personalized AE information representation and analysis.

Implementation of a Medication Reconciliation Assistive Technology: 
A Qualitative Analysis

Theodore B. Wright, MD 1, 2, Kathleen Adams, MPH 1, Victoria L. Church, RN MS CNS 1, Mimi Ferraro, RN 1, Scott Ragland, BS 1, Anthony Sayers, MS, FAC-PM II 1, Stephanie Tallett, BA 1, Travis Lovejoy, PhD 1, Joan Ash, PhD MLS MS BA 2, Patricia J. Abstract

Objective: To aid the implementation of a medication reconciliation process within a hybrid primary-specialty care setting by using qualitative techniques to describe the climate of implementation and provide guidance for future projects. Methods: Guided by McMullen et al’s Rapid Assessment Process1, we performed semi-structured interviews prior to and iteratively throughout the implementation. Interviews were coded and analyzed using grounded theory 2 and cross-examined for validity. Results: We identified five barriers and five facilitators that impacted the implementation. Facilitators identified were process alignment with user values, and motivation and clinical champions fostered by the implementation team rather than the administration. Barriers included a perceived limited capacity for change, diverging priorities, and inconsistencies in process standards and role definitions. Discussion: A more complete, qualitative understanding of existing barriers and facilitators helps to guide critical decisions on the design and implementation of a successful medication reconciliation process.

Introduction

Medication errors are ubiquitous at interfaces in care delivery – including the ambulatory encounter2-4. An estimated one-quarter to one-half of errors are attributed to gaps in information or incomplete medication histories5-11. If undetected, these errors can result in adverse drug events (ADEs) and significant patient harm12, 13. Medication reconciliation (MR) – the process of collecting a medication history, comparing available documentation, and resolving discrepancies12, 13-16. Unfortunately, durable solutions have been notoriously difficult to implement, owing to barriers associated with information technology, organizational culture, and patient health literacy12, 20-26.

A number of promising health information technology (HIT) solutions have been developed to support MR – many of which have extended the capabilities of the Veterans' Affairs (VA) existing information systems12, 23, 24, 26-35. The Automated Patient History Intake Device (APHID) is one such HIT intervention20, 29, 36. Developed at VA Portland Healthcare System (VAPORHCS), APHID provides a standardized way for clinicians to collect and interpret medication information to identify and reconcile discrepancies. In addition to automatically assembling a list of prescriptions from across the enterprise, APHID displays the corresponding medication images in a questionnaire format for the patient and staff to review at the point-of-care. The developers used this approach with the intent to improve patient engagement and medication recall33, 34, 37-40.

It is important to note that APHID – like any decision support system – cannot be a standalone solution. Because it is subsumed under a larger, more complex activity system, implementation of software such as APHID requires a firm understanding of clinic environment, values, and workflow20, 29, 36. The effect of an HIT intervention – particularly one aimed towards improving MR – is heavily dependent upon sociotechnical fit; local culture, business processes, and implementation strategies all mediating successful adoption. Accordingly, accounts of “real-world” implementations are needed to help informaticians and quality improvement specialists identify, label, and manage the significant sociotechnical determinants of change.

To address this gap, we conducted a qualitative study of a MR quality improvement project. Over the span of eight months in an outpatient clinic, an informatics team rolled out a new MR workflow that incorporated the APHID
software. Concurrent to the rollout, we conducted semi-structured interviews with key stakeholders to guide the implementation. By characterizing the sociotechnical context of the clinic and the implementation strategies used by the team, we sought to identify the barriers and enablers to MR software adoption43.

**Background**

Facility leadership charged the informatics department with developing a comprehensive MR solution for ambulatory specialty clinics. This solution had to provide a standardized method for completing and documenting MR at each encounter. Furthermore, the solution needed to generate an updated medication list that could be furnished to the patient upon departure. In response, the informatics team developed and rolled out an “implementation bundle” that included 1) the APHID software, 2) structured note templates (based upon user-furnished requirements), 3) an “after-visit” summary report with medication list, 4) a redesigned workflow, 5) printed educational materials, and 6) at-the-elbow support provided by members of the informatics team.

The informatics team iteratively designed and usability tested software during a series of rapid design “sprints” with representative end-users. The team then introduced the implementation bundle in a phased roll-out, beginning with the nurses, proceeding with the physicians, and concluding with the medical support assistants. The nurses were instructed how to use the APHID software to collect and chart a medication history. Physicians were instructed how to use specially designed templates to review the history and document reconciliation efforts. They were also taught to generate an after-visit summary report. Medical support assistants were expected to print the after-visit summary along with follow-up appointment information at the time of patient checkout.

Despite initial implementation hurdles, the informatics team was able to successfully incorporate the tools and workflow into the clinic. At the time of manuscript preparation, the clinic had been using the MR bundle for four months following implementation. The full details of this implementation along with quantitative quality improvement statistics are described in a separate manuscript (in preparation).

**Theoretical Framework**

While an exhaustive review of implementation theory is beyond the scope of this manuscript, it is useful to briefly describe some of the contemporary theoretical frameworks that informed our approach to this study. Davis’ Technology Acceptance Model (TAM) is an extension of Ajzen and Fishbein’s Theory of Reasoned Action and has been widely used to describe users’ acceptance and adoption of technology in a wide array of disciplines, including healthcare44-46. The model states that an individual’s predilection to use a technology has two determinants: perceived ease of use and perceived usefulness.

Although TAM has been studied extensively and has been said to predict 30-40% of variance in end-user behavior, it is limited in several important ways47. First, TAM was developed outside the healthcare context and it may not suitably capture the complex-adaptive nature of healthcare systems48. Second, TAM only addresses individual difference factors and neglects the social processes associated with implementation such as the voluntariness of HIT use, team-based care interactions, and healthcare governance49, 5047. Finally, the model emphasizes the intent to use or frequency of use, as opposed to the quality or effectiveness of technology use.

To address these limitations, so-called “added variable” models have emerged to describe and explain the interaction between user and setting. Venkatesh developed the Unified Theory of Acceptance and Use of Technology (UTAUT) based on the TAM. The UTAUT is a widely cited model that adds facilitating conditions and has been shown to explain up to 70% of behavioral intention and 50% of actual use51. Our research group developed the Effective Technology Use (ETU) model49, which extends TAM and UTAUT in two important ways. First, ETU includes a parsimonious set of “belief-based” variables that are amenable to manipulation: 1) an internal locus of control (i.e., “Compatibility with Workplace Values”), 2) and two external contextual mediators (i.e., “Compatibility with Work Processes” and “Implementation Climate”). Second, ETU conceptualizes use of technology along a continuum ranging from avoidance to skillful and effective use. We used the ETU to develop semi-structured interview scripts described in the following Methods section. Our research team also used the framework throughout the analysis cycle to organize findings.
Methods

Setting
This study was conducted at a level 1a Veterans’ Affairs facility located in the Pacific Northwest United States from April to October 2016. Nearly 70,000 patients from Alaska, Washington, Idaho, and Oregon receive primary or specialty care from our center; more than 85% of the patients are 45 years of age or older and 91% are male. The informatics department selected the ID clinic as a “demonstration lab” for several reasons. First, the clinic is located in a single physical location, thereby avoiding the need to divide implementation personnel across multiple deployments. Second, ID staff provides primary care and specialty consultation to a medically complex patient population, allowing the implementation team to observe an array of reconciliation challenges. Finally, the ID clinic hosts a small number of physicians – typically, three ID physicians and 1-2 residents or fellows – hence, limiting the training burden shouldered by the implementation team.

Participants
Although we extended interview invitations to all staff members, several were unavailable to participate due to scheduling conflicts or clinical reassignment. Three physicians, two nurse, and five medical support assistants participated in a total of thirteen pre- and mid-implementation interviews.

Interviews
The research team used the ETU model to guide the development of semi-structured interviews scripts. We included questions and probes to address each construct in the model. For example, to gather information about user values we included the question, “how important is it to collect and reconcile a medication history in comparison to other tasks performed during a clinical encounter?” Similarly, to gather information about the climate for implementation we included the question, “how did leadership communicate to you about this implementation?” Questions were open-ended to encourage respondent-directed narratives and to capture emergent concepts.

Interviews were conducted in two discrete phases of the implementation: 1) pre-implementation interviews were completed before technology rollout and 2) mid-implementation interviews were conducted in a rolling fashion as end-users were oriented to the technology. Two research team members were present for each interview. One researcher conducted the majority of the scripted interview while the other acted as scribe, managed the recording equipment, and asked follow-up or clarifying questions.

Each interview guide was informed by the ETU model and began with broad open-ended questions, followed by a series of more specific probes. Specific scripts were developed for each clinical role (i.e., nurse, physician, or clerk). The pre-implementation interviews aimed to gather baseline information about the target users and workplace culture, while mid-implementation interviews focused on gathering information about tools, workflows, and support. The audio recordings were transcribed verbatim. Names were replaced with identification codes to protect individual identities.

Analysis
A team member uninvolved with the implementation completed the initial analysis of transcripts using open coding methods. Codes were applied by labeling each word, line, or passage. Initial codes were then pile-sorted into preliminary categories using a Grounded Theory technique to identify emergent themes. To establish validity, the data were presented to the implementation team for critique and feedback. The investigators then compared sample passages and codes to identify new codes and larger themes. This process was repeated until no new themes could be identified and consensus was reached among team members. Finally, themes were sorted into facilitators and barriers to successful technology use.

Results
After reviewing 132 pages of transcripts, the research team identified a total of five facilitating conditions and five barriers germane to the MR implantation. We outline herewith each facilitator or barrier along with exemplar quotes as well the ETU concept which most closely maps to each.
Facilitators

**Facilitator 1:** The innovation aligned with users’ clinical tasks, values, and priorities; prioritization varied as a function of professional role. (ETU Theme: Compatibility with Workplace Values)

While respondents in each professional role emphasized a different set of core patient care values, each respondent was able to spontaneously draw associations between a core value and one or more facets of the implementation. Medical support assistants emphasized the primacy of fostering patient-centered care:

> “I think that the veteran has had a very positive experience, and they’re very happy to see it, and I think it’s great… I think that it gives them more information, and they have something in their hand” - (MSA1).

Nurses emphasized the importance of delivering accurate and useful information to providers:

> “We want to make sure that we’re not only documenting properly but we’re also informing the provider so that they’re getting that information as soon as possible to address it in the, within the appointment.” - (LPN5)

Physicians emphasized the criticality of prescribing safety and patient communication:

> “I think when we start doing better medication reconciliation the profile will be more accurate… My hope would be that that will make for better patient care.” - (MD4)

> “One thing is that you know the patient has, each time, the right phone numbers and all of that stuff from our clinic, and so they constantly have the right information. I like that.” - (MD5)

**Facilitator 2:** Staff found the software interface easy to use; products were easily incorporated into existing workflows without reducing efficiency. (ETU Theme: Perceived Ease of Use)

Most users believed the software was easy to use and could be adapted to existing workflows:

> “Really, it’s just one more little step than what we usually do. So I think that it’s just very easy. I mean you just click on it, print it out, and hand it to them along with their appointment list. It’s very smooth. No issues” - (MSA1).

Many seemed undeterred by the time required to complete MR:

[Is it worth the time?] – “Yeah, I think so, and honestly, I’m not sure that it takes more time. It took some time to learn the tools, and well, it still is, but I think in the end, I’m not sure that it takes too much more time from us” - (MD5).

**Facilitator 3:** Despite the absence of executive sponsorship, the implementation team successfully used a practice facilitation strategy to establish clinician champions and foster clinic staff engagement. (ETU Theme: Implementation Climate)

Typologies for overarching implementation strategies help broadly categorize and disambiguate between approaches. In general, the implementation team tended to use a “practice facilitation” approach – encouraging clinician uptake by providing intensive support and preparing local champions. This is in contrast to a primarily top-down approach where existing organizational structures such as executive boards or section leaders promote and enforce change directives.

> “I thought the staff [Implementation team] was very helpful. They asked any questions I had or answered all of my questions, and they were very supportive. They asked me if there was anything that I needed or more additional information, and yeah, they were great. They were supportive” - (MSA1).

The implementation team encouraged clinical champions to adopt project ownership…

> “But having the emphasis that medication reconciliation and medication adherence are very, very important for patient outcomes, that’s a very important thing, and then saying we’re providing you with tools to facilitate. You’re doing a good job with medication reconciliation. That’s the other important thing.” – (MD4)
“you have to go with, you have this great opportunity to help the patient, and we’re providing so many tools to make
this so much easier for you and so much more of a streamlined process and as our head infection control nurse always
used to say, the reason bad things happen in medicine is because the holes in Swiss cheese will line up sometimes, and
having two people looking at things from medications from two different perspectives, that prevents these bad things
from happening. So I have to go with the angle of rather than mandating things in a certain way of trying to have tools
to help you help your patients. I think that that is the key” - (MD4).

…despite the absence of executive sponsorship.

“Thinking back to leadership support and stuff, I think it comes back to supporting staffing and supporting you guys to
do it, and supporting the staff to be there to be able to implement it. We just don’t have that. So I find that very
frustrating… Yeah, and I have no idea if. I mean I would assume that the Chief of Medicine would be supporting this. I
don’t actually know because I just haven’t been involved in discussions past MD1” - (MD5).

**Facilitator 4: At-the-elbow support was essential, and more valuable than printed educational materials. (ETU
Theme: Implementation Climate)**

Staff believed at-the-elbow support was a crucial training tool:

“I mean it would have been much more frustrating without having one of you guys there. I think that it was key to
have at least one of you guys sitting in the clinic. Probably, I mean I’m not sure if we needed it for every individual
provider, potentially to save some manpower, but one of you to be in clinic in real time is key” - (MD5).

Notably, users felt supporting staff did not necessarily need to have a clinical background:

[Was there much of a difference with us supporting you with a doctor versus someone else?] – “Not a huge difference;
Yeah, not a huge difference… Yeah, but no, for the technical part of it, it maybe was slightly. I can say if all things
being equal, potentially it would be nice to have a doctor there in kind of he understands that. I mean he really
understands the physician part of the workflow that you’re dealing with, so that’s potentially slightly more helpful. But
it’s almost as helpful to have non-[Physician] there” - (MD5).

Although customized paper educational materials were furnished to each professional role during training, they were
rarely referenced in clinic:

[What educational materials did you use to learn the new tools and processes?] – “It was hands on. You guys just kind
of came up and because I didn’t get to go to the initial walkthrough orientation. So I know that you for sure came out
and kind of explained to me the process…” [Do you remember getting any educational materials from us?] – “I do not
remember getting any educational material from you” – (MSA1).

**Facilitator 5: Providers valued having flexible tools and processes available to accommodate the emergent
properties of complex adaptive systems. (ETU Theme: Compatibility with Work Processes)**

Providers emphasized that the clinical situations encountered – and practice strategies used – are heterogeneous and
often improvised. Therefore, it is critical that tools can be adapted to the circumstances:

“The new note I haven't used at all because I do my own intake notes, and I have a way that I like them... Everybody is
different... But these patients are so complex, and some of them we’ve followed for so long that I have my way that I
like to have things in a specific place and follow them. So it helps me... Sometimes I’ll actually do that note and then
cut and paste it into my other notes (laughter), some of the components of it. So I liked having it there. It’s more. All
of these things to me are tools, but it’s nice to have different tools to be able to use in different circumstances for
different patients. So overall, I think that it’s definitely been helpful” - (MD4).

**Barriers**

**Barrier 1: With severely limited clinical time at baseline, users feared that using new technology would be time
consuming and interfere with care delivery. (ETU Theme: Compatibility with Work Processes)**

Clinicians and staff felt that they had insufficient time to complete even baseline clinical tasks:

“Because the doctors are just as busy if not sometimes more busy than nursing staff. They’re not going to always have
time to get to everything they need to get to in an encounter. In all fairness they’re busy, too” - (LPN2).
“The way the clinic works, there is so much delay I will have them skip vitals and stuff, and have them put them in a room. Or else you’ll inevitably get way behind” - (MD5).

Respondents representing each professional role expressed concerns over the time required to complete MR tasks:

“I think it’s going to be a learning curve a bit. I think it’s going to be time consuming at first. Other than that, I think if all three of us work on it together, the MSA’s, I think it can be successful. My concern is that it’s time consuming” - (MSA1).

Barrier 2: There is no accepted standard for prioritizing clinical tasks; staff tends to prioritize according to their individually-held values. (ETU Theme: Compatibility with Workplace Values)

Our VA facility is a matrix organization; control structures are siloed and clinical personnel tend to report to different managers. As a result, leadership messaging can be unclear or even discordant. We found that in resource-constrained settings, staff used personal and ad-hoc heuristics to organize and prioritize work:

[Regarding clinical tasks] “I don’t know that there really is a prioritization per se, unless they are saying things to trigger the need to look at, ‘I’m depressed or I’m thinking to hurt myself’… at least if we get to a point where we can get something set, where it relieves the guessing game, did we do it for this one, did we not do it for this one? That can slow things down” - (LPN2).

Barrier 3: Staff believed their capacity for change was limited by fixed resource constraints (staffing, environmental space, patient social issues, and medical complexity). (ETU Theme: Implementation Climate)

Staff identified fixed resource constraints such as physical configuration of the clinic (e.g., the number of exam rooms, or distance between exam rooms and waiting area) or medical complexity of patients (e.g., multiple active problems, high medication burden, co-management of patients) as important barriers to change:

“I think it is confusing for them [patients] as well, because they come through those double doors and they don’t know whether to go left, right, straight… I’ve seen a lot of CDU patients come out of the double-doors, and say, ‘where are the elevators, I need to check out.’ They don’t know where to check out” - (MSA3).

Barrier 4: Gaps in codified process standards and unclear role definitions lead to disruptions in workflow. (ETU Theme: Compatibility with Work Processes)

Stakeholders role expectations – including those of the patients – are used to negotiate shared mental models, rules of engagement, and production of deliverables. When these roles are not clear to everyone, workflows are disrupted:

“But the problem we realized at the time of that meeting was that everybody in our group does the process very differently. Has very different goals, and very different… and I was like, ‘this is not going to be easy’” - (MD4).

“I know with (sigh) the medication reconciliation part of it I feel that with patients cause they’re not used to the nurses going through that part … because some of the patients aren’t, either are not comfortable, or it take, just takes a little bit longer to do that, the medication reconciliation with patients that haven’t gone through it with the nurse cause they’re used to doing it with the, a provider” - (LPN5).

Barrier 5: Structured data forms were difficult to use and lacked sufficient expressivity for routine clinical encounters. (ETU Theme: Perceived Ease of Use)

The structured clinical notes requested by the ID staff and developed by the implementation team were found to be over-engineered, not intuitive, and inflexible at the point-of-service:

“I kind of feel bad that we made this whole [clinic] template and created it, and that in practice we’ve found that it really isn’t all that helpful. So I guess I’ve learned or I guess we’ve probably learned that there is some balance of over-scripting and under-scripting these things… I guess the [clinic] template was a little bit surprising. I thought that it would work great, but it didn’t seem to work in the end… I think that it’s over-customized. Yeah” - (MD5).
Discussion

Key Findings

This article is one of the first to use qualitative methods to describe and understand the sociotechnical determinants of MR adoption and, to our knowledge, only the second that explores ambulatory care culture. We identified several important facilitators and barriers to MR adoption that may inform the development and implementation of future MR processes.

Although articulated prioritization heuristics varied as a function of professional role, all users associated new tasks with a deeply held personal value. Medical support assistants typically orchestrated patient navigation activities (e.g., check-in, check-out, scheduling) and, therefore, more often extolled the virtues of our patient-centered documentation. Nurses and physicians, by contrast, valued the completeness of the medication adherence data. When asked why they used the tools, they cited the ability to improve prescribing safety and avoid medication misadventures. Interestingly, nurses also emphasized the significance of team-based care and quality information hand-offs. When end-users believed the innovation purpose aligned with their values, they were more likely to adjust workflows to accommodate the innovation. To summarize, it appears that when process improvement professionals select “practice facilitation” strategies, it is critical to understand the unique values associated with the different professional roles. This information can then be leveraged when recruiting clinical champions and developing information campaigns.

Our findings also suggest that lack of executive sponsorship – while undesirable – does not predict certain failure of an implementation. Although facility executives (i.e., the Chief of Staff Office) sponsored the project, there had been no direct communication with front-line staff regarding participation or expectations. In response, the implementation team adopted a set of “practice facilitation” techniques including 1) identifying and preparing champions, 2) ensuring ongoing training and facilitation, 3) providing audits and feedback, and 4) reminding clinicians of key tasks. In this regard, the implementation team acted as a liaison or proxy for the executives. Respondent reports suggest the implementation team effectively communicated project goals and expectations directly to key stakeholders. Stakeholders, in turn, were encouraged to reach out to the implementation team for questions or issues. Overall, this data supports the contention that an internal locus for change can be cultivated using a number of complementary and synergistic implementation strategies.

Finally, the data suggest that at-the-elbow support was an essential component of implementation success. Printed materials were quickly discarded and all but forgotten, whereas direct hands-on support helped reinforce tasks, navigate trouble spots, and build confidence in the process. This finding is unsurprising; staff training has long been recognized as a relatively weak intervention in process improvement campaigns. What may be more significant is that respondents valued the assistance of non-clinicians as well as clinicians, suggesting that the value of hands-on support is not necessarily limited to clinical colleagues. Future implementations may be able to use more non-clinician staff during training or to otherwise extend training beyond the capabilities of clinician “super-users”.

We identified many implementation barriers – some of which were at least partially addressed with targeted interventions. Fixed external constraints plagued the implementation and caused timeline slippage. Pre-implementation interviews suggested a climate of frustration with systematic barriers facing the clinic, such as clinician time, exam room space, and competing organizational expectations. Although optimism increased by mid-implementation, the research team identified a number of new barriers including unclear role definitions associated with the new workflow and poor note template usability. Fortunately, the structured approach to gathering feedback enabled the team to quickly identify problems and course correct. For example, a 15-minute schedule shift was enacted to provide more nurse-patient contact time. Staff roles were codified and reinforced with at-the-elbow support. Finally, the implementation team invested additional time role-modeling hand-offs to reinforce shared mental models and improve situational awareness.

In general, users indicated the software tools were easy to use, integrating well into existing workflows. The only notable exception appeared to be the initial structured note template. Providers found the input fields to be inefficient and difficult to navigate. Accordingly, the development team quickly abandoned this design for a more flexible MR input dialog that could be called by the user at any point in the workflow. What is exceptional about this finding is that the template was designed according to user-centered principles with requirements furnished and tested by the ID clinicians.
Human factors experts often find that end-users will describe—and build products—according to work-as-imagined rather than work-as-done\textsuperscript{60}. Fortunately, involvement of end-users and domain subject matter experts helped to build trust between implementation team and stakeholders. Furthermore, the collection of qualitative data at mid-implementation helped surface design challenges early and craft an agile response. This finding stands as a reminder that electronic health record documentation tools should balance the need to script workflow and collect computable data with the flexibility required to handle the emergent properties of the clinical environment.

**Implications for Further Work**

In the healthcare setting, technology is becoming nearly ubiquitous. However, advances in technology as well as biomedical knowledge\textsuperscript{61} will continually lead to the development of newer technologies and methods that will have an even greater potential to improve the way physicians care for patients. As such, it becomes ever more important to continue to evaluate and improve our understanding of technology implementation methods. There are many avenues for future research. As patients play a central role in the process, further exploration of the impact that patient values and expectations have on technology acceptance, even if the patient is not the primary user of the technology, would be of benefit for future MR implementations. More research is also needed regarding structured data elements in clinical documentation—How can structured documentation better be implemented without hindering the end user? Finally, in the near future as technologies with alternative input methods such as voice recognition using artificial intelligence as the primary interface mechanism become more available, research analyzing the intricacies of this novelty will be required.

**Limitations**

Limitations of our study include that it was conducted at a single site, limiting the generalizability of findings. Nurses and medical support assistants rotated through clinics at different time points during the implementation. Thus, it was not always possible to recruit the same participants from pre to mid-implementation. Finally, the total number of interviews is relatively low. Hence, this study should be considered exploratory in nature. Larger respondent samples from multiple clinics—or, preferably, multiple organizations—would help to enrich and validate the list of facilitators and barriers.

**Conclusions**

As we increasingly utilize new technologies to improve healthcare processes, more research is needed in how best to implement and integrate these technologies into clinical workflows. The findings in this qualitative analysis of an MR assistive technology implementation identify key sociotechnical aspects of technology adoption. While our findings generally agree with current literature on healthcare technology implementations, some aspects may be more specific to MR processes and these findings may be used to guide future efforts to implement MR processes.

Clinical Named Entity Recognition Using Deep Learning Models

Yonghui Wu, PhD, Min Jiang, MS, Jun Xu, PhD, Degui Zhi, PhD, Hua Xu, PhD
School of Biomedical Informatics, the University of Texas Health Science Center at
Houston, Houston, TX, USA

Abstract

Clinical Named Entity Recognition (NER) is a critical natural language processing (NLP) task to extract important concepts (named entities) from clinical narratives. Researchers have extensively investigated machine learning models for clinical NER. Recently, there have been increasing efforts to apply deep learning models to improve the performance of current clinical NER systems. This study examined two popular deep learning architectures, the Convolutional Neural Network (CNN) and the Recurrent Neural Network (RNN), to extract concepts from clinical texts. We compared the two deep neural network architectures with three baseline Conditional Random Fields (CRFs) models and two state-of-the-art clinical NER systems using the i2b2 2010 clinical concept extraction corpus. The evaluation results showed that the RNN model trained with the word embeddings achieved a new state-of-the-art performance (a strict F1 score of 85.94%) for the defined clinical NER task, outperforming the best-reported system that used both manually defined and unsupervised learning features. This study demonstrates the advantage of using deep neural network architectures for clinical concept extraction, including distributed feature representation, automatic feature learning, and long-term dependencies capture. This is one of the first studies to compare the two widely used deep learning models and demonstrate the superior performance of the RNN model for clinical NER.

Introduction

Clinical studies often require detailed patients’ information documented in clinical narratives. Named Entity Recognition (NER) is a fundamental Natural Language Processing (NLP) task to extract entities of interest (e.g., disease names, medication names and lab tests) from clinical narratives, thus to support clinical and translational research. Researchers have developed computational models and applied them in general clinical NLP systems. Most of the general clinical NLP systems such as MetaMap, MedLEE, and KnowledgeMap, applied rule-based methods that rely on existing medical vocabularies for NER. The clinical NLP community has organized several challenges to examine the performances of state-of-the-art methods. Most of the top-performed systems are primarily based on supervised machine learning models with manually defined features. To further improve the performance, researchers have explored various strategies within the current infrastructure of conventional machine learning models, including ensemble models that combine multiple machine learning methods, hybrid systems that combine machine learning with high-confidence rules, unsupervised features generated using clustering algorithms (e.g., Brown clustering), and domain adaptation to leverage labeled corpora from other domains.

Machine learning methods formulate the clinical NER task as a sequence labeling problem that aims to find the best label sequence (e.g., BIO format labels) for a given input sequence (individual words from clinical text). Researchers have applied many machine learning models, including Conditional Random Fields (CRFs), Maximum Entropy (ME), and Structured Support Vector Machines (SSVMs). Many top-ranked NER systems applied the CRFs model, which is the most popular solution among conventional machine learning algorithms. A typical state-of-the-art clinical NER system usually utilizes features from different linguistic levels, including orthographic information (e.g., capitalization of letters, prefix and suffix), syntactic information (e.g. POS tags), word n-grams, and semantic information (e.g., the UMLS concept unique identifier). Some hybrid models further leverage the concepts and semantic types from the existing clinical NLP systems such as MetaMap, cTAKES. To further improve the performance, researchers have also utilized ensemble methods to combine different machine learning models, such as re-ranking. More recently, researchers also start to examine the unsupervised features derived from large volumes of unlabeled corpora, such as the word clusters generated using Brown clustering and random indexing. The continuous and intensive hard work from the clinical NLP community have boosted the performance of clinical NER, while also identified several bottlenecks that impede further improvement, including:

1) Fragile feature representation. Initially, the dominant feature representation in clinical NER is the bag-of-word model, which is a simplified representation of a piece of text based on the presence/absence of its words...
irrespective of the orders between words, grammatical relation, and semantic information. The bag-of-word model is fragile for clinical NER due to the sparsity problem. For example, the following two similar clinical entities: “mildly dilated right atrium” and “somewhat enlarged left ventricle” have nothing in common using the bag-of-word feature representation. However, they are two related concepts. There is a need for more robust feature representations.

2) Task-specific and time-consuming human feature engineering.27,28 The typical machine learning based clinical NER is composed of two steps: feature extraction and parameter optimization, where feature extraction is the most critical but time-consuming step. In the conventional machine learning solutions, the feature extraction heavily depends on humans while the machine can only handle the parameter optimization supervised by the gold-standard annotations. Researchers manually screen the positive/negative samples to identify possible features (e.g., tokens containing capitalized letters are more likely to have special meanings) and design feature combinations (e.g., body location followed by a disorder mention), commonly referred to as “human feature engineering”. The human feature engineering has several problems. First, the features extracted by human are either incomplete – human cannot enumerate all possible features, or over specified – the same information is repeated in many complex features and feature combinations. Second, researchers must engineer the features again for a different task or different data source. There is an increasing need for automatic feature learning algorithms to release researchers from the time-consuming manual feature engineering.

3) Lack of long-term dependencies.28-30 The typical CRFs based NER systems usually require the set up of a word window for the input sequence of tokens. Many studies that examined the system prediction errors have reported false negatives caused by the lack of long-term dependencies. However, simply increasing the window size cannot solve this problem as it may dilute the signal with more noise into the feature space and greatly increase the training time. The clinical NER need a better architecture to capture long-term dependencies from clinical texts. Recently, there have been increasing efforts to explore a new emerging technology, deep learning31 (or deep neural networks), to improve the current clinical NLP systems. Deep learning is a sub-domain of machine learning that uses deep architectures to learn high-level feature representations. Currently, deep neural networks are commonly used as the unique deep architecture for high-level feature learning. Deep learning models introduced word embedding28,32 as a critical technique to train densely-valued vector representation of words to replace the fragile bag-of-word representation. Each row of the matrix is associated with a word in the vocabulary and each column of the matrix represents a latent feature. The input word sequence can be transformed into a vector by concatenating the corresponding word vectors from the embedding matrix. Deep neural network architectures can learn high-level features automatically to release researchers from time-consuming human feature engineering. To capture long-term dependencies in a word sequence, researchers designed two popular deep architectures, including the Convolutional Neural Networks (CNN)28,33 and the Recurrent Neural Networks (RNN)34. Recent research from the general NLP domain reported that the CNN and RNN developed using only the word embeddings achieved comparable performance as the state-of-the-art CRFs with human engineered features and knowledge from dictionaries.28,34 In the clinical NLP domain, in one of our previous works35, we examined the word embedding trained using a neural network and applied the embeddings to an SVMs model for word sense disambiguation (WSD)36 and a CRFs model for clinical NER. The evaluation results showed that the word embeddings could be used as useful features to improve the state-of-the-art performances of conventional machine learning models for WSD and NER. Later, we developed a CNN based NER method37 and applied it to the Chinese clinical notes, which outperformed a state-of-the-art CRFs model. Jagannatha et al.38 applied RNN for medical event detection from clinical notes and later compared several RNN models with different loss functions. The experimental results using annotated cancer patient notes showed that the RNN outperformed a baseline CRFs model with context features.

However, the previous study by Jagannatha et al.38 compared RNN with a baseline CRFs with only context word features and the evaluation corpus is not openly accessible. Our previous CNN study37 was evaluated using Chinese clinical corpus. It is still not clear which deep architecture is better and whether they could outperform the state-of-the-art clinical NER systems for English clinical corpora. Therefore, it is necessary to further examine the two popular deep architectures, CNN and RNN, using an open challenge corpus and compare them with the most state-of-the-art clinical NER systems. This study is one of the first studies to compare the two widely used deep learning models using an open clinical corpus – the i2b2 2010 clinical concept extraction dataset. We compared the two deep learning models with the state-of-the-art clinical NER systems with human designed features and demonstrated the superior performance of RNN model.
Methods

Data sets

In this study, we reused the word embeddings developed in our previous study\(^3\) using the unlabeled Multiparameter Intelligent Monitoring in Intensive Care (MIMIC) II corpus\(^9\). The MIMIC II corpus is composed of 403,871 notes from four different note types including discharge notes, radiology notes, ECG and ECHO notes. Table 1 shows the detailed information about the MIMIC II corpus. We used the labeled corpus developed for the Concept Extraction task of the 2010 i2b2 NLP challenge for model training and evaluation. We used the same training and test data sets as in the challenge, which consisted of 349 notes for training and 477 notes for testing. For each note, annotators manually extracted entities about Problem, Treatment, and Test. Table 1 shows detailed information for both the training dataset and the test data set.

Machine learning models

Baseline CRFs systems

The CRFs model approaches clinical NER as a sequence labeling problem that tries to find the best label sequence \(Y^* = y_1, y_2, ... , y_N\) for a given input sequence \(X = x_1, x_2, ... , x_N\). The clinical concept extraction task can be converted into a sequence labeling problem by assigning the annotated entities with appropriate tag representations. This study used the standard "BIO" schema to convert the named entity annotations into sequence labeling tags, in which each word is assigned to a label as following: B = beginning of an entity, I = inside an entity, and O = outside of an entity. As the i2b2 2010 concept extraction challenge focused on three types of clinical concepts, we used a total number of seven different tags (B-problem, B-test, B-treatment, I-problem, I-test, I-treatment, O). For comparison, we constructed three CRFs baseline systems using features extracted at different levels. The first system used only the context word and n-gram features. Based on the basic features, the second systems further added linguistic features and document level features (section names). Similarly, the third system further added knowledge features derived from general clinical NLP systems (MedLEE, MetaMap and KnowledgeMap) and dictionary match features from existing vocabularies (UMLS). All the baseline systems were developed using the CRFs implemented in the CRF++ package.

State-of-the-art NER systems

To challenge the deep learning models, we selected two state-of-the-art systems among all studies regarding the i2b2 2010 clinical concept extraction challenge dataset. The first system is the best-performed system developed by Debruijn et al.\(^1\). This system explored many typical NER features including word features from different linguistic levels, knowledge from existing clinical NLP systems, and Brown clustering. Authors proposed a semi-supervised Markov model solution and achieved the best F1 score during this challenge. The second system\(^2\) applied SSVMs model and further examined the distributional word representation feature generated by Random Indexing algorithm. To the best of our knowledge, this system achieved the best after-challenge performance on the i2b2 2010 dataset up until now.

Deep learning based NER system

Similar to the CRFs model, deep learning models formulate the clinical concept extraction task into a sequence labeling problem using the same “BIO” tagging schema. The input of deep learning models is quite different with conventional machine learning models. The input of CRFs model is human designed features represented in bag-of-word style vector. Whereas, the input for deep learning model is the raw sequence of words in the sentence without human engineering. We applied a word embedding layer to transform the sequence of words into densely-valued vectors, where most of the values are non-zero. Next, we train a deep neural network to learn high-level feature...
representations, capture long-term dependencies, and global features to help identify clinical entities. This study explored two deep architectures including CNN and RNN.

**CNN architecture:** This study adopted a popular CNN architecture using sentence level log-likelihood approach proposed by Dr. Ronan Collobert. This architecture consists of a convolutional layer, a non-linear layer using the hard version of the hyperbolic tangent (HardTanh), and several standard linear layers. This architecture achieved state-of-the-art NER performance in the general English domain and later was applied to many other NLP tasks later. Using word embeddings, each word in the input window can be mapped to an N-dimension vector (N is the embedding dimension). Then, a convolution layer captures the long-term dependencies (or global features) in the hidden nodes. Both the local features and the global features are then concatenated together and fed into a standard neural network trained using stochastic gradient descending. Finally, the classification layer utilized a sentence level log-likelihood approach to calculate the loss supervised by gold-standard annotations. Detailed information for this CNN architecture can be found from our previous study.

**RNN architecture:** RNN is an emerging new deep architecture for sequence data. Recent studies have shown that RNNs have good ability to capture long-term dependencies for sequence data. In this study, we adopted a RNN architecture implemented using the Long Short Term-Memory (LSTM) by Lample et al. The LSTM is the most popular implementation of RNN architecture. A basic LSTM unit is composed of three multiplicative gates, including an input gate to control the proportion of input information transferred to a memory cell; a forget gate to control the proportion of historical information from the previous state; and an output gate to control the proportion of output information to pass on to the next step. We also applied several standard deep learning techniques including character embedding and dropout. For the input layer, we combined the word embeddings and the character embeddings in an input vector. The word embeddings were pre-trained from the MIMIC II corpus and the character embeddings were initiated with random values. The final classification layer of the RNN used a CRFs loss function, which is similar to the CNN architecture examined in this study.

**Experiments and Evaluation**

This study used word embeddings with 50 dimensions, which was pre-trained from the MIMIC II corpus in one of our previous studies. We used a neural network with negative sampling to train the embeddings as our previous study showed that this embedding is better or at least comparable to the word2vec algorithm. For CNN, we used a Java implementation developed in one of our previous study. We compared several combinations of network parameters based on our previous study and finally used the following parameters for CNN: learning rate at 0.01, the word embedding dimension at 50, and hidden node number at 300. For RNN, we adopted a Python implementation using Theano package. Based on the parameters reported by Lample et al., we examined the character embedding sizes and learning rates. The final RNN model used the following parameters: word embedding dimension at 50; character embedding dimension at 25; the LSTM layer for word level is 100 and the LSTM layer for the character level is 25; learning rate at 0.005; dropout probability is 0.5. A Nvidia Tesla K40 GPU was used to train the RNN model. The official evaluation scripts provided by the i2b2 organizers were used to calculate the strict micro-averaged precision, recall, and F1-score.

**Results**

Table 2 compares the performances of the baseline CRFs, the Semi-Markov (best system during the challenge), the SSVMs (current best system developed after the challenge), the CNN and RNN using the i2b2 2010 test dataset. All evaluation scores were based on exact matching. For the baseline CRFs, the linguistic and document level features improved the baseline F1 score from 77.33% to 79.87%. The knowledge base features further boosted the score to 83.60%. For the state-of-the-art systems, the semi-Markov model developed by Debruijn et al. during the challenge further explored a semi-supervised word cluster feature using Brown clusters and applied a semi-supervised Markov model, which achieved the best F1 score at 85.23%. Later, Tang et al. explored the SSVMs model and distributional word representation from the Random Indexing algorithm and further improved the F1 score to 85.82%, which is the best performance score reported using the i2b2 2010 dataset. For deep learning models, the CNN with only word embeddings outperformed the baseline CRFs with word, linguistic and document level features. However, the performance of CNN did not outperform the baseline CRFs further combined with knowledge features. The RNN architecture implemented using bi-direction LSTM neurons outperformed the current best system and achieved the best F1 score (85.91%) on this data set using only the word/character embeddings.

Discussion

This study examined two deep learning architectures to extract concepts from clinical texts. We constructed three baseline systems using the CRFs model with different levels of features. Two deep learning architectures, including a CNN and an RNN, were developed. We compared the deep learning architectures with the state-of-the-art clinical NER systems using i2b2 2010 corpus. The experimental results using the standard training, test and evaluation showed that the RNN model trained with only word embeddings achieved the new state-of-the-art performance for clinical NER, which outperformed the best system during the challenge and the current best system based on an SSVMs model. This study shows the advantage of using deep neural network architectures for information extraction from clinical texts. To the best of our knowledge, this is the first study comparing two popular deep learning architectures (CNN and RNN) for clinical concept extraction.

All deep learning models developed using only word embeddings outperformed the baseline CRFs with basic word level, linguistic level, and document level features, showing the efficiency of automatic feature learning from large unlabeled corpora. The performance improvements of the deep learning architectures are mainly from the recall (from 72.92% to 86.56% for RNN), showing that the unsupervised feature learning can capture extra features that did not exist in the training dataset to boost the recall. The RNN outperformed other systems with a new state-of-the-art F1 score at 85.94%. To the best of our knowledge, this is the best performance ever reported for the i2b2 2010 clinical concept extraction dataset. The RNN architecture outperformed CNN, another deep neural network architecture designed to learn high-level feature representations, showing that the RNN architecture is more efficient for sequence labeling tasks.

As an emerging technology, deep learning provides distributed word representation to replace the fragile bag-of-word model, automatic high-level feature learning to release researchers from time-consuming feature engineering, and deep architectures to capture long-term dependencies. We do observed differences between the general NLP and clinical NLP when applying deep learning models. For example, the clinical NLP have more knowledge bases (e.g., UMLS) with decent coverage. However, it is very hard to generate such comprehensive knowledge bases with decent coverage in the general NLP domain. Therefore, we can see that most of the top-performing clinical NER systems utilized the knowledge from dictionaries and integrated with other clinical NLP systems, which may make it hard for the deep learning models using only word embeddings to compete with the traditional clinical NER models in the clinical domain. For example, the CNN architecture outperformed the state-of-the-art NER systems on both the general English NER dataset and the Chinese clinical corpus, where there are limited knowledge bases. Whereas, the CNN model did not outperform the state-of-the-art clinical NER systems on the i2b2 corpus, where the top
systems utilized many knowledge bases and were hybrid systems using multiple general clinical NLP systems. The success of the RNN architecture shows the promise of using deep learning architectures for clinical NLP: machines can learn features better than humans, given the correct deep neural network architectures and advanced optimization algorithms.

This study has limitations. We only explored hidden layer dimension and learning rate but used arbitrarily selected network parameters according to previous studies. More robust and efficient parameter tuning strategy is needed. We compared RNN with the current best NER system and reported a new state-of-the-art performance on the i2b2 data set. Although the numeric improvement looks small, this study demonstrated the efficiency of RNN using the minimal feature engineering. Deep learning architectures provide a unified solution for clinical NLP, which may simplify the complex system architecture of current state-of-the-art clinical NLP systems to speed up their application in practical NLP systems. With the distributed word representation and high-level feature abstraction, deep learning may achieve the state-of-the-art performance without the requirement of combining with other models and systems. It worth further investigating on how the deep learning models can be applied to practical clinical NLP systems.

Conclusion

This study compared two deep learning models, including the CNN and RNN, to extract clinical concepts from clinical texts. We compared CNN and RNN with baseline CRFs using different levels of features as well as the state-of-the-art clinical NER systems using the i2b2 2010 clinical concept extraction corpus. The experimental results show that the RNN outperformed the best clinical NER system based on SSVMs with a new state-of-the-art F1 score at 85.94%. The RNN model can be adapted to other clinical NLP tasks to improve their performances and to release researchers from time-consuming feature engineering.

Abstract

To develop a workflow-supported clinical documentation system, it is a critical first step to understand clinical workflow. While Time and Motion studies has been regarded as the gold standard of workflow analysis, this method can be resource consuming and its data may be biased due to the cognitive limitation of human observers. In this study, we aimed to evaluate the feasibility and validity of using EHR audit trail logs to analyze clinical workflow. Specifically, we compared three known workflow changes from our previous study with the corresponding EHR audit trail logs of the study participants. The results showed that EHR audit trail logs can be a valid source for clinical workflow analysis, and can provide an objective view of clinicians’ behaviors, multi-dimensional comparisons, and a highly extensible analysis framework.

Introduction

In recent years, clinical data capture and documentation has been increasingly supported by computer systems, especially Electronic Health Record (EHR) systems, as incentivized and regulated by the HITECH Act and the Meaningful Use1,2. While computer-based documentation (CBD) may be preferred due to its potential improvements in information availability and sharing as well as enhancement in patient care3,4, CBD may introduce negative effects if not designed properly. One significant negative effect is that a poorly designed CBD system contributes to cumbersome documentation activities and inaccurate and incomplete data capture when it fails to consider clinical workflow5.

In order to address this issue and design a workflow-supported CBD system, a critical first step is to understand and measure the current workflow and documentation behaviors, which has been frequently achieved by gold standard techniques such as Time and Motion (T&M) studies6. T&M studies, however, are often costly and incapable of collecting data in a large scale because of the challenges in recruiting numerous participants and observers as well as coordinating observation sessions. Meanwhile, T&M studies are inherently limited in accuracy due to human observers’ cognitive overload and biases, resulting in suboptimal quality of behavioral data such as incompleteness and misinterpretation.

An alternative method to make sense of clinical workflow is through the secondary use of EHR data, which has drawn significant attention from researchers. For example, Ozkaynak et al. (2015) characterize the workflow in pediatric emergency rooms by analyzing encounter and diagnosis data using Markov chain and visualization tools7. Kirkendall et al. (2014) understood the workflow of medication order-dosing alerts by simulating order activities in a testing EHR environment8. Redd et al. (2014) measured the efficiency of documentation by extracting the chart open and completion time in each patient encounter9. These studies, although suitable for their purposes, only utilized EHR data on a surface level. The data and methods in these studies did not have the ability to uncover more nuanced behavioral patterns of a large number of individual clinicians.

The clinicians’ behavioral patterns can be uncovered by a special type of EHR data, EHR audit trail logs, which automatically and minutely record clinicians’ EHR interactions for security and privacy purposes. These logs can be a cost-effective alternative to characterize clinicians’ documentation behaviors and have the potential to facilitate the understanding of clinical workflow and processes. For example, Hirsh et al. used audit files to understand time spending in primary care10. However, to our knowledge, there is no study evaluating EHR audit trail logs as a valid
source for clinical workflow analysis. This study therefore bridges this methodological gap by assessing the ability of these logs to provide supportive evidence to known workflow changes. Specifically, the study analyzed a sample of EHR audit trail log data extracted from an ambulatory healthcare organization. This organization launched an EHR enhancement project in mid 2013, resulting in subsequent workflow and behavioral changes as identified in our previous study. The present study chooses three findings to evaluate the ability of the EHR audit trail logs to provide supportive evidence. The implications of utilizing such log data for clinical workflow analyses are discussed. It is worth noting that these evaluation standards were validated based on the triangulation of our previous semi-structured interviews, ethnographic observations, and T&M studies. The qualitative analysis is out of the scope of this paper and will be published in another venue.

Methods

Study Site

The participating study site was a not-for-profit ambulatory healthcare organization located in an urban area in the western United States (Organization West). This organization contained more than 20 branches and affiliated locations including both primary care and specialty clinics. Organization West served several states over a widely rural area, with over 50% of patients being rural residents and around 50% of who are on Medicare/Medicaid. After nearly 10 years of use of a vendor EHR system, Organization West launched a significant update to enhance the system capability in 2013, including an electronic patient homepage, a standardized message center, a new computerized provider order entry (CPOE), and an e-prescribing functionality. During the EHR enhancement, one of the clinics experimented with a “Core Team Model,” in which a provider was teamed up with three clinical staff members to eliminate inefficiencies and patient wait times.

Data Collection

This study targeted three clinics in Organization West, including a primary care clinic in the main hospital (Primary Care 1), another primary clinic that experimented with the “Core Team Model” (Primary Care 2), and an Ear Nose Throat clinic (Specialty Care). A total of 24 clinicians were participated and equally distributed in each clinic. For each primary care clinic, the study participants included four providers, two nurses, one medical assistant, and one receptionist. For the specialty care clinic, the study participants included five providers, two nurses, one medical assistant, and no receptionist. The providers included in the study were physicians (MD), ophthalmologists (OD), nurse practitioners (NP), and physician assistants (PA). The participants’ EHR audit trail logs were extracted before, during, and after the EHR system changes. This data allowed the comparison of clinicians’ behavioral changes in many dimensions, e.g. primary care vs. specialty care; with and without the "Core Team Model"; and providers vs. non-providers. Since the quantitative analysis team (DW, NS, and KZ) was not physically located in the study sites, the log data were de-identified and exported as CSV files for analysis.

Data Manipulation

The log data were stored in a standalone SQLite database and manipulated using Structured Query Language. Specifically, the log data were categorized into three stages based on the timestamp: 1) PRE: log records comprised of a period of eight weeks prior to the launch date, 2) DURING: log records for a period of four weeks after the launch date, and 3) POST: log records of the eight weeks after the end of the DURING stage. The analysis in this study only focused on the data in the PRE and POST stages to examine the potential differences. The start and end of a week was set from Monday to Sunday. Moreover, the date and time information of the timestamps were parsed and stored separately, e.g. date, hour, and day of the week. The time information was further categorized into three types: 1) Regular hours (REG): time between 7am and 6pm from Monday to Friday; 2) off hours (OFF): time not in regular hours from Monday to Friday; and 3) weekend hours (WKN): anytime during Saturday and Sunday only. The start and end of the regular hours was determined based on our previous interviews and observations.

In addition, the clinical roles in the log data were marked as Provider (P), Nurse (N), Medical Assistant (A), and Receptionist (R). Note that the study created seven new event categories in addition to the original event names and tasks defined by the EHR vendor, including: 1) Communication, 2) Entering, 3) Login/Logout, 4) Processing, 5) Reading, 6) Printing, and 7) Other. Each event was first mapped to a category separately by the first two authors. Then, the mappings were discussed and an agreement was reached. If a consensus of an event mapping cannot be reached, this event will be categorized as “Other”.

1804
Hypotheses

The primary objective of this study was to evaluate the ability of EHR audit trail log data to provide supportive evidence to the known workflow changes. In particular, it aimed to reflect documentation-related behavioral changes among clinicians after the rollout of an EHR enhancement project. Three previously validated findings were chosen as the reference standards of the present study. The first evaluation involved a workaround order-placing behavior in Primary Care 1, where a provider likely had to prescribe a medication more than once in order to achieve the desired dose in the POST stage. For example, a provider would place two medication orders, one at 1.5 mg and the other at 0.5 mg, to equal the total intended dose of 2 mg. Since the order dosage was not captured in the log data, the providers in Primary Care 1 were alternatively hypothesized to have more number of order logs daily. Their patient volume in the PRE and POST stage was hypothesized to remain stable.

H1: After the EHR enhancement, the providers in Primary Care 1 had more number of order logs, but their patient volume remained stable.

The second evaluation was a shift of tasks in Primary Care 2, where providers spent less time on computer-related tasks after the EHR enhancement, while other clinicians consumed those tasks due to the implementation of the Core Team model. The providers in Primary Care 2 were hypothesized to have fewer “Computer Entering”-related logs in the POST stage, compared to the PRE stage. On the other hand, non-providers in the POST stage were hypothesized to have more “Computer Entering”-related logs.

H2: After the EHR enhancement, the providers in Primary Care 2 had fewer number of “Computer Entering”-related logs, while the non-providers had more such logs.

The third evaluation was the phenomenon of “deferred documentation” in Specialty Care clinic, highlighting differences in dictation. It is noted that providers in the PRE stage would dictate findings between patient visits, while in the POST stage they tended to document patient visits at the end of a day. It is hypothesized that providers in Specialty Care would have an increased number of logs in the off hours (and even weekends) in the POST stage.

H3: After the EHR enhancement, the providers in Specialty Care had more number of logs in the off hours.

Data Analysis

The data were analyzed through self-developed Python scripts, which were implemented using libraries such as pandas, numpy, scipy, and xlrd. The data analysis used two primary measures, namely, the number of logs and the percentage of logs. The analysis began with a statistical summary of all logs, followed by the statistical tests of the three hypotheses. For the first hypothesis (H1), the log records related to “adding an order” were selected based on keywords. The total number of orders placed per day was counted using the order identifiers stored in the logs. The days without any orders placed were dropped. On the other hand, the daily patient volume was estimated by the total number of patients accessed per day. For the second hypothesis (H2), the log records were manually coded into the seven high level categories, followed by the calculation of the number and percentage of logs in each category (e.g. Computer Entering). For the third hypothesis (H3), the same measures as H2 were used to quantify the off-hour and weekend logs. All the above measures in the PRE and POST stage were compared using a two-tailed, unequal variance t-test.

In addition, in H2 the fragmentation of the log events was assessed based on their categories. This measure calculated a fragmentation score representing the level of cognitive overload (12). The higher the score is, the more switches between categories the clinician had in the log data, and the more likely this person was suffered from cognitive overload. It is worth noting that a person may have multiple logs with varying categories but identical timestamp because multiple documentation behaviors may happen, or be triggered, at the same time. Fragmentation was detected if there was no overlap between any event categories of the current timestamp and its previous one. A daily fragmentation score was defined as the total number of detected fragmentation over the total number of timestamps on that day. The clinicians’ daily fragmentation scores in the PRE and POST stage were compared using the same t-test technique as the hypotheses.

Results

Statistical Summary

A total of 2.65 million EHR audit trail logs were extracted from Organization West in both PRE and POST stage, for a period of eight weeks each. Overall, the log volume of Primary Care 1 & 2 was approximately the same, whereas the log volume of Specialty Care was half of the previous two (Table 3.1). This is likely due to the differences of clinical practices between a primary and a specialty care clinic. In terms of the log volume by clinical roles, the
providers in Primary Care 2 had a much lower number than their nurses (87,600 vs. 141,090). In comparison, the average number of logs of the providers and nurses in Primary Care 1 were more comparable (111,351 vs. 116,078).

A further examination of the log volume considering the PRE and POST stage is listed in Table 3.2. This table shows that the nurses in Primary Care 1 had a 20% decrease of their log volumes and the providers had a 20% increase and in the POST stage. On the other hand, the nurses in Primary Care 2 had a 11% increase in their log volumes while the providers maintain a similar number of logs. This observation might be attributed to the implantation of the Core Team model in Primary Care 2, which increased the nurses’ documentation responsibility.

Hypothesis One

As shown in Table 3.3, the statistical test indicated that the providers in Primary Care 1 placed significantly more orders in the POST stage (all p<0.05) and maintained the same number of patients seen, which confirms our hypotheses. The same statistical test was further extended to the providers in Primary Care 2, which didn’t show the same pattern. As shown in the second half of Table 3.3, two of the four providers in Primary Care 2 had no significant change in their order numbers, with one of them seeing more patients in the POST stage. This finding suggests that changes of EHR systems may impact clinicians’ behaviors differently even though they operate within the same health system and have similar clinical practice.

Hypothesis Two

The second evaluation began at coding the log events to the seven high-level categories. The first two authors achieved 81% agreement on coding the event categories initially, and resolved most of the discrepancies afterwards. Table 3.4 lists top ten frequent events that were assigned to “Computer Entering”, and their vendor defined names and types as well as their frequencies in Primary Care 2.

The statistical test examined the differences of the “Computer Entering”-related events between the PRE and POST stage. The results (Table 3.5) showed that the participated nurses (BC2-11 & 19) and the medical assistant (BC2-22) had a significant increase (3-5%) in their percentage of computer entering logs as hypothesized. However, the receptionist (BC2-45) had an unexpected drop in their percentage of entering-related logs (53% -> 49%). On the other hand, the providers had a slight but not significant decrease in their number and percentage of logs, which is also unexpected.

* 0.05 significance

The workflow fragmentation analysis of these providers (Table 3.6) indicated that three out of four providers had a lower level of fragmentation, although only one of them was statistically significant. The other providers had a slight but not significant increase in the level of fragmentation (0.398 -> 0.401). Together, the analysis of the second evaluation supports the hypotheses of shift clinical workflow, where the nurses and the medical assistant had an increased percentage of “Computer Entry”-related logs. While the providers didn’t have a significant increase, they had an improved level of fragmentation in the POST stage, which may help reduce their cognitive overload, leading to their positive attitude toward the EHR change (i.e. more time with patients).

Table 3.6. The workflow fragmentation analysis of the providers in the Primary Care 2. The higher the score is, the more switches between log event categories the clinician had, the more likely cognitive overload happened.

Hypothesis Three

The initial statistical test of the providers’ weekly off-hour logs in Specialty Care, unfortunately, did not find any significant change at the 0.05 level. The statistical tests of the weekend logs also found no significant differences. A further exploratory analysis using visualization (line charts) suggested that the providers in Specialty Care had an increased number of logs right after 5pm (Figure 3.1). The data were therefore re-grouped and tested on an hourly basis. As shown in Table 3.8, four of five providers in Specialty Care had a significantly higher number of logs. They deferred documentation activities in at least one of the hours between 5pm and 10pm. The other provider (BC3-01) seemingly had already deferred the documentation activities in the PRE stage, which makes the EHR change less impactful in the POST stage.

Discussion

This case study demonstrated the validity of using EHR audit trail logs to analyze clinical workflow. The results indicated that EHR audit trail logs contained rich information of clinicians’ documentation behaviors. The analyses base on the log data successfully produced supportive evidence to the three known behavioral and workflow changes. For the first hypothesis, the data confirmed that the providers in Primary Care 1 placed more orders and maintained the same patient volume. For the second hypothesis, the data supported that the nurses in Primary Care 2 had more “Computer Entering”-related activities, while the providers may have a lower cognitive overload. For the third hypothesis, the data indicated that the providers in Specialty Care deferred their documentation behaviors, although each provider had a different working timeframe.

The study showed several benefits of using EHR audit trail logs to analyze clinical workflow. First of all, since the log data were recorded automatically and consistently, an analysis of one clinic can be easily applied to another clinic with almost no extra cost. Take the first hypothesis for example, the changes of the order numbers and patient volumes was initially examined in Primary Care 1 and then directly applied to Primary Care 2 with nearly no extra effort. This benefit of easy extension makes this method more attractive than other workflow analysis tools, e.g. Time and Motion studies and work sampling.

Another benefit of using EHR logs for workflow analysis is to provide an objective view of clinicians’ EHR behaviors and to verify the findings derived from other methods. Take the second hypothesis for example, the previous study suggested that the providers in Primary Care 2 had more time for patient communication because they shifted documentation responsibilities to other clinicians as a result of the Core Team model. The analysis of the present study, however, showed that the providers’ EHR log volume did not drop significantly although other clinicians, especially nurses, indeed had a significant increase of the log volume. One possible explanation is that EHR audit trail logs may not fully capture the documentation process as they are not design for such intension. Another explanation of this phenomenon, as suggested by the workflow fragmentation analysis, is that the providers may have less fragmented documentation activities, leading to a smoother workflow and higher quality of patient interactions.

Still another benefit of using EHR logs for workflow analysis is the ability to compare and contrast results in multiple dimensions. In this study, the dimensions included clinical roles (providers vs. non-providers), care types (primary vs. specialty), care models (normal vs. the core team model), time (regular vs. off-hour), and event categories (Entering vs. Other). Moreover, EHR audit trail logs enable detailed comparison showing the differences of individual clinician’s behaviors. Take the third hypothesis for example, the analysis not merely supported the hypothesis of deferred documentation in Specialty Clinic, but further indicated which hour(s) the documentation activities were deferred to, which were varying among the five providers.

Although the rich information in EHR audit trail logs has several benefits, it can introduce analytical challenges. One such challenge is the high complexity and high level of noise in the log data. It could be very difficult to identify meaningful patterns solely based on EHR log data. The present study voided this problem by utilizing the findings from the previous study to shed light on the analysis. This suggests that using EHR logs for clinical workflow analysis may require mixed methods, e.g. integrating the qualitative results to the quantitative analysis. It may also require extensive effort on data exploratory, which can be supported by visual analytics techniques. Another challenge is that EHR logs may require high-level categorization to reduce their complexity and to make them more meaningful. For example, in the present study, the logs were manually categorized into seven groups in order to compare “Computer Entering” activities with other kinds of activities. Since each vendor has a different mechanism capturing audit trail logs, and since each study has different analysis goals, it seems that researchers would need to spend a significant amount of time labeling EHR logs. Data mining and machine learning techniques may help facilitating this process.
This study has several limitations. First, this study only analyzed EHR audit trail logs of one organization in a community-based, ambulatory setting. Since this is a proof-of-concept study, we believe that the scope is adequate. Future research can consider expanding the scope to analyze EHR logs in an inpatient setting, of different EHR systems, and/or from multiple organizations. Second, the study did not obtain the EHR audit trail logs of all clinicians in the targeted organization, but only the logs associated with the 24 participants in the three selected clinics. This limitation prevents the study from performing a comprehensive patient-centered analysis because the selected participants may not work on the same patients in the study period. Third, although we conducted interviews, observations, and T&M studies to understand workflow and behavioral changes in our previous study, we did not compare step-by-step how clinical behaviors are recorded to form audit trail logs. Rather, we understood the log data based on the description of the attributes, the sequences, and the timestamps of the logs. We formed an interdisciplinary research team to mitigate potential biases in this interpretation. Next, we only employed two volume-related measures in this study. We have been working on applying data mining techniques, especially in sequential pattern mining, to uncover unexpected but interesting workflow patterns from the EHR audit trail logs. Last but not least, many results were not significant at the 0.05 level, and even not significant at the 0.1 level. However, a statistically insignificant difference may still have clinical impact. These insignificant differences still showed changes (increase or decrease of the means) aligned with our hypotheses.

Conclusions
This study evaluated the validity of using EHR audit trail logs for clinical workflow analysis. The three evaluations successfully provided supporting evidences and justify the use of this type data. Future research includes developing a generalized framework capable of analyzing log data from any EHR systems, advanced computational and visual-based methods to uncover more nuance patterns of clinicians’ behavioral changes, and a real-time monitoring system to detect workflow bottlenecks, physician burnout, and opportunities to support medical education.

Abstract

Increasing learning ability from massive medical data and building learning methods robust to data quality issues are key factors toward building data-driven clinical decision support systems for medicine prescription decision support. Here, we attempted accordingly to address the factors using a multi-task neural network approach, benefiting from multi-task learning’s advantage in modeling commonalities to increase learning performance and neural network’s robustness to imprecise data. By mining electronic health record data, we learned medicine prescription patterns of multiple correlated antidiabetic agents in blood glucose control and antihypertensive drugs in blood pressure control scenarios. We achieved AUC increases of 0.02 to 0.06 in single drug prescription and an accuracy increase of 0.05 in prescription pattern prediction compared to logistic regression, demonstrating the efficacy of multi-task neural network approach in learning medicine prescription patterns.

Introduction

Clinical decision support systems (CDSSs) are health information technology systems that assist clinical decision-making tasks. CDSS can be broadly divided into two types of approaches: knowledge-based that relies on digitalized clinical guidelines, and data-driven that relies on gathering evidence from real-life medical data. Many publications convey the belief that CDSS, especially on electronic health record (EHR) platform, will provide decision support to achieve large gains in clinical performance, improving its quality, safety, and cost efficiency¹-³. The accumulation of EHR data has allowed us the opportunity to use big data analytics approaches for data-driven CDSS. Prior work on EHR data includes mining association rules and Bayesian networks between clinical orders and diagnoses⁴, ⁵. Data-driven CDSS from EHR can be regarded as learning from collective experience of many practitioners to automatically generate evidence for clinical decision support.

Though interest in data-driven CDSS has grown, its application remains limited. The reasons are primarily two-folds: the quality of data, and the ability to learn from data. EHR data suffers from three main data quality issues: incompleteness, inaccuracy, and inconsistency⁶. Incompleteness is reflected by missing values of many attributes. Inaccuracies are unavoidable during typing and are frequently caused by inappropriate use of ICD codes. Inconsistency is also reflected by the inconsistent ICD code use and the inconsistent value-unit match for laboratory tests. Apart from these EHR data quality issues, uncertainty and inconsistencies abound in clinical decision making due to a lack of consensus view on a same clinical condition and evidence to confirm or deny the efficacy of each view⁷, rendering each diagnosis, clinical order, and prescription less of a ground truth. Even with perfect data, the effectiveness of data-driven methods still depend on the capacity of machine learning algorithms to solve the problem.

In response to the limitations, efforts toward data-driven CDSS can be made from three perspectives: increasing data quality, increasing tolerance to data quality issues during learning, and increasing learning ability. The last two perspectives can be addressed in machine learning by using neural network. Neural networks have remarkable capability to derive meaning from imprecise or complicated data though suffering from a major disadvantage of difficulty in interpretation.

In this paper, we use neural networks to learn doctors’ medicine prescription patterns in chronic disease treatment by mining EHR data to benefit from neural network’s properties of robustness to imprecise data and capacity to learn
complex tasks. Blood glucose control medication and blood pressure control medication in type 2 diabetes patients were considered. Seven types of anti-diabetic agents were considered for blood glucose control: alpha-glucosidase inhibitors (AGIs), dipeptidyl peptidase-4 (DPP-4), thiazolidinediones (TZDs), biguanides, glinides, sulfonylureas, and insulin. Seven types of antihypertensive drugs were considered for blood pressure control: angiotensin-converting-enzyme inhibitors (ACEIs), alpha blockers, angiotensin II receptor blockers (ARBs), beta blockers, calcium channel blockers (CCBs), diuretics, and hydrochlorothiazide. In a typical medicine prescription for blood glucose control, a doctor can prescribe one to several of the seven kinds of drugs. Thus, to learn doctors’ prescription behavior, prescribing a certain kind of anti-diabetic agent or not can be formulated into a binary classification problem, resulting in seven binary classifiers that can each be modeled by a neural network. In our observation, the prescription of the seven drugs are not mutually independent. To benefit from their commonalities while preserving the differences, a multi-task learning approach was used to learn the prescription combination of the seven drugs. Multi-task learning has been applied in healthcare settings to solve various problems like disease risk prediction, disease onset prediction, and disease progression for its good representation learning capability. In anti-diabetic agent prescription prediction, our multi-task neural network has shown AUC increases of 0.02 to 0.06 compared to logistic regression in the prediction of each single drug, and an accuracy increase of 0.05 in the prescription pattern prediction. In antihypertensive drug prescription prediction, the multi-task neural network has shown AUC increases of 0.02 to 0.03 compared to logistic regression in single drug prediction, though no accuracy increase in prescription pattern prediction was observed.

Our contribution is that we used a multi-task neural network approach to learn doctors’ medicine prescription pattern of multiple correlated drugs in blood glucose control and blood pressure control scenarios by mining EHR data, and has demonstrated its usefulness in solving these prescription problems.

Methods

Scenarios. Two scenarios were considered in this work: learning anti-diabetic agent prescription for blood glucose control and learning antihypertensive drug prescription for blood pressure control. Data was each constructed and processed.

Data preparation. Deidentified EHR data of type 2 diabetes patients from Xiamen, China within a four-year period (August 2012 to April 2016) was used in this study. Each case is defined as a patient encounter that has a prescription of at least one of the drugs concerned. Features used are summarized in Table 1, including demographics, physical examinations, laboratory tests, recent prescriptions, and disease history. The prescription of each drug is concerned as a class label, resulting in seven class labels in each of the two scenarios.

Data imputation. In this work, missing values of categorical variables were imputed by randomly sampling a category from a discrete probability distribution calculated from non-missing values, while missing values of continuous variables were imputed by randomly sampling a number from a normal distribution fit with non-missing values.

Feature engineering. Demographics were first extracted and imputed. For physical examinations, the most recent ones before the patient encounter were used if multiple sets were available. The immediate ones after this patient encounter were used in the absence of previous ones. Missing values were imputed. In antihypertensive drug prescription prediction, cases with imputed blood pressures were excluded. Two laboratory tests were used for anti-diabetic agent prescription since blood glucose level is a major indicator of such prescriptions, but were not used for antihypertensive drug prescription due to the rare availability of these tests. Test results within three months before or after the case were taken as valid. Only cases with valid test results were used for the anti-diabetic agent prescription prediction. Disease history was constructed using ICD codes, where the ICD-10 coding hierarchy was collapsed to the first three characters. A case would be assigned a ‘1’ for a disease if the corresponding ICD code was observed within the past year.

Data summary. After feature engineering, only 4,480 cases remained for anti-diabetic agent prescription prediction due to vast missing of laboratory test values, while 153,470 cases were preserved for antihypertensive drug prescription prediction. Antidiabetic agent prescription frequency and antihypertensive drug prescription frequency were each summarized in Table 2 and Table 3. Here, the anti-diabetic agent prescription frequency is significantly different from that in the whole population before removing cases, as is evident from the high frequency of insulin use. This reflects a

bias that cases with blood glucose levels recorded in the system may have more serious conditions compared to others.

**Drug dependency study.** From statistics’ point of view, prescription of two drugs A and B are independent if their joint probability equals the product of their probabilities:

\[ P(A \cap B) = P(A)P(B) \]

The dependency of drug A and B in this work is thus measured as:

\[ dependency = \frac{P(A \cap B)}{P(A)P(B)} \]

It can be rewritten with conditional probabilities as:

\[ dependency = \frac{P(A|B)}{P(A)} = \frac{P(B|A)}{P(B)} \]

This is equivalent to the support A provides for B, or the support B provides for A in the Bayesian interpretation, where a value larger than 1 indicates positive correlation, while a value smaller than 1 indicates negative correlation.

**Baseline classifier.** Logistic regression (LR) was used as the baseline classifier. The prescription of each drug is modeled by an LR, resulting in seven LR models in each scenario.

**Multi-task learning.** Multi-task neural networks were constructed as in Figure 1 for multi-task learning (MTL). Two intermediate components were illustrated: representation learning layers and classifier layers. A consensus representation relevant to the prescription tasks was learned in the representation learning layers. Out of the consensus representation, classifier layers were constructed for each classification task to make a distinction between the tasks while optimizing jointly a cost function considering the cost of all classification tasks. After training, the MTL model can intake the features and output the prediction of the seven drugs at the same time.

### Figure 1: A schematic representation of multi-task neural network. For each instance, a set of features and several class labels for the tasks are used for training. Input layer is followed by representation learning layers to learn the common representations, then followed by multiple classifiers to deal with the distinctions, after which an output layer is constructed for each classifier.

**Threshold selection.** For both LR and MTL, the output is produced as the probability of a case to be positive (or ‘1’). A threshold translating a probability to a class was such selected as to maximize the F1 score (explained in Table 4).

**Method assessment.** In a typical run of the experiment, the input data is first split into training data (70%) and testing data (30%). Either LR or MTL is trained on training data, with its performance assessed on testing data. For LR, 50 runs were conducted in each scenario with different training/testing splits to account for split randomness. For MTL, 150 runs were conducted for each task, 3 runs each on the 50 different training/testing splits to account also for the randomness in neural network training. A list of measurements used in this work is summarized in Table 4. The performance of a classifier for single drug prescription prediction is evaluated by AUC. The performance in combined prescription prediction is firstly measured by average Jaccard similarity between the predicted and the actual prescription pattern. The performance in combined prescription is also measured by prediction accuracy, where a predicted prescription pattern is counted accurate only if single drug prediction is accurate for all seven drugs.

**Statistical analysis.** Prediction by MTL is called AI (artificial intelligence) prescription in contrary to doctor prescription. To explore the justification for AI prescription, we conducted statistical analysis to evaluate the importance of each disease in disease history to the prediction. The importance is assessed for each disease in the prescription of each drug, where having this disease or not is counted towards having this drug prescribed or not. Odds ratios and Wald confidence intervals were calculated as in Table 4. A disease is considered significant in the prescription of this disease when the confidence interval does not include 1.

$Lower 95\% CI = \exp(\log(OR) - SE)$ 
$Upper 95\% CI = \exp(\log(OR) + SE)$ |

Results

Drug dependency. In antidiabetic agent prescription, around 13% cases have more than one drug prescribed (Table 2). Dependency of antidiabetic agents is shown in Table 5. Many drug pairs show dependency other than 1, suggesting correlation between the drugs. As an example, the support glinides provides for AGIs is 2.46, suggesting elevated level of combined use. Also, the support sulfonylureas provides for insulin is 0.28, suggesting less combined use. DPP-4 has some large dependency values, probably a bias caused by its rare use. Similarly as in antihypertensive drug prescription, around 28% cases have more than one drug prescribed (Table 3). Dependency of antihypertensive drugs are summarized in Table 6, showing many dependency other than 1. These suggest the relatedness in prescribing the drugs, forming the basis for multi-task learning to model information sharing.

Performance comparison in antidiabetic agent prescription prediction: MTL vs LR. In LR, the prescription pattern is predicted by constructing an LR classifier for each drug and joining the predictions from them. MTL is capable of predicting prescription pattern together. Their performances are compared in Table 7. AUC is used to evaluate the prediction of each single drug, with its mean, standard deviation (SD), and maxima in all runs listed. For all the seven drugs, MTL has higher AUC than LR, with the highest increase in glinides, a mean AUC increase from 0.788 to 0.850. In the prediction of combined prescription, MTL has a mean Jaccard similarity of 0.600 compared to 0.569 achieved by LR. In terms of accuracy (percentage of predictions that have all seven drugs correctly predicted), MTL has an accuracy of 0.493 compared to 0.445 of LR.

Performance comparison in antihypertensive drug prescription prediction: MTL vs LR. Similar comparison as in antidiabetic agent prescription prediction was conducted for antihypertensive drug prescription prediction, with performances summarized in Table 8. In single drug prediction, MTL has about 0.02 increase in AUC compared to LR in all seven drugs. However, MTL and LR have similar performance in combined prescription prediction, both mean Jaccard similarity and accuracy. This may be explained that though AUC is an important measure of binary classifier performance, it is difficult to be translated to a measure while solving a real-life problem since a threshold is needed to make a prediction based on the probability given. In this work, we selected the threshold that maximized the F1 score, bearing our intension to balance precision and recall. Under such selection, the accuracy of combined prescription prediction may well be the same between MTL and LR.

Disease history relevant to insulin prescription. Disease onsets (denoted by ICD codes) within a year from the time of case were evaluated for their relevance to insulin prescription both by doctor and by AI. A list of ICD codes was identified as significant for doctor prescription and AI prescription. We first tried to figure out AI’s ability in capturing doctors’ intension for insulin use. AI made a successful capture if an ICD code significant to doctors’ prescription was also significant to AI’s prescription. We thus present Figure 2 for visualization. From the figure, the majority of the diseases significant to doctors’ prescription were also identified as significant in AI prescription (OR >1 in Figure 2A or OR <1 in Figure 2B). A few exceptions were identified and summarized in Table 9. Out of the 121 ICD codes significant to increased doctor insulin prescription (OR >1), 15 (12.4%) were missed by AI prescription,

suggesting AI’s ability in capturing most diseases. However, some potentially important diseases were missed, like high blood pressure, lipid disorder, and diseases related to eye, limb, and bone, raising more expectations on AI methods. Out of the 47 ICD codes significant to decreased doctor insulin prescription (OR <1), 10 (21.3%) were not significant to AI prescription, suggesting AI has denied the association between some diseases and decreased insulin use. Some of these diseases may not be related to decreased insulin use, like embedded and impacted teeth (K01), which suggests AI’s capability in reducing impact of less related features. We also tried to figure out AI’s inherent logic in prediction after learning from doctors’ prescription. AI prescription identified 147 ICD codes associated with increased insulin prescription, and 97 ICD codes associated with decreased insulin prescription. This number is greater than in doctor prescription, indicating that AI is inflating the importance of features in prediction to make a greater distinction between different predictions. Diseases significant only in AI prescription are listed in Table 9. However, the interpretation of the results are complicated, which are discussed in the discussion section.

Figure 2: Characterizing ICD codes significant to doctor prescription of insulin and their corresponding significance in AI prescription. Odds ratios and confidence intervals of ICD codes that are significant to doctor prescription of insulin are plotted in A (odds ratio $>1$) and B (odds ratio $<1$). Each pink row represents an ICD code’s statistics, with the odds ratio plotted as a black dot and confidence interval plotted as a pink line. The blue line immediately below a pink line denotes the ICD code’s odds ratio (black dot) and confidence interval (blue line) in AI prescription of insulin. The red vertical lines represent the line of $x=1$. In A, confidence intervals beyond 75 are not explicitly plotted.

Discussion

Application of AI methods in clinical practices. While AI may never be able to act the role of human doctors completely, it can learn from doctors’ behavior to provide support for further actions. In this work, we present an effort toward learning doctor medicine prescription patterns. The potential application of such efforts in clinical practices is supporting doctors who have less experience, providing them with clinical decisions learned from other doctors’ experience. We are aware that a major critique of such AI methods is a lack of interpretability compared to clinical guidelines that can explicitly be formatted into a series of if-then rules.

Data quality. As mentioned in the introduction section, data quality is a limiting factor of the application of data-driven CDSS. Data quality issue in our work can be viewed from two perspectives. First, missing data. We encountered plenty of features with missing values in EHR. Mostly, we either imputed the missing values or discarded the feature. However, this is not a proper choice for features vital to drug prescription, blood glucose levels, for example. In our antidiabetic agent prescription problem, cases without blood glucose levels tested were discarded, resulting in extremely reduced number of cases. Second, it may be problematic to learn from doctors’ prescriptions without assessing effectiveness. The prescription of one doctor may not be proper, or may not be the only proper prescription. Some drugs may have highly overlapping functions and the choice is highly doctor-specific or hospital-specific. Under such circumstances, AI can hardly tell the differential use of the drugs. And unfairly in performance evaluation, the prediction of AI may be judged as wrong if it predicts a drug while the doctor used its counterpart.
Disease history as features for prediction. The use of demographics, physical examinations, laboratory tests and recent prescriptions in learning doctors’ prescription is less debatable as they are more or less self-evident. However, how to make use of disease history remains an open question. While many traditional studies pick only a few clinically relevant diseases in analysis, we include nearly all, benefiting from big data approaches’ merit of being able to learn feature importance and in the hope of finding hidden factors to better explain doctors’ behavior. Here we collapsed the ICD-10 code hierarchy to the first three characters since in real-life settings, the more detailed the ICD code goes, the less accurate it is. However, this collapse from the nomenclature point of view may not actually capture the hierarchy and relatedness of diseases, which, in itself, is a complex task. Moreover, since ICD-10 contains codes for not only diseases, but also signs and symptoms, abnormal findings, complaints, social circumstances, and external causes of injury or diseases, it is a rather mixed representation, which is currently not treated with special care.

Caveats of disease relevance to drug prescription. We have discussed about disease history relevant to insulin prescription in the results section. Several ICD codes were associated with increased or decreased insulin prescription either by doctor or by AI. However, the interpretation of the association should be made with caution. Some diseases associated with increased insulin use are potential complications of type 2 diabetes (N18: chronic kidney disease, and N19: unspecified kidney failure, for example), thus can be used as an indication of exacerbating disease condition and an indication of insulin use. Some diseases negatively associated with insulin use may not be a reason not to use insulin but a result of no previous insulin use. Taking elevated blood glucose level (R73) as such an example. Previous insulin use can decrease the onset of elevated blood glucose level, making the onset of it an indication of no previous insulin use and thus an indication of no insulin prescription. Some may have rather complex reasons. Vitamin B12 deficiency anemia (D51) is significantly correlated with decreased insulin use in both doctor and AI prescription. Existing studies have well demonstrated that long term metformin treatment increases the risk of vitamin B12 deficiency\textsuperscript{11}. This is also observed in our data that D51 is strongly associated with increased biguanides use (OR=12.88, 95% CI = [2.73, 60.76]). Besides, in our drug dependency study, use of biguanides decrease the use of insulin. These altogether lead D51’s association with decreased insulin use. As the same with all association studies, it is hard to infer causation from such results. After all, it is not necessary for big data analytics to know causation to infer decision.

Conclusion

In this paper, we use a multi-task neural network approach to learn doctor medicine prescription pattern of multiple correlated anti diabetic agents in blood glucose control and antihypertensive drugs in blood pressure control scenarios by mining EHR data. We have demonstrated that for single drug prescription, multi-task learning achieves 0.02 to 0.06 increases in AUC compared with logistic regression. In prescription pattern prediction, we achieved an accuracy increase of 0.05 in antidiabetic agent prediction, showing the efficacy of multi-task learning approach in learning doctor prescription patterns.

Predicting Changes in Pediatric Medical Complexity using Large Longitudinal Health Records

Yanbo Xu, MS¹, Mohammad Taha Bahadori, PhD¹, Elizabeth Searles, RN, MBA², Michael Thompson, BS, MBA², Javier Tejedor-Sojo, MD², Jimeng Sun, PhD¹
¹Georgia Institute of Technology; ²Childrens Healthcare of Atlanta

Abstract

Medically complex patients consume a disproportionate amount of care resources in hospitals but still often end up with sub-optimal clinical outcomes. Predicting dynamics of complexity in such patients can potentially help improve the quality of care and reduce utilization of hospital resources. In this work, we model the change prediction of medical complexity using a large dataset of 226K pediatric patients over 5 years from Children's Healthcare of Atlanta (CHOA). We compare different classification methods including logistic regression, random forest, gradient boosting trees, and multilayer perceptron in predicting whether patients will change their complexity status in the last year based on the data from previous years. We achieved an area under the ROC curve (AUC) of 88% for predicting non-complex patients becoming complex and 74% for predicting complex patients staying complex. We also identify the factors associated with the change in complexity of patients.

1 Introduction

Medically complex or fragile children need intense medical care due to multisystem dysfunction, technology dependence, or complex medication needs¹. It is estimated that children with special health care needs constitute about 18% (near 12.6 million) of all US children². Given the large portion of complex children in consumption of hospital resources³, the Institute of Medicine has identified Children with Special Health Care Needs (CSHCN) as a priority population for study⁴.

Medically complex pediatric patients consume a significant disproportionate amount of care resources in hospitals³. For example, Simon et al.³ report that complex patients “accounted for 8.9% of US pediatric admissions in 1997 and 10.1% of admissions in 2006. These admissions used 22.7% to 26.1% of pediatric hospital days, used 37.1% to 40.6% of pediatric hospital charges, accounted for 41.9% to 43.2% of deaths, and (for 2006) used 73% to 92% of different forms of technology-assistance procedures.” Advances on several fronts of research in medically complex children have improved outcomes, increasing survival rate and decreasing healthcare cost¹, 5.

With the massive amount of Electronic Health Record (EHR) data collected at Children’s Healthcare of Atlanta (CHOA), it is possible to develop predictive models to gain insights into underlying complexity risks. It is important to identify high risk patients who are rapidly becoming complex so that early intervention could be applied. Furthermore, identifying the key risk factors contributing to the complexity of the patients could lead to a better understanding of medical complexity.

Statistical models such as logistic regression have been used to identify the medical codes that are associated with complexity¹, 6–10. Often, manual features are also constructed to help the predictive analysis⁷. Logistic regression¹¹ and decision trees¹² have been used for quantifying the odds of readmission of medically complex patients. Performance for other machine learning algorithms such as methods based on sparse logistic regression and boosting have also been assessed for predicting readmission¹³, and more involved models such as hierarchical mixed-effects logistic regression models have been used to study contributing factors to medical complexity¹⁴.

In contrast to majority of the previous works which study the factors associated with being complex, in this work we study the dynamics of complexity in pediatric setting. That is, we develop predictive models to accurately forecast the change in complexity for children using a large EHR dataset from Children’s healthcare of Atlanta. To this end, we design two cohorts: (i) a dataset including patients that are initially not complex and either stayed non-complex or become complex, and (ii) a dataset with patients that are complex in the initial period. To formally quantify medically complexity, we use three criteria: (i) the clinical risk group’s definition of complexity (CRG level 5b or above), (ii) the hospital cost (top 5% high utilizers per year), and (iii) the number of specialities required for patients (3 or more...
specialities). We intuitively consider a patient complex if he or she satisfies all the above criteria.

Our methodology includes two steps to fulfill our prediction goal on the two cohorts. First, we use $L_1$ regularized Logistic regression to filter out irrelevant features and reduce feature dimensionality. Second, we apply four state-of-the-art predictive models, including logistic regression, random forests, gradient boosted decision trees, and multilayer perceptron. From our results, multilayer perceptron is found to be the best classifier (0.88) on cohort (i) in terms of ROC-AUC and random forest is found to be the best classifier (0.74) on cohort (ii). However, the gradient boosted trees method provides the best predictions on both cohorts (0.16 for (i) and 0.74 for (ii)) in terms of PRC-AUC, a metric that measures the accuracy in only predicting the change to complex status. Lastly, random forests gives the best $F_1$ score on both cohorts (0.56 for (i) and 0.67 for (ii)) by thresholding the predictive probabilities with 0.5.

For the rest of the paper, we will first describe the data collected from CHOA in Section 2, introduce our methodology in Section 3, report our results in Section 4 and finally conclude in Section 5.

2 Data

In this work, we analyze a large longitudinal EHR dataset from Children’s Healthcare of Atlanta (CHOA). We extract structured fields from the visit records in the dataset, which include various medical codes such as diagnosis, medication, and procedure. In total, the data consists of 951,885 patients with total number of 3,760,691 visits from year 2010 to 2015. Below we describe in details how we construct the cohort and the features for the purpose of our study.

2.1 Cohort Construction

We are interested in predicting the dynamics of medically complexity in patients. Specifically, we divide each patient’s visits into an observation window and a prediction window, then aim to predict if a patient who was not medically complex (MCP negative) in the observation window becomes complex (MCP positive) in the prediction window — and vice versa. Here, as shown on top of Figure 2, the prediction window is defined to be the 1-year duration before a patient’s last visit recorded in the data and the observation window is the 1-year duration before the prediction window.

![Figure 1: Medically complex patients defined within the observation window in the cohort](image)

We consider medically complex patients as the group of patients who have more serious health conditions, need more medical specialty services, and therefore incur higher medical charges. In the CHOA dataset, the severity level of a patient’s health condition can be captured by the pre-defined Clinical Risk Grouping (CRG) score, ranged in {1, 2, 3, 4, 5a, 5b, 6, 7, 8, 9} with higher orders denoting higher severity levels. For specialties, as listed in Figure 1(b), we only consider the 10 specialties that were evaluated by CHOA as essential services to Multiple Chronic Condition
Therefore, to construct the cohort, we include the patients who have at least one visit in the observation window and at least one record of CRG score, one visit of specialty and one hospital charge in both windows. As a result, we obtain a cohort containing 228,128 patients with total number of 2,150,256 visits.

**Figure 2:** Number of patients from the cohort in a 2-by-2 transition table of MCP status

**Definition of Medically Complex Patients:** Formally, we define medically complex patients (MCP) as the patients who have CRG $\geq 5$, number of specialties $\geq 3$, and total hospital charge $\geq$ $31,027$ (ranked in the top 5% for charges in the cohort) within 1-year windows. Figure 1(a) illustrates our MCP definition within the observation window. There are in total 5,094 MCP in the observation window and 5,378 in the prediction window.

In addition, Figure 2 shows the number of patients in the cohort that are contained in each group of MCP as they transition from the observation to prediction window. In summary, about 50% of the patients who were observed MCP positive become negative in the following year, and about 1.3% of the patients who were observed MCP negative become positive in the following year. More statistics of the cohort prior to the prediction window are summarized in Table 1.

**Table 1:** Basic statistics of the cohort.

$2.2$ Feature construction

We extract demographic features per patient and medical codes per visit from the data. Demographic features include age, gender and race, where gender is binary, race is categorical with 6 categories, and age is continuous valued by the index time (years since birth to the beginning of the prediction window). Medical codes recorded in the data include ICD-9 diagnosis codes, Current Procedural Terminology (CPT) codes and PHARMA CLASS medication codes that are provided by CHOA. In our cohort, there are total number of 4,497,616 medical codes recorded prior to the prediction window, including 1,521,956 ICD-9 codes, 1,934,116 CPT codes, and 1,041,544 PHARMA CLASS codes. For the sake of dimension reduction, we group the raw diagnosis and procedure codes by using the Clinical
Classification Software (CCS) codes. As a result, the total number of unique codes reduce from 8,643 to 9,49. We list the top 10 most frequent raw codes and group codes that were prescribed for the MCP positive and MCP negative respectively in Table 2. More basic statistics of the features prior to the prediction window are summarized in Table 3.

Further, we count the encounters of each CCS and PHARMA code per patient preceding the prediction window. Since, for each patient, most of the codes appear less than 100 times (shown as the blue line in Figure 3) and rarely appear more than 200 times, we transform the counts into $\log_{10}$ space (shown as the orange line in Figure 3) and group them into 15 bins ranging from $\log_{10}(1)$ to $\log_{10}(200)$. Using this transformation over the original counts gives us a prediction gain of 2% in terms of ROC-AUC in general for all the prediction methods we describe in the next section.
3 Methodology

Our analysis has two steps: we perform feature selection (Section 3.1) followed by prediction (Section 3.2). For implementation, we use the publicly available machine learning toolkit scikit-learn\(^1\) in Python.

3.1 Feature Selection

Feature selection—i.e., filtering out the irrelevant factors from the predictive analysis—is a common approach in data analysis procedures. An efficient feature selection algorithm not only helps with interpretability of the results by excluding spurious factors, but it also reduces the dimensionality of the input and allows us to run more complex predictive models.

Feature selection algorithms can be divided to two categories: (i) Univariate feature selection techniques rank the features based on their relevance to the target label using a non-parametric score such as mutual information. They allow us to select the top \(k\) relevant features using the ranked list. (ii) Multivariate feature selection techniques assume a multivariate regression model (e.g., logistic regression) and impose sparsity inducing regularization such as \(L_1\) regularization to allow only a small fraction of features to be included in the model. Multivariate feature selection is usually more accurate than the univariate approach as it performs joint feature selection and prediction; thus, the ensemble of features selected by the multivariate approach are often more predictive of the target.

In this paper, we use \(L_1\) regularized logistic regression for multivariate feature selection. We control the number of selected features by varying the regularization parameter \(c\) ranging from 0.001 to 1.

3.2 Prediction

Given the features selected, we investigate four classification methods for two prediction tasks: (i) predicting among all the regular patients who will become medically complex patients, i.e., the change of status from MCP negative to MCP positive/negative (Neg2(Pos/Neg)), and (ii) predicting among existing MCP patients who will stay MCP and who will become non-MCP, i.e., the change of status from MCP positive to MCP positive/negative (Pos2(Pos/Neg)).

We start with a simple generalized linear model Logistic Regression (LR) and two ensemble classification methods Random Forest (RF) and Gradient Boosting Decision Tree (GBDT). The ensemble methods fit a number of weak classifiers and classify a new patient by taking a (weighted) average of their predictions. These methods usually make better predictions than a single method, and result at better performance when the number of weak learners increases. However, a large number of weak learners can lead to over-fitting. In our setting, we set the number of trees in RF as 300 for both tasks, and in GBDT as 300 for the smaller task Pos2(Neg/Pos) and 800 for the much larger task Neg2(Neg/Pos). In addition, we use 3-fold cross validation to grid search the hyper-parameters used in each method. Particularly, we use gini importance as the criteria for RF splitting, and grid search min sample split in

\(^1\)http://scikit-learn.org/stable/
Figure 4: Feature selection using $L_1$-Logistic regression for the two prediction tasks. Only small number of features (252 for Neg2(Pos/Neg) and 73 for Pos2(Pos/Neg)) are sufficient to construct great predictive models \(\{3, 5, 15, 18, 20\}\) and \(\text{min samples leaf} \in \{2, 5, 7, 10, 15\}\); we use a \textit{learning rate} of 0.01 for GBDT, and grid search the \textit{max depth} in \(\{1, 3, 5\}\). Moreover, there exists imbalance problem in the task Neg2(Pos/Neg): only 1.3\% of the negative patients change to be positive in the prediction window. To address this, we adjust the class weights inversely proportional to class frequencies in the training data.

\textit{Multilayer Perceptron (MLP)} is another approach to increase the learning capacity of the logistic regression. It is based on stacking layers of linear transformation followed by a non-linear activation function (rectified linear units in our case). MLP is able to transform the input data multiple times and learn a form of input that allows more accurate prediction of the target label. For training the neural network, we use both dropout\(^{21}\) and batch normalization\(^{22}\) and train the network using the Adamax\(^{23}\) stochastic optimization algorithm.

4 Results

To evaluate our methodology, we randomly pick 90\% of the cohort as training patients and the remaining 10\% as test patients. For task Neg2(Pos/Neg), this results at 200,581 patients for training and 22,453 patients for testing. For task Pos2(Pos/Neg), it gives 4,580 patients for training and 514 patients for testing. We report the prediction results in terms of three metrics: Receiver Operating Characteristic (ROC) curves and its area-under-curve (AUC), Precision-Recall Curves (PRC) and its area-under-curve (AUC), and $F_1$ score with thresholding 0.5 on the predictive probabilities. We report PRC-AUC because the Neg2(Pos/Neg) task is extremely challenging due to the imbalance and PRC-AUC provides a better metric for evaluating predictions on the positive class.

\textbf{Feature selection.} We first plot the ROC-AUC scores obtained from LR, RF, and GBDT given different values of the regularization parameter $c$ used by the $L_1$-Logistic regression in Figure 4. The number of features that are selected given different $c$’s are also provided at the bottom of the figure. We can see that the prediction methods can achieve optimal performance on both tasks by only selecting a small number of features, that is 252 features for Neg2(Pos/Neg) and 73 for Pos2(pos/Neg). Moreover, we investigate the CCS diagnosis codes from the top predictive features that are selected for predicting Pos2(Pos/Neg) (see the biclustering heat map of Figure 6 in Appendix). There we observe several interesting diagnosis groups including metabolic disorders, immunity disorders, epilepsy, and cancer.

\textbf{Prediction.} We report the optimal accuracy results (ROC-AUC, PRC-AUC, and $F_1$) obtained from the four classification methods for the two tasks in Table 4. Overall, the three more complicated methods outperform the single linear method LR: MLP gives the best ROC-AUC score for predicting Neg2(Pos/Neg) and RF gives the best score for predicting Pos2(Pos/Neg); GBDT gives the best PRC-AUC score for both tasks; and RF gives the best $F_1$ score for the two tasks. More specifically, we plot the ROC and PRC curves respectively in Figure 5.

Figure 5: Prediction Results (ROC and PRC)

Different metrics provide different perspectives for different purpose of evaluations. ROC evaluates the performance of the classifier with its discrimination threshold varied. Specifically, it measures the trade-off between *true positive rate* (TPR, known as *sensitivity* and *recall*)—the rate of MCP positive patients correctly classified as positive—and the *false positive rate* (FPR, known as 1-specificity)—the rate of MCP negative patients incorrectly classified as positive. An ROC curve indicates better performance (reported as a larger area under the curve (AUC)) when the curve gets closer to the top-left corner. However, sensitivity and specificity individually measure the correct classification rate within each group of the positive patients and the negative patients, so combining these two measurements has ignored the information between the two groups. As a result, the ROC curve can still obtain a high AUC score even if the classification result is not precise enough. In such cases, PRC becomes a better metric. Especially, when the purpose of classification is focused on identifying the MCP positive patients, who occupy only a small portion of the cohort (e.g., 1.3% in the Neg2(Neg/Pos) task), PRC becomes a more useful metric. Specifically, PRC measures the trade-off between *precision*—the rate of the classified MCP positive patients actually labeled as positive—and the *recall*. A PRC curve indicates a better performance (reported as a larger area under the curve (AUC)) when the curve gets closer to the top-right corner. Lastly, $F_1$ score is a similar measure as *accuracy* that requires a threshold on the prediction probabilities, but instead it calculates an harmonic mean of *precision* and *recall*. 
Note that we obtain consistently high ROC-AUC scores for predicting the Neg2(Neg/Pos) task due to the heavily skewed data (98.7% of the cohort are labeled MCP negative). That is, even though all classifiers get much more false positives than true positives (therefore they get low PRC-AUC scores), the FPR becomes small after being divided by the large denominator; similarly the TPR becomes large after being divided by a small denominator (therefore they get high ROC-AUC scores). Thus, for evaluating the Neg2(Neg/Pos) task, PRC-AUC becomes more useful since it provides the precision in predicting the positive events.

5 Conclusion

We study the dynamics of medically complexity in children by applying machine learning techniques on a massive observational dataset collected at Children’s Healthcare of Atlanta. We formalize two prediction tasks: (i) predicting the risk of a non-complex patient becoming complex, and (ii) predicting the risk of a complex patients staying complex. We first use a statistical model to automatically identify important medical codes for the two prediction tasks, and follow up with a comparison of four state-of-the-art classification models for completing the prediction. We report the results using three different metrics that can be used for different purposes in evaluation and demonstrate that the four investigated methods can predict the dynamics of complexity with reasonable accuracy.

Abstract

We propose an approach to identify high health care utilizers using residuals from a regression-based health care utilization adjustment model to analyze the variations in health care expenditures. Using a large administrative claims dataset from a state public insurance program, we show that the residuals can identify a group of patients with high residuals whose demographics and categorization of comorbidities are similar to other patients but who have a significant amount of unexplained health care utilization. Additionally, these high utilizers persist from year to year. Correlation analysis with 3M™ Potentially Preventable Events (PPE) software shows that a portion of this utilization may be preventable. In addition, these residuals can be useful in predicting future PPEs and hence may be useful in identifying impactable high utilizers.

1 Introduction

The Agency for Healthcare Research and Quality (AHRQ) reports that in 2012, the top 10% of the health care-utilizing population accounted for 66% of overall health care expenditures in the United States. This highly disproportionate spending pattern frequently is interpreted as a sign of inefficient health care delivery. Furthermore, when such spending is driven by health care events believed to be avoidable, health care utilization is considered preventable and/or unnecessary. In this context, stakeholders have argued the need for higher efficiency health care for such patients, sometimes referred to as "high utilizers". For example, the deployment of managed care organizations (MCOs) and the capitation payments system in the United States public health programs provide incentives for health care providers to deliver services in a more cost-effective way.

The Centers for Medicare and Medicaid Services (CMS) recommends in their report that state Medicaid programs determine the extent to which expenditures driven by high utilizing populations represent impactable costs. Nationally, in 2010, potentially avoidable emergency department (ED) encounters accounted for $64.4 billion, 19.6% of ED episodes, and 2.4% of national health expenditures. As an example at the state-level, the Minnesota Department of Public Health found that nearly 1.3 million visits to hospitals in the state in 2012, representing nearly $2 billion in associated costs, could have potentially been prevented.

Most existing studies identify high utilizers based on the total number of visits or total expenditures or some combination thereof. While using such methods may be a relatively straightforward starting point for Medicaid programs with limited analytic resources, the approach can result in the inclusion of patient populations with health conditions unresponsive to efforts to reduce inappropriate spending. To illustrate the problem of relying on these criteria alone to identify impactable patient populations, consider the following examples. First, during flu season, elderly patients with little-to-no access to primary care may generate a large number of ED visits resulting in relatively inexpensive treatments. Second, patients with serious conditions, such as cancer or traumatic injuries, may require expensive medical treatments that are entirely appropriate and necessary.

An alternative cost-reduction strategy may involve more sensitive data-driven approaches that identify more impactable subpopulations of high utilizers even though they may not incur the highest absolute expenditures. We assume that this group of patients is "over-utilizing" the health care system because they spend more than their expected costs based on adjustments for health care-utilizing factors. Though clinical diagnostic classification tools such as the New York University ED profiling algorithm and 3M™ Potentially Preventable Events (PPE) are designed to improve
the ability to identify preventable or avoidable conditions, they have a number of limitations, including a limited population scope, lack of transparency due to commercial considerations, and others.

This paper proposes an approach to address such limitations. Briefly, using claims data typically available to state Medicaid programs, our data-driven approach calculates expenditure expectations for specific health care conditions and other measurable factors first; we then identify patients whose expenditures are higher (i.e. overutilization) than expected. The magnitude of overutilization is quantified by the degree to which cost residuals deviate from the model for each patient. Thus, those with higher residuals are hypothesized to represent potentially preventable high utilizers. Our models cannot account for all factors (e.g. genetic variations, socioeconomic status) expected to be predictive of health care utilization. However, we hypothesize that a non-trivial fraction can be potentially preventable.

Briefly, the key contributions of our paper are as follows:

- Using a large administrative claims dataset from a public insurance program with millions of patients and spanning for 4 years, we identify a best-fitting regression model to account for patients’ acute and chronic conditions loads and demographic characteristics.
- We identify populations with the highest deviations from expected after adjustment and examine their characteristics. Furthermore, we examine whether the model identifies patients that overutilize consistently through time. The results suggest that our approach identifies a significant proportion of health care costs that are consistent from year to year.
- We stratify the model by service settings (inpatient hospital, emergency department). In each setting, we compare our approach with an existing clinical tool, the 3MTM PPE.

The rest of this paper is organized as follows: In Section 2, we introduce the dataset and methods used for the study. Specifically, we find the best fitting model and define how residuals are used to identify high utilizers. Section 3 examines the demographics, clinical characteristics, utilization profiles and temporal consistency of the high-utilizing population. In Section 4, we compare the residuals approach with the 3MTM PPE tool. Section 5 concludes the paper.

2 Data and Methods

Study Population In this study, we use an administrative claims and encounter dataset from the Medicaid program of the State of Texas. As this is a repeated cross-sectional study, we set the inclusion criteria at a yearly basis. For each year from 2011 through 2014, we include adult (18-60 years old) Texas Medicaid beneficiaries, excluding pregnant women, with nonzero expenditures. The resulting size of the study population for 2011 to 2014 is 464572, 530242, 514601, and 535422 respectively. *

Data Preprocessing We normalize the health care expenditures to a per-member per-month dollar amount (total medical expenditure divided by number of months enrolled in Medicaid). This measure is commonly used for expenditure analyses in Medicaid programs12. To more meaningfully summarize the 21,374 unique diagnosis codes (International Classification of Diseases, Ninth Revision, Clinical Modification, ICD-9-CM) identified from the dataset, we group ICD-9-CM codes into 283 categories using AHRQs Clinical Classification Software13.

Model Regression-based adjustment models3 have been widely used in Medicare capitation payments as they systematically account for spending associated with specific health care conditions. Generally, we can write the model into the equation below:

\[ y = \beta x + \epsilon \] (1)

where \( y \), \( x \), and \( \beta \) represent expenditure, a vector of exogenous health care utilization factors and their linear coefficients respectively. If all the factors associated with health-care expenditures are exogenous, inclusion of these factors

*This study is approved by the IRB of the University of Florida.
would perfectly explain all the variations in health care expenditures except for a normally distributed error \( \epsilon \). If this is the case, the residuals, which are the observed error term \( \epsilon \) in (1), should follow the normal distribution. This is also an assumption of classical linear regression. If the residuals have a longer right tail than the normal distribution, we would expect that unmeasured factors are driving health care utilization. We set up the linear regression as specified in Table 1 to account for the patients’ health care conditions, demographics and health insurance plan differences. Note that we adjust for only the exogenous variables largely considered non-modifiable, such as health conditions, demographics, residence county, etc., but not for the endogenous variables like frequency of health care visits. We use ordinary least squares (OLS) to find the best fit for the health care utilization adjustment model (the model).

**Fitting the Model**  As described, the residuals analysis starts by setting up a model to account for exogenous factors. The models are highly significant for each year from 2011 to 2014 \((p < 0.001)\) for the \( F - test \). We also run multiple standard statistical diagnostics to check if the residuals meet the assumptions described previously.

We examine the distribution of our dependent variable and identify significant skewness. As a result, the residuals are not well aligned with the normal distribution as assumed (Figure 1a). Therefore, we log-transform the per-member per-month expenditure with base 10. Consequently, normality improves as shown in Figure 1b. Also, the R-squared of the model improves from 0.27 to 0.57 on average. Thus, all results discussed are based on the log-transformed model. This model shows a long tail on the right hand side, implying higher-than-expected value of residuals. We will later proceed to examine whether this represents potentially preventable utilization.

Although multi-collinearity is detected among the independent variables of the model, we retain all correlated variables in the model for the following reasons. First, our goal is not to interpret any individual independent variable or estimate its effects. Second, from the adjustment point of view, as long as the independent variables are not completely linearly correlated, we deem them acceptable for inclusion.

Heteroscedasticity also could affect the distribution of residuals. If strong heteroscedasticity exists among the patients, the high residuals could be those with error terms \( \epsilon \) of larger variances. We investigate the residuals versus predicted plot (Figure 2) and find that the residuals are distributed along the x-axis with similar variances. Although the Breuch Pagan test does suggest that heteroscedasticity exists \((p < 0.05)\), after we adopt the heteroscedasticity-consistent standard errors and re-run the model, it remains statistically significant. We conclude that heteroscedasticity is not a major issue for our dataset.

**Identifying the High Residuals Population**  We define an empirical threshold to discriminate the high residuals population from the rest of the patients. We select the residuals value as the cutoff threshold where the long tail begins to consistently deviate from the normal distribution. The process is described graphically on the Q-Q plot in Figure 3 based on our hypothesis that unexpected high utilizers are contained in the right long tail. In the following discussion, the term “high utilizer” always refers to the high residuals population.

Overall, we observe higher-than-expected total cost residuals on the right tail. We hypothesize that this may represent overutilization in the health care system and is worth investigating. We compare the high utilizer group to other patients using demographics, utilization patterns and overall chronic health condition burden using the Charlson Comorbidity

**Table 1: Model Specification**
Figure 1: Quantile-to-quantile plot (Q-Q plot) of standard normal distribution and 1,000 sample residuals obtained from the model for year 2014. In the left panel, the dependent variable, per-member per-month expenditures, is not transformed. Due to its strong skewness, the residuals significantly deviate from normal distribution. In the right panel, we log-transform the dependent variable with base 10 and re-run the model. The Q-Q plot better fits a normal distribution. The right and left ends are heavy-tailed, indicating over/under utilization.

Index. We examine temporal consistency using the following two-step process to test the Pearson product-moment correlation between residuals rank percentiles in different years from 2011 through 2014.

Step 1: Rank order all the patients in year 1 and year 2 based on residuals magnitude.

Step 2: Compute the Pearson product-moment correlation coefficient between the rank percentiles in the two years.

Stratified Model We stratify the adjustment model to specific service settings of inpatient hospital and emergency department (ED). For this purpose, in each setting, the study population is limited to those who had nonzero expenditures in the corresponding setting. In addition, we construct dependent variables based on the setting in which the expenditure occurred. Otherwise, our modeling approaches are the same as above. We compare our results with 3MTM PPE as a quasi-validation tool. To be specific, we examine if there are differences in PPE statistics between high residuals patients and all others. Also, we compute the Pearson correlation coefficient between PPE measures and residuals. Additionally, we test if the residuals are predictive for future PPEs.

3 Characterizing the High Utilizers

In this section, we take a closer look at the high residuals population. We first descriptively show their characteristics and then study their temporal consistency.

Demographics, Health Conditions, and Utilization For 2014, we summarize the demographics, health conditions, and health care utilization of high utilizers and other patients in Table 2. These results do not vary significantly by year. In terms of demographics, there are more male and Hispanic patients in the high-utilizer group. We use an integrated score, Charlson Comorbidity Index, to represent patients’ overall disease burden. The two populations vary little on this measure, which means the categorization of comorbidities is similar. Thus, we argue that there are no significant differences in demographics and categorization of comorbidities. This is not surprising because we expect the model to account for all these factors.

However, the levels of health care utilization in the two groups are completely different. In general, the high utilizer group has annual expenditures about four times higher than other patients, and they consistently have more expen-
ditures in each service category. The only exception is that high utilizers visit the ED less frequently than the other patients do. But because ED visits comprise a small fraction of high utilizers’ overall costs, ED expenses have less impact on the overall cost. In the next section, our stratified models examine costs incurred in the ED more specifically.

The findings in this section support our hypothesis that a group of patients whose demographics and comorbidities looks similar to other patients has a significantly higher amount of unexplained health care utilization.

Temporal Consistency of Residuals  
Next, we examine the extent to which this excessive utilization persists through time. Generally, if high unexplained variance occurs at random from year to year, then preventing such health care events would be extremely challenging. Otherwise, non-random correlation from year to year may suggest the persistence of health care-utilization factors that might be discoverable. To examine, we compute the Pearson product-moment correlation coefficient between the rank percentiles of residuals for any two subsequent years from 2011 to 2014, as shown in Table 3. Results show significant correlation between residuals from year to year. As expected, the correlation is strongest to the immediate subsequent year and decreases with time. The strong, significant correlation is visually well-represented as a dense diagonal on the scatter plot of rank percentiles of residuals of 2013 and 2014 in Figure 4. We observe an even stronger consistency for the high utilizers because the upper right area is denser. To be specific, the high utilizers of 2011, 2012 and 2013 on average rank 72%, 78% and 79% respectively in residuals percentile for the next year. In comparison, other patients has an average rank of 50%.

This correlation structure indicates that expenditures do not vary randomly from year to year and implies that unobserved factors drive high utilization. In conclusion, the subpopulation corresponding to the high residuals shows an excessive amount of utilization that is temporally consistent and driven by unknown factors.

4 Stratified Models by Service Settings

In the previous section, we have shown that the residuals indicate an unexplained high amount of health care utilization. Next, we examine whether this utilization is associated with preventable costs. The 3M™ PPE software identifies potentially preventable health care events in the inpatient hospital and ED settings. The software is proprietary but its validity has been verified and widely accepted. In this section, we examine the correlation between the 3M™ PPE approach and our own. 3M™ Potentially Preventable Readmissions (PPR) Grouping Software identifies clinically

Figure 2: Predicted versus residuals plot for 2,000 observation random sample for 2014. No obvious heteroscedasticity is observed from the plot.

Figure 3: Decide threshold of high utilizer from Q-Q plot: The red dashed line indicates where the long right tail of residuals consistently deviates from the normal distribution quantiles. The analysis identifies 10,121 high utilizers for 2014.

related and potentially preventable inpatient hospital readmissions. 3M\(^{TM}\) Potentially Preventable Emergency Visits (PPV) Grouping Software identifies ED visits that relates to ambulatory-sensitive conditions and may result from lack of access to primary care. Thus, we can identify potentially preventable utilization in two important service settings, inpatient hospital and ED. We modify the dependent variable to reflect expenditures incurred only in those settings. By comparing the PPE statistics and resulting residuals from the stratified model, we examine our hypothesis that our approach can effectively identify preventable health-care utilization.

### Residuals and Potentially Preventable Readmissions (PPR)

Table 4 presents the PPR statistics for the high utilizer group versus other patients. The high utilizer group has a significantly (MannWhitney U test, \(p < 0.05\)) higher amount of PPR events and PPR expenditures than all others. The difference is consistent from 2011 to 2014. This suggests that the high residuals are associated with a substantial amount of potentially preventable hospitalizations. The Pearson correlation coefficients between the residuals and PPR expenditures tell the same story. PPR expenditures are log-transformed to scale with the residuals. We compute the correlation coefficient with the residuals obtained from the stratified model using inpatient hospital expenditures as the dependent variable, as shown in Table 5. The correlation is always significant through the years, suggesting a strong association between residuals and PPRs.

Figure 4: Scatter plot of rank percentiles of residuals: 2013 and 2014.

(a) Scatter plot for overall population

(b) Scatter plot for high utilizers

Residuals and Potentially Preventable Emergency Department Visits (PPV) We replicate the analysis for potentially preventable ED visits. The population is limited to patients with nonzero ED expenditures. The dependent variable is changed to per-member per-month ED expenditures and log-transformed. The statistics of PPVs of high utilizers versus other patients are presented in Table 6. The correlation test results are shown in Table 5. All results imply that the residuals also identify a significant amount of preventable ED utilization. However, comparing the level of differences in mean statistics in Table 4 and 6, the relationship for PPVs and residuals is weaker compared to PPRs and residuals. This generally makes sense because ED visits are more incidental than inpatient hospital visits.

Residuals and Future Potentially Preventable Events In Table 4 and 6, we also show the PPR and PPV statistics for the year following the year from which we compute the residuals (index year). Although the differences in PPR and PPV utilization amounts between high utilizers and other patients are narrowed from the index year, the high-utilizers group still has significantly more PPRs and PPVs, as well as associated costs. The correlation coefficients of the next year in Table 5 also indicate a decreased but still sizable temporal correlation. Thus, the residuals are also good predictors for future PPRs and PPVs. This finding is consistent with the strong temporal correlation of residuals we present in the previous section.

To summarize the section, using the 3M™ PPE software, we have demonstrated that the residuals from the models, when stratified to inpatient hospital and ED settings, are strongly associated with potentially preventable utilization of

the same year as well as the next year, implying promising potential to identify impactable high utilizers.

5 Conclusion and Discussion

In this paper, we propose a novel approach to analyze variations in Medicaid health care expenditures based on using higher-than-expected values of the residuals from health care utilization adjustment models. We conducted our analyses on a large administrative claims dataset from a state public insurance program. Our approach identifies a

significant amount of unexplained health care utilization. This utilization fraction is shown to be largely preventable as it produces results similar to the 3MTM PPE software. Thus, other state Medicaid programs could potentially use this approach to identify impactful high utilizers and possibly reduce inappropriate health care spending.

This study is limited in several dimensions. First, though our model tries to include a large number of exogenous variables in the claims dataset, it is not comprehensive. For example, important variables that contribute to health care expenditures, such as health condition severity measures, are missing. The residuals we obtain from our current model are likely to be affected by these unadjusted exogenous variables. Second, we have not conduct case studies to follow up on specific clinical details about the high utilizers. Such an investigation could reveal more information about clinical factors contributing to the variation. Third, though the residuals prove to be highly associated with potentially preventable utilization, they do not point to specific pathways to inform policy. Thus, to impact high utilizers, we need to decompose the residuals and identify the source of variation.

Our future work will try to address these limitations. We will gather more data, such as social determinants of health, to adjust as many exogenous factors as possible. We also plan to conduct medical record reviews with clinical and health care policy experts to identify components of care that could be addressed to reduce preventable utilization. More importantly, we will extend this exclusively data-driven approach into an iterative process16 between health care practitioners and informatics researchers to better understand impactable health care conditions and progress toward interventions to reduce inappropriate health care utilization.

Abstract
Cancer stage information is important for clinical research. However, they are not always explicitly noted in electronic medical records. In this paper, we present our work on automatic classification of hepatocellular carcinoma (HCC) stages from free-text clinical and radiology notes. To accomplish this, we defined 11 stage parameters used in the three HCC staging systems, American Joint Committee on Cancer (AJCC), Barcelona Clinic Liver Cancer (BCLC), and Cancer of the Liver Italian Program (CLIP). After aggregating stage parameters to the patient-level, the final stage classifications were achieved using an expert-created decision logic. Each stage parameter relevant for staging was extracted using several classification methods, e.g. sentence classification and automatic information structuring, to identify and normalize text as cancer stage parameter values. Stage parameter extraction for the test set performed at 0.81 F1. Cancer stage prediction for AJCC, BCLC, and CLIP stage classifications were 0.55, 0.50, and 0.43 F1.

Introduction
Cancer staging is the categorization of the severity of cancer progression based on patient and disease characteristics. Clinically, cancer stage can be used to determine the most appropriate treatment option or to predict prognosis. In research, cancer stage facilitates outcomes analysis by allowing comparisons between patients with similar severity of disease. Numerous stage classification schemes may exist for each cancer type and are sometimes quite complex. Further, cancer stages are not reliably recorded in the electronic medical record (EMR) in either structured or unstructured form [1]. Even when collected, the accuracy of recorded stages may be incomplete or inaccurate [2–6]. Automatic classification of staging has many benefits in cancer research. A successful system would circumvent the need for separate data abstractors to perform work that is resource-intensive, expensive, and error-prone. An automatic system would be scale-able to large volumes of data. Free text narrative is the preferred modality of choice in the clinical setting and an automated system would give the benefits of classifying patients into cancer stages without altering clinical workflow. Additionally, an automatic classification system could be deployed to assign stage using multiple staging systems or could be adapted for changes in staging systems.

This study focuses on automatic cancer stage classification for hepatocellular carcinoma (HCC), also known as primary liver cancer, using free-text clinical and radiology notes and four laboratory values. The three HCC staging systems we used, American Joint Committee on Cancer (AJCC), Barcelona Clinic Liver Cancer (BCLC), and Cancer of the Liver Italian Program (CLIP), depend on a mixture of tumor characteristics, e.g. tumor size, assessment of liver dysfunction, e.g. ascites, and patient characteristics, e.g. performance status, as factors in its staging algorithms [7]. The purpose of this study was to extract each of those factors in the staging algorithms and use that information to classify cancer stages.

Background
There are more than six different liver cancer staging systems world-wide, reflecting various ways to assess liver function as well as cancer spread [7]. We pooled the common factors used for the staging of the three commonly used staging systems (AJCC, BCLC, and CLIP) and provide common categories for each parameter that can be used to calculate the final stage classifications. A brief description of each stage classification system and the final stage parameter follows. Figure 1 shows an example of how stage parameter values translate to a stage classification for BCLC.

Figure 1. Example of stage parameters used for BCLC staging

1841
Stages

AJCC has classifications (I, II, IIIA, IIIB, IIIC, IVA, IVB) and is based on the TNM stage framework that primarily addresses tumor characteristics and spread (tumor size, number, metastasis) but not liver functioning statuses.

BCLC has classifications (A1, A2, A3, A4, B, C, D) and is the only staging scheme that takes into account overall patient performance status, using Eastern Cooperative Oncology Group’s (ECOG) classification system.

CLIP has classifications (0, 1, 2, 3, 4, 5, 6) and is the only staging scheme that takes into account the relative size of the tumor to the liver. This stage classification takes into account alpha fetoprotein level, a lab value.

Stage parameters

Ascites: accumulation of fluid in the peritoneal cavity (e.g., “no significant ascites”, “does not endorse abdominal swelling”) with values (None, Mild, Moderate-Severe)

Child-Pugh: a measurement of liver cirrhosis severity (e.g., “Child’s B”, “his CTP score would be 5”) with values (A, B, C)

ECOG (Eastern Cooperative Oncology Group) Performance Status: a scaled measure of general well-being where 0 is fully active and 5 is dead (e.g., “ECOG 0”, “She notes good energy”) with values (0, 1, 2, >=3)

Extrahepatic invasion: direct spread of cancer outside of the liver (e.g., “No evidence of extrahepatic extension”, “the tumor may […] extend from the liver to the right ribs or muscular wall”) with values (No, Yes)

Hepatic encephalopathy: confusion or altered consciousness attributed to liver cirrhosis (e.g., “patient denies confusion, forgetfulness, or other symptoms of hepatic encephalopathy”, “lactulose” in the medication list) with values (None, Mild, Severe)

Macrovascular invasion: spread of cancer to nearby blood vessels (e.g. “vascular invasion: possible involvement of middle hepatic vein branches”, “no evidence of portal vein thrombosis”) with values (No, Yes-minor branch, Yes-major branch)

Metastasis: spread of cancer to outside the liver, such as to lymph nodes (e.g., “lymph nodes suspicious for metastatic involvement: none”, “no lymphadenopathy”) with values (No, Yes-regional, Yes-distal)

Portal hypertension: elevation of hepatic venous pressure gradient to greater than 5 mm Hg (e.g., “no evidence of cirrhosis or portal hypertension”, “patient had an endoscopy which showed small varices”) with values (No, Yes)

Tumor morphology: number and size of tumor relative to the liver (e.g., “small segment 7 hepatic mass”, “two new liver lesions noted […] suggesting hepatomas”) with values (Massive >= 50% of liver, Multinodular < 50% of liver, Uninodular < 50% of liver)

Tumor number: number of liver tumors (e.g., “1 lesion measuring 2.1 x 1.7 cm […] HCC”) with values (<3 cm, 3-5 cm, >5 cm).

Though many stage parameters factor into the stage classifications of at least two staging systems, some parameters are specific to a single staging system. For example, BCLC is the only system that incorporates ECOG, meanwhile only CLIP uses tumor morphology. It is also important to note that classification decisions for a stage category may depend on only a single stage parameter, or at other times many stage parameters. For example, in BCLC staging, an ECOG score of 3 automatically places the patient in Stage D regardless of other variables.

Related work

There are few published work in automatic cancer stage classification from free text reports where stages are not explicitly written. Several systems that do exist include the lung cancer staging work by Nguyen et al. [8,9] and McCowan et al. [1] and the prostate cancer staging from pathology notes by Martinez et al. [10,11]. The most evolved systems required division of classifications to handle several stage parameters, mixed method modalities (e.g. sentence versus document classification), and some rules. For example, McCowan et al. [1] classified sub-stages for Tumor-Node-Metastasis (TNM) staging from least to most severe, e.g. classifying for T0 before T1 and so on. Most of these classifications were sentence classifications with two steps, the first for relevance to the sub-stage (yes or no for T0) the second to identify positives. In Nguyen et al. [9], concepts were identified and normalized through the Systematized Nomenclature of Medicine - Clinical Terms vocabulary with stage classified through symbolic logic rules. Martinez et al. [10] used a sentence classification for numeric stage parameters and a document classification for nominal stage parameters for TNM staging and Australian clinico-pathological staging (ACPS) staging. Other works focus on identifying and structuring specific aspects of cancer information, which could be used for cancer staging after processing [11–14]. Cancer stage classification, in the cervical cancer domain, from structured data using neural network methods have also been explored [15,16].
To our knowledge, this is the first reported system developed for HCC staging. HCC staging presents unique challenges in that staging parameters require incorporation of free-text derived from multiple data sources, including radiology reports, clinic visit notes, and laboratory results. Further, some staging systems such as BCLC require derivation of parameter values for complex concepts such as severity of hepatic encephalopathy. This work is unique in its integration of multiple text extraction systems with component- and application-level evaluations.

**Methods**

**Creation of a gold standard**

Our proposed methods sought to use several information extraction methods to identify and normalize free text to each stage parameter and its severity, e.g. *ascites - mild*. Afterwards, the patient value for each stage parameter would be determined and used to classify final patient-level stages for each staging system. In order to train and evaluate these extraction techniques, we needed to create a gold standard incorporating text level and patient level annotations.

**Dataset**

Following Institutional Review Board approval, a retrospective cohort was drawn from new patients visiting the University of Washington Medical Center liver cancer clinic from 1/2011-12/2013. Data for each patient comprised of: (1) all clinical notes from the day of clinic visit (2) all laboratory results within 30 days prior to and following the visit day, and (3) radiology reports within 3 months prior to and 1 month following the visit day. This study focused on the subset of patients that had at least one clinical report, at least one radiology report, and the full set of laboratory results needed for staging (Albumin, Alpha Fetoprotein, Bilirubin, Prothrombin INR). After manually excluding patients with irrelevant diagnosis, the final dataset included 200 patients with 545 documents.

**Annotation**

During annotation, text evidence was identified and normalized to stage parameters and patient-level stage parameter and stage values were identified and labeled. This corresponded to roughly two annotation phases. Phase I consisted of text annotation, similar to those shown in Figure 1 in which parts of text were highlighted and assigned to a stage parameter label and value.

![Figure 2. Text annotation](image)

![Figure 3. Patient-level annotation. Highlighted text from Phase I annotations appears in the left panel, where as laboratory values appear on the right panel. Annotators choose the patient-level 11 stage parameters and 3 stage classifications with the drop-down menu buttons on the bottom panel.](image)
We used a sparse annotation approach in which annotation of the repeated information within a document were omitted. The exact rules for which text to mark were specified in annotations guidelines (phekb.org/phenotype/568). Phase II consisted of patient-level annotation, shown in Figure 2, in which patient-level stage parameter and stages were marked. Patient-level annotations were performed by the consensus of two HCC domain experts. The relevant stage parameter and stage description and values were described previously. Figure 1 illustrates how stage parameters can be used to calculate BCLC stage. Phase I annotation agreement was at 0.73 F1 for partial text overlap and 0.91 F1 at the patient level. Phase II annotations were done in consensus therefore annotator agreement is not applicable. The details of this annotation may be read in a previous paper [17], however we will emphasize several subtle points of interest here.

Firstly, Child-Pugh and ECOG are themselves stages. Child-Pugh is a classification for liver cirrhosis with values that range from A-C; ECOG is a classification for general well-being with values that range from 0-4. Both require multiple sets of criteria in their staging algorithms. We define explicit text evidence as those text clues that do not require using the Child-Pugh or ECOG staging calculations to arrive at the proper normalization, e.g. “Patient is Child-Pugh A”. Non-explicit Child-Pugh stages were not annotated, but they were calculated from ascites and hepatic encephalopathy (both text stage parameters) as well as 3 laboratory values, according to the logic of Table 1. Meanwhile, non-explicit ECOG stage evidence, e.g. “patient is confined to a wheelchair”, were annotated with explicit ECOG. Secondly, the tumor-related stage parameters may sometimes be clearly written as text, e.g. “1 lesion suspicious of HCC, 6.0 cm”, however, oftentimes this is not the case. In fact, taking the radiology report extract from Figure 4 as an example, only after reading the full report can we ascertain that tumor morphology Uninodular and < 50% of liver of the liver, there is a single malignant tumor, and the tumor size is <3 cm.

Finally, while some of the text evidence of the stage parameters may be more explicit, e.g. “no ascites”, this is not always the case. Often medical knowledge or inference is required. For example, some “free fluid” in the abdomen, by definition, is considered ascites-mild. The medication “lactulose” implies hepatic encephalopathy – mild, as it is used to treat this condition. Macrovascular invasion requires reasoning not only about whether a tumor invaded blood vessels but also whether or not said blood vessels are considered major or otherwise. Signs and symptoms can also give clues regarding certain conditions, for example “no lymphadenopathy” (enlarged lymph nodes) implies there are no signs of local metastasis – though the converse is not true; enlarged lymph nodes does not imply that there is metastasis, regional or distal.

Training and test sets were separated according to a 160/40 patient split. A subset of 101 radiology reports, randomly sampled from the training set, was further annotated for tumor-related entity and relations, reference resolution, and tumor characteristics to train a tumor characteristics extractor, which is described previously [18].

### System design

Stage parameter text evidence passages were identified from documents using one of three ways: (1) a two-step regular expression extraction module, (2) a sentence classification module, and (3) a tumor characteristics extraction module. Then (3) the patient-level stage parameters were determined using a rule-based heuristic. Finally, (4) the stage classifications were labeled using a rule-based expert logic. Figure 5 shows a diagram of the system and each subsystem are described in the following sections.

---

**Table 1.** Child-Pugh score. Each variable is given points depending on the patient condition. The sum from each variable is used to calculate Child-Pugh according to the following mapping. 5-6 points: Child-Pugh A, 7-9: Child-Pugh B, and 10-15 points: Child-Pugh C.
(1) Two-step regular expression extraction module:
This module was used to find text evidence for Child-Pugh class and ECOG parameters from clinical notes. The two-step regular expression extraction module was used to find explicit Child-Pugh and ECOG stage parameter text evidence only. The first step regular expression identifies a trigger term, e.g. “Child-Pugh” or “ECOG”. Once a trigger term had been identified, a second regular expression looks at the remaining part of the sentence for a stage cue, e.g. the “6” in “Child-Pugh score 6”, and maps it to the appropriate stage value, e.g. “A”.

(2) Sentence classification module:
Six stage parameters label and values (ascites, extrahepatic invasion, hepatic encephalopathy, macrovascular invasion, metastasis, and portal hypertension) were identified and normalized to the described predetermined categories using a sentence classification method. The sentence classification applied a multi-label classification approach. Features included 1-, 2-, 3-grams, their asserted versions (whether or not the term is negated, probable, etc), and asserted UMLS concepts, identified using MetaMap [19,20]. For example, in “Ascites: None”, a 1-gram “ascites” feature would be accompanied by “[NEGATED]-ascites” and “[NEGATED]-[UMLS:C0003962-ascites]”. We employed statistical feature selection using several measures: t-test, chi-squared, and point-wise mutual information for the n-grams and asserted UMLS concepts. A configurable number, N, was used to select the top scoring features. Only those features associated with the top N significant values for 1-, 2-, and 3-grams (with its asserted values) and asserted UMLS concepts were used as final features in a maximum entropy classifier. This module was applied to clinical notes for hepatic encephalopathy, to all note types for ascites, and only to radiology notes for remaining parameters.

(3) Tumor characteristics extraction module:
Because the stage parameters tumor morphology, tumor size, and tumor number required reasoning over the entire report, we needed to build a separate module that processed radiology reports. The overall sub module is represented in Figure 6. First template extraction, which identifies tumor-related entities, attributes, and relations, was

---

**Figure 5.** System design

**Figure 6.** The tumor characteristics extraction module does several processing steps, before distilling information to the tumor morphology, size, and number stage parameters.
performed on the Findings or Impression section of each radiology report. Entities were identified through a conditional random field (CRF) entity extractor. Relations and attributes were identified using a maximum entropy relation classifier [18,21]. Sections were identified using our statistical in house section identifier [22]; we used CRFSUITE [23] for CRF classification and MALLET [24] for maximum entropy classification.

Tumor reference resolution was performed to identify coreference cases and parent-child cases of tumor mentions. Using the above elements and reference resolution information, a rule-based characteristic annotator classified documents for whether 50% of the liver was invaded, the largest tumor size, and the number of tumors represented in a report. A rule-based transformation outputted the final values for tumor morphology, size, and number. This is described in more detail in another paper [25].

(4) Patient-level stage parameter classifier:

Patient-level stage parameter classifications were determined using a simple heuristic: given text evidence for stage parameter labels and values, choose the most severe case. For example, if there were mentions of both Child-Pugh A and Child-Pugh B, the patient value was assigned to Child-Pugh B. If no values were mentioned, the patient’s value defaulted to the least severe value. Child-Pugh values were taken from explicit regular expression extraction, as well as a rule-based calculation of Child-Pugh using ascites and hepatic encephalopathy text evidence.

(5) Patient-level stage classifier:

Lookup tables were created that accounted for all stage parameter combinations. Ambiguous guideline cases were adjudicated by an interventional radiology expert. Our rule-based patient-level stage classifier used the logic stored in our lookup tables for stage classification.

Training for (1) and (2), (all stage parameters except tumor morphology, tumor number, and tumor size) were performed with 5-fold cross validation of the 160 training patients. Training for tumor-related stage parameters were performed on the 101 radiology reports randomly sampled from the training set, then applied to the entire corpus.

Performance evaluation

We implemented several baselines for text extraction (1)-(3), the patient level stage parameter classification (4), and for patient level stage classification (5) evaluation. Since these baselines were used as intermediate evaluations for building the final system classification algorithm, they were only applied on the training set in cross-validation.

Text extraction baseline: We used a previously published document-level classification baseline, which used the same five-fold validation splits here, to compare text extraction results [17]. (Because of our sparse annotation, it was not appropriate to use a sub-document evaluation as baseline.) The baseline consisted of the best out of five machine learning classifiers (c4.5 decision tree, binary decision tree, maximum entropy, naïve bayes, and support vector machine) using lower-cased unigram, bigram, and trigram counts after tokenization and punctuations removed. The classification was a binary value {positive, negative} value for each label and value, e.g. ascites-none.

Patient level stage parameter and stage classification baselines: To evaluate against the simple patient-level stage parameter text evidence to patient-level classification (4), the baseline labels every instance with the most prevalent class (if ascites-none appears the most frequently in training, label all patients with this class). Patient level stage classifications (5) were measured against two baselines: a straight classifier the uses the most prevalent class (B1) and a maximum entropy 1-, 2-, 3- gram, and UMLS concepts document classifier with frequency features (B2).

Results

Table 2 shows the results for the regular expression, sentence classifier, and tumor characteristics extraction modules resolved for the document-level for the training and testing sets, where TP=true positive, P=positive, R=recall, F1= 2*P*R/(P+R). Reflecting the complexity of stage parameters, expectedly, the regular expression variables (Child-Pugh and ECOG) were the best-performing, whereas tumor-related parameters were the least. Table 3 shows the performance of the rule-based stage parameter aggregation heuristic against the majority class classifier baseline.

Patient-level stage classifications are shown in Table 4 for the 3 staging schemes, with the majority class classifier baseline (B1) and document classification baseline (B2). Relaxing evaluation where sub-stages are merged, e.g. AJCC stage IVA and AJCC stage IVB are mapped to AJCC stage IV, the relaxed system performance for training was at 0.68, 0.69, 0.55 F1 for AJCC, BCLC, and CLIP training, and 0.60, 0.50, and 0.43 F1 for test.

In addition, we include a sensitivity analysis (Table 5) in which each patient-level stage parameter was substituted with the gold-standard value and the impact on F1 score was assessed. Performance increases in vital cancer parameter (e.g. metastasis, macrovascular invasion, tumor morphology, tumor number, tumor size) substitutions led to overall improvements in the F1 scores, (e.g. CLIP, tumor morphology improves +0.19 and +0.37 F1 for train and test). We also show the results of the opposite substitutions, where gold-standard values of stage parameters were
used excepting one patient-level system value. Tumor morphology and number were shown to degrade stage classifications the most (e.g. CLIP, tumor morphology degrading by -0.31 and -0.42 F1 for train and test).

Table 5. F1 stage classification results with sensitivity analysis. Stage parameter columns represent substitution with 1 gold/system standard with otherwise 10 other system/gold stage parameters used to calculate stage).

Error analysis

(1) Two-step regular expression extraction module:

The largest challenge with the regular expression module were hedge cases. For example, in “child-pugh score of 6 or 7” only “child-pugh 6” is captured, but “child-pugh 7” is not, though labeled in the gold standard. This similarly occurred for ECOG, such as in “ECOG 0-1”. The effect of these would cause underestimation of liver cancer stage. Child-Pugh errors included non-capitalized version of “child” such as in text evidence “child a”. We also miss cases for ambiguous acronyms such as “CPA”, which may stand for “cardiopulmonary arrest”, or “childhood physical abuse”. ECOG errors were mainly due to non-explicit evidence, e.g. “He [...] needs a wheelchair to walk”.

(2) Sentence classification module:

The sentence classification module had the most problems with lowly populated subcategories such as ascites-moderate/severe, as these categories often simultaneously had the most variation. For example, there are relatively fewer ways to say “no” in “no ascites” or “ascites none” compared to adjectives for severe cases such as “gross”, “extensive”, or “refractory”. In macrovascular invasion, the two other populated cases had more semantic variations expressing the blockages of blood vessels, e.g. “involvement”, “infiltrated”, “distending” or “occluded”. Disambiguation between variations and word-orders was another hurdle for normalize between major and minor blood vessels, e.g. “the portal vein” versus “superior mesenteric vein” or “anterior branches of the right portal vein”, which was necessary for classifying between macrovacular yes-major or yes-minor. Another problem was with correlated concepts. For example, though “diuretics” and “cirrhosis” are related to ascites (the former is used to treat, the latter is a cause of it), they are not exact surrogates to ascites. Other challenges include evidence that
relies on more complex inferences. For example, “he only complains of mild, occasional confusion” or “has well-compensated cirrhosis […] has not had any significant complications” informs about hepatic encephalopathy (mild in the first case, none in the second case).

(3) Tumor characteristics extraction module:
Several transformations were required for tumor morphology, tumor number, and tumor size factors, which allowed several opportunities for error introduction, e.g. errors due to relation classification or reference resolution, etc. We found the most challenging piece was the need for reference resolution. For example, determining the number of malignant tumors for tumor number requires reasoning over multiple sentences to, firstly, identify the malignancy status of each tumor and to, secondly, sum unique mentions of the same tumors. Tumor morphology, which depends on both determining the number of tumors and if >50% of the liver is invaded, was limited by the poor performance of ascertaining tumor number. Tumor size required automatically identifying which tumor mentions in radiology reports were malignant, which may not be expressed in a single sentence, before finding the maximum size.

(4) Patient-level stage parameter classifier:
Given the automatic annotations resulting in the previous extraction systems, there were several options to arrive at patient-level stage parameter values, such as taking the highest frequency versus highest value. For our system, we used the simple heuristic of taking the most severe finding for each category. Lower performance with gold-standard annotations of ECOG is because experts preferred to take least severe values during disambiguation.

(5) Patient-level stage classifier:
Using gold-standard annotation inputs for stage parameters for stage classification, we found performances of 0.98, 0.97, 0.96 F1 for AJCC, BCLC, and CLIP stages respectively. This signals that our rule-based algorithm was highly accurate. Unfortunately, cascading errors from upstream modules led to significant degradation of performances. Reviewing the sensitivity analysis in Table 6 reveals that improvements in certain stage parameters led to large gains in stage classification. For example, tumor number and tumor morphology were simultaneously crucial cancer stage parameters and were the most challenging stage parameters. Substituting gold-standard annotations for these classifications, performance improved tremendously. Conversely, errors would drop significantly after substitution of system values.

Conclusions
HCC staging is a complex task that requires reasoning over multiple sources for and with many variables. This work (1) systematically identifies information extraction subtasks for overall patient stage prediction, such as with stage parameter normalization; (2) provides several classes of solutions to identify and normalize stage parameters and stage patients, for example sentence classification vs. regular expression; and (3) characterizes challenges to the problem, most salient of which were reference resolution and patient-level classification. We have shown that several modules performed well, e.g. Child-Pugh and portal hypertension extractions and patient-level stage parameter prediction. Limitations of this work include that the data came from a relatively small group of patients from a single institution. Because some parts of the system included hand-crafted heuristics, our models and overall algorithms may not be generalizable to other datasets. Inclusion of other centers’ data would address unwarranted over-training of our algorithms for this particular study. Our data was skewed towards patients in the early and intermediate stages as patients with late stages were less likely to be referred for treatment. The strength of this work includes is trace-ability and modular design. We envision applications of this algorithm to support accelerated staging by highlighting supporting evidence in text and outputting classifications along with the uncertainty of its predictions. Human reviewers, given highlighted information, may then review uncertain classifications. Additional labeled data and improvements in various components, in turn, will lead to improvements in the overall system. In this work, we contributed insights into various issues with complex patient phenotype classification using primarily text data. Future work includes expanding the dataset and testing our algorithms on other institution datasets.

Talking About My Care: Detecting Mentions of Hormonal Therapy Adherence Behavior in an Online Breast Cancer Community

¹Vanderbilt University, Nashville, Tennessee, USA

Abstract

Hormonal therapy adherence is challenging for many patients with hormone-receptor-positive breast cancer. Gaining intuition into their adherence behavior would assist in improving outcomes by pinpointing, and eventually addressing, why patients fail to adhere. While traditional adherence studies rely on survey-based methods or electronic medical records, online health communities provide a supplemental data source to learn about such behavior and often on a much larger scale. In this paper, we focus on an online breast cancer discussion forum and propose a framework to automatically extract hormonal therapy adherence behavior (HTAB) mentions. The framework compares medical term usage when describing when a patient is taking hormonal therapy medication and interrupting their treatment (e.g., stop/pause taking medication). We show that by using shallow neural networks, in the form of word2vec, the learned features can be applied to build efficient HTAB mention classifiers. Through medical term comparison, we find that patients who exhibit an interruption behavior are more likely to mention depression and their care providers, while patients with continuation behavior are more likely to mention common side effects (e.g., hot flashes, nausea and osteoporosis), vitamins and exercise.

Introduction

Breast cancer is the most prevalent cancer among American women¹ and the second leading cause of death among women with cancer (just behind lung cancer)². It is estimated that close to 12% of American women will eventually develop invasive breast cancer during their lifetime³. A common initial treatment for breast cancer is surgical intervention (e.g., lumpectomy or mastectomy), while adjuvant therapy (i.e., treatment after surgical intervention) is often invoked to reduce the risk of cancer recurrence⁴. In particular, hormonal adjuvant therapy is a popular treatment with a proven track record of significantly improving the long-term survival rate of patients with hormone-receptor-positive breast cancer⁵. This is notable because this disease subtype comprises 75% of all breast cancer cases¹. To maximize this benefit of hormonal therapy, patients are prescribed a regimen of medication that is expected to continue for a minimum of five years⁶. For instance, taking tamoxifen (an oral hormonal therapy drug) for five years reduces breast cancer mortality by 33% in the decade after initial treatment⁷. Moreover, more recent evidence⁸ suggests that maintaining a tamoxifen regimen for an additional five years can further reduce mortality by approximately 50%.

Despite the benefit of hormonal therapy for women, only around half complete a full five-year treatment⁹. There can be various reasons why breast cancer patients would fail to complete the regimen, ranging from adverse side effects¹⁰ to progression of the disease into a terminal form¹¹,¹². Still, there are many women who fail to stay on a recommended regimen for less obvious reasons¹⁰. As such, learning the factors associated with why women choose to stop (as well as stay on) hormonal therapy is critical to improving a patient’s treatment experience. While there have been various investigations into regimen adherence¹¹,¹³–¹⁷, most studies rely on traditional clinical resources and methodology, such as formal survey-based studies¹³,¹⁵,¹⁶,¹⁸, electronic medical records (EMRs) and other clinical resources¹¹,¹⁷,¹⁹. Though such traditional methods and data are valuable in healthcare research, there are certain drawbacks that should be recognized. In particular, survey-based methods are limited in that they typically incur high costs in time and money, often restricting a study to a smaller number of participants. Moreover, considering that breast cancer patients with hormonal therapy generally only have follow-up with their doctors every six months, this leads to a large information and time gap in traditional EMR systems about the patients’ treatment (e.g., their feelings and experiences) between two visits.

The Internet, and social media in particular, has provided patients with the opportunity to seek and share treatment experiences in online environments. For instance, the BreastCancer.org website maintains an online discussion board for breast cancer patients to discuss any aspect of their daily lives they deem relevant. This includes, but is not limited to, their concerns, diagnoses, treatments, side effects and social support structure. This self-reported information
provides a new opportunity to learn about breast cancer patients’ treatment adherence - and on a much larger scale. With thousands of patients posting and interacting regularly and accumulating tens of thousands or greater (up to millions) of posts on discussion boards such as BreastCancer.org, one immediate research challenge that arises is how to efficiently leverage such rich text, ideally in an automated and less labor-intensive manner. More concretely, notable research challenges in this domain include: 1) mapping behavioral and health research questions to ad hoc self-reported information and 2) extracting useful knowledge from an environment that lacks formal mediation where true signals are often hidden in a vast amount of noise (e.g., patients can discuss anything they wish, including topics that are not directed related to cancer).

In this paper, we aim to develop a machine learning framework to distinguish mentions of hormonal therapy adherence behavior (HTAB) from other less relevant free-text contents in online health forums. In particular, we are interested in studying patient behaviors (and their associated factors), such as taking a prescribed medication or interrupting treatment (e.g., stopping or pausing a regimen, or switching to a different medication). In our framework, the task of distinguishing mentions and non-mentions of HTAB is cast as a classification problem. To maximize the predictive performance of our framework, we extensively adapt and compose preprocessing and feature engineering techniques, as well as to interpret their effects. Our framework demonstrates that, through applying natural language processing and machine learning techniques, we can obtain an effective classifier to automatically detect mentions (and non-mentions) of hormonal therapy treatment adherence behaviors. Finally, we perform content analysis (through medical terms) to gain insight into the factors affecting how people communicate taking medication behavior and interrupting medication behavior.

Our work contributes to the field of user (or patient) generated online data (e.g., in social platforms and discussion communities), specifically where it is applied to supplement traditional data sources (e.g., EMRs) to study health related problems. In this research domain, we acknowledge that there is a growing collection of studies that cover a range of areas, including flu trends20, mental health11,12, privacy issues about health mentions21,22 as well as how to build online communities to provide local cancer support23. Further, regarding this specific research topic, Freedman et al.24 studied a large number of posts mentioning cancer treatments (including hormonal therapy) and identified treatment barriers that manifest from various aspects, including emotions, preferences and religious belief. Mao et al.25 found that joint pain is the main reason patients stop taking Aromatase Inhibitors (AIs) treatment in online discussions of drug side effects. There have also been several studies that focus on BreastCancer.org, as discussed in a recent review26, though the focus has been on different prediction problems.

**Methods**

Our goal is to build an automatic framework to distinguish HTAB status (mentions and non-mentions) and learn their associated factors. Figure 1 shows the three main components of the proposed framework: 1) data preparation, 2) classifier building and 3) content analysis. Specifically, free-text data from users’ postings are first collected from the hormonal therapy forum in breastcancer.org online discussion board. This yields a large amount of unlabeled text. Next, a subset of sentences containing at least one of seven common hormonal therapy medication keywords (e.g., Tamoxifen) are manually labeled based on their contents through a majority voting model. The labeled sentences are then applied to fit several candidate classifiers and the model with the best performance is applied to boost the number of labeled data. Finally, after extracting different HTAB, a regression analysis is applied to study associated factors.

**Data sources**

The online breast cancer community studied in this paper is maintained by Breastcancer.org, a non-profit organization that provides information about breast cancer. There are more than 170,000 registered members and 80 main forums in this online health community. Each forum is organized into different threads. Each thread has an initial post indicating a general topic (e.g., a question) that will be discussed (asked), with zero or more posts that follow the initial post. However, the posts that follow do not necessarily respond the initial post and could simply respond to each other. Additionally, certain threads may have a very small number of posts, while others could span years and consist of hundreds of posts. In this paper, we focus on one particular forum, Hormonal Therapy - Before, During and After1.

---

1https://community.breastcancer.org/forum/78/
Figure 1: Framework for studying HTAB through an online breast cancer forum data. Three core components are highlighted in the figure: 1) data preparation, 2) HTAB mention classifier and 3) HTAB comparison.

We collected all the posts published in this hormonal therapy forum before June 22, 2016. There are 9,996 users who participated in 5,995 threads with more than 130,000 posts over a 9-year period.

Data Annotation

In this study, we rely on supervised machine learning to distinguish mentions from non-mentions of HTAB. To engineer efficient classifiers, we manually annotated a gold standard dataset. Considering the rich context of the posts (e.g., posts in this forum can consist of multiple paragraphs), we focus on features at the sentence-level for the classification task. This is because we observe that most sentences used in this forum follow general grammatical rules and are sufficiently verbose to convey information of interest. However, there still exists a substantial number of irrelevant sentences and building a classifier on such an unbalanced dataset would seriously affect its performance. As such, we further constrain our classification objects to those sentences containing at least one of seven common hormonal therapy medication keywords (Arimidex, Aromasin, Femara, Tamoxifen, Evista, Fareston and Faslodex). We also extend the keywords to include their corresponding generic names (Anastrozole, Exemestane, Letrozole, Tamoxifen, Raloxifene, Toremifene, and Fulvestrant, respectively) to account for variation in communication.

The goal of annotation is to obtain binary labels that indicate whether a given sentence communicates an HTAB or not. However, directly providing such labels to annotators may not be sufficient for them to understand the task. Thus, we adopted the hierarchical labeling strategy that was applied in21. Specifically, based on our observation of how patients discuss their treatments in the forum and guidance in a decision making codebook introduced by Beryl and colleagues in a hormonal therapy survey16, we provide seven options for annotators to choose from to best describe whether a given sentence, containing at least one of the seven common medication keywords as mentioned above, conveys information about: 1) taking medication action, 2) stopping taking medication, 3) switching medication action, 4) taking medication intent, 5) not taking medication intent, 6) not decided yet, and 7) none of the above. The first three options correspond to mentions of HTAB, while the other four options belong to non-mentions of HTAB. We randomly select 1000 sentences and assign them to each of two annotators who are familiar with the online discussion forum to obtain labels. A third annotator is called upon if the first two annotators do not agree in their labels. The final label of each sentence is based on a majority rule.

HTAB Classification

N-gram features. There are two important steps in a typical classifier fitting process to note: feature extraction and algorithm tuning. While both steps can influence the performance of a classifier, in this task we focus on feature
extraction with several common off-the-shelf learners. In text mining and natural language processing, term frequency-inverse document frequency (TF-IDF) is a common technique to help extract features. As the name suggests, the intuition behind this concept is that if a term is frequent in a document (high TF) but scarce in other documents (high IDF), then the term will be distinctive to this document. As a result, the higher the TF-IDF value that a term exhibits, the more important the term is to distinguish the document from others. A natural choice for a term is a single word in a document. However, using words as features to represent a document loses the power in the ordering of the words. An alternative solution is to apply an n-gram word combination (i.e., linking n adjacent words together) as a term (e.g., "hot flash" as a 2-gram). Further, to reduce the impact of sparsity in natural language, the term could also be an n-gram of characters. Compared to other traditional high dimensionality reduction techniques (e.g., PCA), the advantage of this technique is that it maximizes interpretability.

**Low dimensional representation features.** Recently, another popular technique aimed at high dimensionality reduction in text mining is based on learning a low-dimensional representation of a word. These techniques make use of large amounts of data to discover the semantic similarities between terms through an embedding. For instance, word2vec is a technique where each word is represented as a vector of a predefined dimension (e.g., 100). By building a model to predict terms through their neighbors, the model has been shown to learn vector representations of terms quite well. For example, when applying our collected hormonal therapy forum data to fit a word2vec model for tamoxifen, the ten most similar words provided by the model (based on cosine similarity) were: taxmox (0.97), tam (0.91), arimidex (0.89), tamoxifin (0.88), tamo (0.87), femara (0.85), aromasin (0.79), anastrozole (0.78), letrozole (0.77) and armidex (0.77). The model provides semantically similar words (e.g., other hormonal therapy medications such as femara, aromasin and anastrozole), as well as its common misspellings (e.g., taxmox, tam and tamo). This is notable from a natural language processing perspective because they serve as a different type of feature to fit a classifier, while accounting for misspellings and abbreviations, which is common in online environments.

**Classification Design.** In this paper, we extract both n-gram words and n-gram characters from sentences as features (2 ≤ n ≤ 5). We also introduce the mean of the vector representation (word2vec) of words in a sentence as another type of feature. For classification, we rely on logistic regression (LR), a SVM classifier (SVC) and a random forest classifier (RFC). To compare the performance of different classifiers, we rely on stratified 10-fold cross-validation (CV), whereby for each 10 times of randomly data shuffling, we use 900 labeled sentences (out of a total of 1000) for training and the remaining 100 for testing. Note that CV can be applied for either 1) model parameter tuning to avoid overfitting or 2) performance evaluation to mitigate the effect of randomness. While it is rigorous to create another test data set from all of the collected corpus to evaluate the models performance, we did not apply CV to tune the hyperparameters in the model. Instead, we directly applied it to test the model. We report the average accuracy, precision, recall, F1 score and area under the receiver operating characteristic curve (AUC), along with their standard deviations. We also applied a t-test to ascertain if there is a significant difference in the performance of the classifiers.

We trained the word2vec model by feeding all of the posts we collected (after removing the labeled sentences) into an implementation of gensim (version 0.31.0). We empirically set the dimensionality of the model to 100 and removed all of the words with frequency smaller than 5. The LR, SVC and RFC models were trained using scikit-learn (version 0.18), where the hyperparameters were left as the default in the package.

**HTAB Comparison**

In this task, we aim to boost the amount of the labeled data using a machine learning technique. As such, we can continue to extract HTAB and conduct further behavior analysis. We will subsequently apply the classifier with the best precision to detect HTAB mentions from the remaining unlabeled sentences. In this paper, we mainly focus on two types of HTAB: 1) taking: where a user claimed that she is under treatment with some hormonal therapy medication, and 2) interruption: where a user claimed that she stops (or pauses) a regimen, or switches to another different medication. We use patterns that we observed during labeling process to filter these two types of HTAB. For instance, we apply patterns that include (but are not limited to) started, been on and stay on to extract taking HTAB, and apply patterns such as switched/switch, took me off, back on and stopped taking to extract interruption HTAB.

After filtering the sentences, we retained the posts mentioning either a taking behavior or an interruption behavior (but not both). While people may have different reasons for interrupting a treatment, and they may even talk about the same
behavior multiple times in the forum, in this study we do not aggregate posts published by the same user on the same type of behavior. This is because, when discussing a behavior such as taking, a person’s feelings and health conditions may change with time. Moreover, a person may discuss their taking behavior with respect to different medications. Thus, to obtain meaningful concepts, we rely on ADEPT, a conditional random field (CRF) based classifier aimed to identify medical terms from patient-authored text. Due to space limitations, we refer the reader to the original publication for details on model performance. As such, we removed non-medical related terms from further analysis. However, even if we focus on medical concepts only, more than 20,000 medical terms would remain. Thus, we applied two strategies to mitigate the high dimensionality problem: 1) we empirically retain the top 2,000 medical terms based on their TF-IDF values and 2) we use LR with lasso regularization, where posts mentioning an interruption behavior form the positive class and posts mentioning a taking behavior form the negative class. While lasso can serve as a feature selection approach by forcing the coefficients of many terms to zero, it has been found to be unstable. This is because, given a different sample and random state, it may result in different coefficients. To resolve this problem, we adopt stable selection. The basic idea behind this technique is to subsample the training data and fit a lasso regularized LR model, whereby the features that are repeatedly selected across multiple runs of randomization receive higher scores (with a range from 0 to 1, the higher, the better). However, the scores cannot communicate which behavior the corresponding terms are informative for. Thus, to obtain directionality, we rely on the Pearson biserial correlation between the terms and the two behaviors. We apply the implementation of stable selection sklearn (version 0.18) and the implementation of Pearson biserial correlation in scipy (version 0.81), with all possible hyperparameters set to their default.2

Results

Data Annotation

Table 1 shows the distribution of labeling results. There is an approximately even number of HTAB mentions and non-mentions. The two primary annotators exhibited a very good agreement level (Cohen’s $\kappa = 0.80$) at the mentions vs. non-mentions level and a good agreement (Cohen’s $\kappa = 0.72$) at the seven detailed options level. For the sentences designated as an action-related option, approximately 80% are about taking hormonal therapy medication, while only about 8% are about discontinuing hormonal therapy medication and 12% are about switching hormonal therapy medications.

Model Performance

Table 2 shows the performance of models fitted with various features and algorithm combinations. For each measure, the mean values and the standard deviations are reported. The maximal mean value of each measure is highlighted in blue. There are several notable findings to recognize.

First, models fit with word2vec features have a significant improvement over models fit with either single word or word n-gram features for almost all of the five metrics. For instance, in comparison to RFC fit with word features, RFC fit with word2vec had a 13.9% improvement on AUC, 11.9% improvement on precision, 21.5% improvement on recall, 16.2% improvement on F1 score, and 12.8% improvement on accuracy. This suggests word2vec features have a positive influence on HTAB mention detection.

2 Recently, open-vocabulary approaches has become popular in natural language processing. In particular, while topic modeling is appealing and has the potential to complete a similar task, its results are often difficult to interpret. Further, the number of topics has to be determined ahead. Thus, we focused on medical terms because they have domain-specific meaning and their interpretation is relatively straightforward.

Table 1: The distribution of options in the 1000 labeled sentences (after the third annotator broke ties).
First, hormonal therapy medications, such as Aromatase Inhibitors (AI) (e.g., femara, exemestane (aromasin),
and arimidex (anastrozole)), are more likely to be mentioned in posts related to an interruption behavior.

Second, models fit with character n-gram features exhibited significant improvement in AUC over models
fitted with either single word features or word n-gram features ($p < 0.01$). As an example, the improvement for
RFC was $8 \sim 9\%$. Further, the LR model fitted with character n-gram features significantly improved on the
LR model fitted with single word features on all measures ($p < 0.01$).

Third, while the LR model fitted with character n-gram features have a similar performance to the LR model fitted
with word2vec features, the latter improved both RFC and SVC on AUC, precision, F1 score and accuracy.

However, given the same type of features (e.g., either n-gram or word2vec features), there is no significant difference
among the algorithms on the majority of the measures. It should also be noted that SVC with either single word features
or character n-gram features obtained a perfect recall but with a severe cost of precision (almost equivalent to
a random guess).

Based on Table 2, we can conclude that, for HTAB detection, word2vec features result in the best performance,
followed by character n-gram features, and then word related features. Based on this finding, we chose to apply RFC
fit with word2vec (with the highest average precision) to classify all of the remaining unlabeled sentences for further
analysis. Moreover, the smaller standard deviation suggests that RFC is not overfitting.

### Comparing Medical Terms Between HTAB

After filtering with the taking and interruption behavior patterns and extracting the medical terms, we obtained
19,174 posts published by 5,251 users. Among those posts, 13,461 (70.2\%) discuss a taking behavior (the negative class),
while 5,713 (29.8\%) discuss an interruption behavior (the positive class). Among these users, 4,548 (86.7\%) men-
tion a taking behavior, 1,961 (37.3\%) mention an interruption behavior, and 1,258 (24.0\%) mention both taking and
interruption behaviors.

After applying stable selection through 200 randomly generated subsamples, Table 3 shows the 50 medical terms
that were most important for distinguishing between posts that mention a taking behavior and an interruption behavior.
The Pearson biserial correlation between all of the terms was significant at the 0.01 level ($p < 0.01$). The goodness of
fit measured with AUC is 0.765 \pm 0.004, suggesting that the lasso models used in stable selection fit the observations
well. Here, there are several notable results to highlight.

First, hormonal therapy medications, such as Aromatase Inhibitors (AI) (e.g., femara, exemestane (aromasin),
and arimidex (anastrozole)), are more likely to be mentioned in posts related to an interruption behavior. It should also be
noted that some users may switch between different AIs, as stated by one user:

**Example 1** “... I had this problem with Femara and was taken off and switched to Aromasin ...”

</table>

Table 3: 50 medical terms that are the most useful in distinguishing posts mentioning taking behavior from posts mentioning interruption behaviors. The Pearson biserial correlation between all of these terms is significant at a level of 0.01 ($p < 0.01$).

Second, common side effects of hormonal therapy medications are more likely to be mentioned with a taking behavior, such as hot flashes, hair (loss), nausea, sweating, and osteoporosis. Common drugs or supplements mentioned with a taking behavior include Tylenol, vitamin and calcium. By contrast, depression, pain, and fog are often likely to be mentioned with an interruption behavior. As a user complained:

**Example 2** “This spring I switched to Exemestane due to terrible depression, sleep issues, back/shoulder/neck pain.”

It is not surprising to see that Wellbutrin, an antidepressant, is also more likely be mentioned with an interruption behavior. Note that methotrexate, a medication to treat cancer and “usually given after other medications have been tried without successful treatment of symptoms” is also more likely to be mentioned with an interruption behavior. Heart-related terms such as carpel, cortison and ekg are also more likely to be mentioned with an interruption behavior.

Third, there are some types of terms that are mentioned with only one of the two types of behaviors. For instance, professionals (e.g., oncologist or onc) are more likely to be mentioned with an interruption behavior. This suggests that these users’ interruption behavior may be associated with their physicians and possibly with permission (or the suggestion of) other care professionals. As one user stated:

**Example 3** “In the 3 years I’ve been on Femara, I have negotiated 2 one-month “vacations” from Femara with my onc when the S/Es got too bad ...”

People are more likely to mention exercise when discussing their taking behavior, but may mention recurrence when talking about an interruption behavior. As one user said:

**Example 4** “I actually felt so bad on tamoxifen that I went off of it last year, then had recurrence 4 months later ...”
Finally, people with an interruption behavior tend to mention surgery, which may be a possible reason why they pause a medication. People with a taking behavior are more likely to mention lumpectomy, ultrasound, chemo, radiation, and period.

Discussion

Findings. In this study, we built a framework to learn about hormonal therapy adherence behaviors, with a focus on classifier design and content comparison between taking and interruption behaviors. There are two notable contributions in this work: 1) we find that features based on embeddings (e.g., word2vec) can assist in establishing efficient detectors of HTAB mentions. For instance, compared to an RFC model fit with single word features, an RFC model fit with word2vec features resulted in a ~21% improvement of recall and a ~12% improvement on precision. The performance of the model ensures high quality for the extracted content; 2) by focusing on medical terms, we gain insights into the different factors associated with taking and interrupting hormonal therapy treatment behavior. For example, we find that people with an interruption behavior tend to mention depression and related antidepressant. This is in alignment with other studies\textsuperscript{36,37} where depression was found to be significantly associated with non-adherence to hormonal therapy treatment. Our findings further suggest that certain common side effects (e.g., hot flashes, nausea and osteoporosis) may not be as likely to induce an interruption behavior severe as depression.

It is further interesting to note that people exhibiting an interruption behavior are likely to mention their care professionals. This suggests that their interruption behavior may be an artifact of, or even suggested by, their care professionals (e.g., take a break due to the following surgery). This is noteworthy because this interruption behavior might still be under their care professionals’ control.

Implication. By relying on natural language processing techniques, machine learning models and statistical inference tools, we built an automated framework to study treatment adherence through an online breast cancer community. Given that patients with long-term hormonal therapy tend to see an oncologist only twice per year, our framework provides a supplemental perspective (beyond routine clinical information) to learn about these patients’ treatment experiences. Our findings, which are based on a comparison of medical term predictive ability, demonstrate the potential power of this type of online data to conduct treatment adherence research. Moreover, this framework may be extendable to assist in the study of adherence for other chronic diseases (e.g., depression or diabetes) through patient-authored online data. However, we acknowledge that domain-specific knowledge would be needed to customize behavior patterns for each disease. Still, once such information has been generated, the framework proposed in this paper could easily be adopted.

Limitation and further work. There are certain limitations that we highlight, which can serve as guidance for future research. First, we did not tune the hyperparameters of the models. It will be useful to determine if a combination of the proposed features can boost model performance. Second, we applied our observed patterns to filter the taking and interruption behaviors. While this strategy leads to high precision, it will miss adherence behavior mentions that fail to follow these patterns. Thus, as a next step, we anticipate including posts that communicate both taking and interruption behaviors with algorithms that achieve higher fidelity. Finally, we extracted medical terms without consideration for the grammar and context in which they are situated. We believe that more efficient models may be develop to detect different types of behaviors and interpretable medical concepts.

Conclusion

In this paper, we proposed a framework to learn about hormonal therapy treatment adherence behaviors (HTABs) through an online breast cancer discussion forum. The framework consists of three core components: 1) data preparation, 2) classifier engineering and 3) comparison of HTABs. We analyzed a dataset consisting of over 130,000 posts across a 9-year period and demonstrated that features based on embeddings (e.g., word2vec) can help build a more efficient and effective classifier for HTAB mentions in online generated data. Furthermore, by comparing the predictive capability of medical terms used in describing taking and interruption behaviors, we discovered that people with an interruption behavior are more likely to mention depression and their care professionals, while people with a taking behavior are more likely to mention common side effects (e.g., hot flashes, nausea and osteoporosis), vitamins and exercise. This study demonstrates that an individual’s discussion of hormonal therapy in an online environment may
provide insight into treatment adherence behaviors. We further believe that this framework has the potential for extension to learn adherence for other chronic diseases treatment (e.g., diabetes and depression), provided domain-specific guidance is available.

Abstract

We report the baseline usability of a novel web-based application, the Population Health Record (PopHR), designed to facilitate the effective use of population health information by public health professionals and to support evidence-based decision-making. The usability test was conducted with ten potential users who each completed eight tasks using the PopHR system. Participant responses were recorded, including timestamps for each data entry. Overall, the task completion rate was 96% while the success rate was 88%. The average time-on-task was 3.11 minutes, with more time spent on tasks requiring a user to stratify data along multiple dimensions, such as age, sex, or geographical region. Usability scores indicated that the current version of PopHR has good usability. Potential improvements identified included adding supporting information, offering different visualizations, and enhancing system stability. These findings are examples of addressable usability problems encountered in developing a population health record system.

Introduction

Despite a broad consensus that evidence-based decision-making can improve the effectiveness of the public health system, decision-makers are currently unable to access information and combine it with evidence to make important choices about the health of their communities1. Information is scattered across ‘siloes’ or multiple systems1 and is difficult to extract2. Evidence regarding interventions is generally not integrated into information systems, and is available only through online repositories of systematic reviews3. Paradoxically, practitioners suffer from information overload4 while being unable to find the information they need2 and align it with evidence5.

These problems with using information and evidence in practice indicate that existing information systems do not effectively address important barriers to evidence-based public health6-8. To address these barriers, professional bodies9 and expert panels1 have called for the creation of a new breed of information systems, called Population Health Records (PopHR), which are designed using principles from cognitive science and biomedical informatics to improve decision-making in the public health system10. We designed a knowledge-based system to meet these requirements11 and developed a software application according to this design12. The first version of the system is now ready for use and we are implementing the application with our public health partners for initial use by early adopters. Here we report on the first formal usability evaluation of the PopHR software.

Usability testing is essential for user-centered design as it allows the designer to determine if their conceptual model of the application is effectively conveyed to users through the interface13. A well-accepted definition of usability is “the degree to which a product or system can be used by specified users to achieve specified goals with effectiveness, efficiency and satisfaction in a specified context of use”14. Thus, usability can be measured by the accuracy and completeness of users solving specified tasks, the effort required to achieve goals effectively, and the degree of satisfaction with using the system. Systems with poor usability may result in user errors, a waste of resources, and low adoption rates15, 16, therefore, assessing the usability early in the design process and enhancing the system based on user feedback is critical.

Although population-based health systems exist, such as CDC WONDER17, Infocentre18 and Snapshots19, these systems have been assessed through user satisfaction surveys only20, no usability evaluations were conducted. In the biomedical informatics literature, usability evaluations have been reported mainly for the clinical and hospital information systems21, with few examples of usability challenges and solutions for population health systems. The goal of an information system in clinical medicine is to assist clinicians in tasks such as diagnosis and management so that they can deliver optimal healthcare in a high volume and time critical working context. In contrast, the goal in population health is to support practitioners in monitoring the health status of a defined population so that they can deploy and manage, efficient, effective, and equitable programs to promote health and prevent diseases22. As the goals, tasks, and context in public health differ from clinical medicine, the absence of evidence about the usability of population health information systems is an important gap. Therefore, we conducted a user-centered usability evaluation of the current version of the PopHR system. The objective of this study was to measure the effectiveness,
efficiency and end-user satisfaction of the PopHR system, to identify usability issues, and to inform the future development of the PopHR and other population health information systems.

**Method**

*PopHR description*

PopHR is a semantic web platform, designed to organize, make interpretable, and disseminate information and evidence to support population-health decision makers. It centralizes multiple sources of heterogeneous data, estimates indicators of population health, and uses epidemiological knowledge to contextualize and facilitate the interpretation of health indicators. The integration and exploration of large-scale population health data in a conceptually coherent manner is made possible through PopHR’s explicit semantic model of population health\(^ {12, 21}\). Health indicators are organized according to a determinants of health framework\(^ {22}\), with each indicator linked to relevant concepts about diseases or risk factors. Consensus knowledge, expertise and scientific literature were used to establish the links between concepts\(^ {24}\). The implementation of PopHR used for this study integrates data for an open cohort sampled randomly (25%) from the general population of the Census Metropolitan Area (CMA) of Montreal, Canada (approximately 1 million individuals in the cohort). The provincial government health insurer, RAMQ, provides individual-level health services utilization data (physician claims, hospitalizations, drug dispensations), while partners at the province’s public health agency, INSPQ, provide validated case definitions and algorithms for calculating the health indicators from these data. Finally, data from Statistics Canada and other sources were used to generate indicators of area-level risk factors and upstream determinants of health.

*PopHR Interface*

The PopHR interface includes six distinct views to visualize information: causal graph, bar graph, table, map, time series, and dashboard views (Figure 1). The entry page of PopHR is the causal graph view, showing a directed acyclic graph centered on a selected health concept (i.e., a health determinant or disease) along with its determinants and downstream diseases known to have causal links to the concept. The user can also visualize Spearman’s rank correlations between default indicators of each concept computed ecologically between values for geographical regions, through overlaid color and thickness representing direction and strength, respectively. Upon selecting a concept, the user chooses an indicator (e.g. prevalence, incidence) from an ‘indicator box’, a visualization option (map, bar graph, data table, or time series), as well as stratification levels for geography (various levels of health regions), age, and sex. Direct standardization by age, sex, or both can also be selected to account for different demographic distributions in regions being compared.

![Figure 1. Six views in the PopHR application: causal graph, bar graph, table, map, time series, and dashboard view (left to right, top to bottom).](image)

*Participants and testing environment*

The usability test was approved by McGill University’s Research Ethics Board. Ten participants were recruited from graduate-level programs in the department of Epidemiology, Biostatistics, and Occupational Health at McGill
University and none of the participants had used PopHR before. All participants were present at a half-hour training session held by the research team. Afterwards, participants conducted the usability test independently on their personal computers, in their own work or study environments during the period of February 8-22, 2017.

Task development and testing procedures

In comparison to clinical information systems, the usability test methods we used here to evaluate a population-health system do not place an emphasis on the user environment. Although the environment in which the system is used is an important factor in assessing the usability of a system, its effect is more significant in clinical settings, such as in emergency departments or intensive care units. Therefore, we adopted a user-task-system evaluation framework for our study, omitting consideration of context. Eight usability tasks were developed and subsequently reviewed by the research team domain expert (DLB) to fit predefined use cases of the application. Tasks were variants of queries in PopHR accomplished with the purpose of identifying population health patterns. Successful completion of the eight tasks required the use of all the features in the application except those in the dashboard view.

In the training session, a member of the research team described the usability test procedure and introduced the PopHR application to the participants through a 3-minute video tutorial. After the session, each participant received an Excel file containing the application link, the test procedure, questionnaires, and usability tasks. After completing a baseline questionnaire about demographic characteristics and experience with population health information systems, participants performed eight tasks sequentially. For every task, participants read the task, clicked on a “Start” button in the file, switched to PopHR to find the answer, and then returned to the spreadsheet to write the answer in the corresponding cells. After every task, participants answered three questions from the after-scenario questionnaire (ASQ) and participants were strongly encouraged to provide feedback on the usability issues they encountered during the task and express their expectations. Following the completion of all tasks, participants completed the System Usability Scale (SUS) questionnaire. Two additional questions asked participants to rate the PopHR application in comparison to other population health information systems they had experience with and to rate the usefulness of the application. All participants were advised to interact with the application for several minutes before starting the first task and to take breaks only between tasks.

Data collection and analysis

Participants’ performance on tasks, usability scores and feedback were examined to evaluate the usability of the PopHR application. Performance on task was measured in terms of task completion rate, task success rate and time-on-task. The time-on-task was determined as the time elapsed between a participant clicking on the “Start” button and writing down the answer. The time was tracked using the NOW function in Microsoft Excel, which was hidden from the participants. ASQ and SUS scores were calculated to provide task-specific and overall usability assessment of the application, respectively. We conducted thematic analysis with the qualitative data collected from participants’ written feedback. The themes used to categorize the usability issues were modified from previous studies. Additionally, Google Analytics was used to track and analyze the site traffic attributable to the participants during the test period.

Results

Participants characteristics

In total, ten students were recruited for this study. Of the ten participants, seven were under 25 years old and three were between 25 to 29. Seven participants had 1-2 years of working experience in the public health field, while others had less than one year of experience. All participants made use of computers for at least 3 hours per day for their professional use, and rated themselves as skilled Internet users. In terms of experience in accessing chronic disease indicators, only one participant reported that he often searched for indicators, while others reported they did so sometimes (5/10) or rarely (4/10). Statistics websites and research papers were the main sources from which participants accessed indicators.

Task performance

The usability performance captured in this test will be treated as the baseline measurements of the PopHR system and will be used in comparison with the usability results of subsequent versions. The summary of the usability test is shown below (Table 1). The overall completion rate was 96.25%, with only 3 tasks (task 3, 4, 5) not completed by all participants. A system error and failure to find a view allowing multiple stratifications were the reasons for the uncompleted tasks. The overall success rate, defined as the percentage of tasks that participants completed correctly, was 87.5% ranging from 70% to 100% for each participant. The average time was 3.28 minutes for successful tasks and 3.11 minutes for all tasks, ranging from 1.61 to 4.72 minutes. Considering only completed tasks gives a cleaner
measure of efficiency, while using the time for all tasks could better reflect the overall participants’ experience in a real-world situation. There was generally little variation in the time-on-task across participants except for one participant who spent on average of 7.16 minutes compared to the average of 2.5 minutes for all other participants.

The score from the ASQ after each task showed that 77.5% (mean agreement rating =2.54) of the participants found it easy to complete the task, 83.75% (mean agreement rating =2.29) were satisfied with the time to complete the task, and 86.25% (mean agreement rating =2.32) agreed there was adequate supporting information within the application. Across tasks, the ASQ scores ranged from 2.12 to 3.85.

*Satisfaction score is the average rating across the 3 post-task questions: ease of completing the task, amount of time it took to complete the task, and the support information in the system. The satisfaction rating scale ranged from 1 (strongly agree) to 7 (strongly disagree).*

**SUS results**

The average SUS scores from the post-test questionnaire was 70.75 (SD =14.24) out of 100 points. This score is above the average score for web applications, indicating good usability29 of the PopHR system. Among all participants, four scored above 80, four between 60 to 80 and two participants reported “OK” usability around 50. Seven out of ten participants stated in the questionnaire that they would use the PopHR system frequently and eight agreed the application was useful for their work or study. Compared to the main statistics websites participants use to search chronic disease indicators, the majority of participants found PopHR performed better in terms of data visualization, analytics functionality, data quality and ease of navigation. However, only four out of ten agreed that PopHR outperformed the comparison websites regarding the amount of information provided.

**Google Analytics results**

During the usability test period, there were 1,864 page views (1,025 unique page views) and the average time on page was 46 seconds. All six views were explored for more than 200 times each except the dashboard view which was viewed 20 times in total. Although the causal graph is the entry page (372 page views), the bar graph was explored most often (607 page views) by participants. Excluding the dashboard view, the shortest average time on page was the bar graph (16 seconds), while the longest was in the causal graph (74 seconds).

**Descriptive findings from participants’ feedback**

In total, 64 comments were provided. Participants praised the causal graph as a meaningful way to organize related variables (e.g., upstream health determinants, and downstream health conditions) and provide domain knowledge.
Four participants found the application was easy to navigate and one stated the system was easy to learn. Features such as the time slider and time series were noted for their usefulness.

From participants’ feedback, usability issues were identified and a table below (Table 2) shows the themes, the frequency of the usability problems mentioned by participants, and the example of usability issues or user expectations. All usability issues were categorized into four themes: 1) function; 2) information; 3) visualization; and 4) system status. Information and visualization were further divided into other categories. Function problems were brought up most often and most issues were related to the lack of a function for filtering data, which has not been implemented in the current version of the PopHR system. This issue becomes more pronounced as a user selects more stratification categories. For instance, in task 8, all participants could find the time trend of the indicator values stratifying by geographical regions (15 categories) and sex (2 categories). However, with 30 trend lines displayed, eight out of ten participants found it hard to read and interpret the results. A filtering feature would allow users to remove information for regions that are not of interest, facilitating interpretation of the most relevant information.

Seven participants mentioned issues about labeling in the application, especially in relation to the causal graph view and the “data linked” function. Most participants were not able to easily understand the difference between the lines indicating a causal relationship (based on knowledge from the biomedical literature) and lines indicating a correlation between indicators calculated from the data within the application. More labels and tooltips explaining the graph were expected by the participants. Visualization issues including the layout, resolution, and graphics problems were stated 11 times. Four comments criticized the stability of the system, noting the webpage needed to be refreshed following a system error.

<table>
<thead>
<tr>
<th>Theme</th>
<th>Frequency</th>

<td>The system was sometimes unstable and users needed to reload current page or return to the home page</td>
</tr>
</tbody>
</table>

**Discussion**

In this study, we assessed the usability of the first implemented version of a knowledge-based population health information system, the PopHR. Users achieved a completion rate of 96% for tasks meant to be representative of those in public health practice. However, the evaluation uncovered issues with how effectively and efficiently the application communicated information and evidence. Unlike previous evaluation studies on public health information systems that mainly focused on the assessment of data quality, our principal objective was assessing how well our system allows for evidence-based decision making, and thus how it communicates information and evidence. Findings indicative of effectiveness issues included a low success rate for two tasks (1 and 6). Our results showed that usability issues, such as inadequate supporting information and an unclear interface, can lead users to draw incorrect inference and may lead to poor decision making. For instance, forgetting to change the year and geographic resolution was the reason for users failing to successfully complete those two tasks, and this type of error can be easily avoided with better labeling. The efficiency with which information is conveyed should also be a critical attribute in evaluating public health information systems as this characteristic of the system is directly related to user experience and influences the productivity of public health professionals. In our study, for all tasks where users took longer than 3
minutes, the success rate was high (94%). This result indicates that even though users could find the right answers, they did not find the information immediately. When users took longer to complete a task, they tended to report a lower satisfaction level.

Among all the usability problems identified through the test, opportunities to improve the application were pinpointed and should be relatively straightforward to address, such as the information and visualization issues. The new functions characterized by the participants coincides with the research team’s design for the next version of the application. While more development effort is needed to implement a filter function and a more flexible search bar, these two features should help users to locate relevant information more efficiently and effectively.

Although the number of participants in this usability study was limited, their interactions with the application were extensive as seen in the Google Analytics results. Additionally, most usability problems were identified repeatedly by different participants indicating that the issues identified most likely represent the majority of the total usability problems. Another limitation of the study is that the participants were all graduate students. In terms of the work experience, age, and computer skills, the students are not fully representative of our target users, who are public health planners and analysts with a focus on non-communicable diseases. This limitation may result in overlooking some disease-specific or computer skill-related usability issues. However, our research team has recently completed an additional usability test with employees from provincial and city public health departments, and those results should support more generalizable conclusions. The third limitation lies in the evaluation method used in this study. The usability test was conducted without an instructor on site and time-on-task may have been tracked less accurately compared to a screen recording approach. However, the method used in this study can reflect the user experience with the system in real working circumstance and may eliminate an evaluator effect. Additionally, this method provides a much more efficient way to conduct a usability assessment and is valuable for development teams with a rapid iterative design cycle.

In this study, we assessed the baseline usability performance of the PopHR system, identified its usability issues and reported user expectations. Our results showed that the usability of the current version of PopHR is good, but can be improved through adding new functions, offering more supporting information, enabling new visualizations, and improving system stability. The usability issues identified will be addressed in subsequent releases of PopHR to ensure the effective use of the application. Meanwhile, as PopHR continues to evolve, more data from various sources and new functions (e.g. integrating public health intervention knowledge) will be added to the application. We anticipate that continuing to improve the usability of the system while adding new features will present additional challenges.

Abstract

To facilitate the identification of contralateral breast cancer events for large cohort study, we proposed and implemented a new method based on features extracted from narrative text in progress notes and features from numbers of pathology reports for each side of breast cancer. Our method collects medical concepts and their combinations to detect contralateral events in progress notes. In addition, the numbers of pathology reports generated for either left or right side of breast cancer were derived as additional features. We experimented with support vector machine using the derived features to detect contralateral events. In the cross-validation and held-out tests, the area under curve score is 0.93 and 0.89 respectively. This method can be replicated due to the simplicity of feature generation.

Introduction

Contralateral breast cancer is defined as a solid tumor developed in the opposite breast after the detection of the first primary breast cancer. Woman with a first primary breast cancer has two to six folds of increased risk to develop a contralateral breast cancer compared to the normal population1. Understanding the etiology of contralateral breast cancer can not only help us understand the risks associated with breast cancer development, but also help monitor the effects of treatments2. Efforts have been devoted to study the shared risk factors between the first and second primary breast cancer, including family history3, environmental exposures4, and genetic mutations5. These studies require us to identify the group of patients with contralateral breast cancer accurately. The prevalence of Electronic Health Records (EHR) has enabled large cohort study for different clinical problems, including the contralateral breast cancer. The abundant available information in EHR makes deep phenotyping in large cohort studies more achievable. However, in most cases, identifying contralateral events are still based on manual chart review, which is time consuming and labor intensive.

Because contralateral event is a progressive event, a patient may have been associated with risks of developing such an event for an extended period along his/her life time. The amount of work to capture and maintain pathophysiologic data along the development of risk factors and to identify new events is not trivial. On the other hand, the patient’s progressive information and clinical status are well recorded in the progress notes during the course of a hospitalization or over the course of outpatient care. In addition, the progress notes are readily and prevalently available. Moreover, in most cases, every diagnostic procedure of breast cancer generates at least one pathology report. Usually, if a patient has bilateral breast cancer, the patient should have at least one pathology report generated for each side.

In this study, we proposed a new method for detecting contralateral breast cancer using the narrative text in progress notes and the numbers of pathology reports generated for each side of the breast. With such a model, users can identify the group of patients with contralateral breast cancer among a large cohort efficiently.

Related Work

Capturing contralateral breast cancer events is one of the major tasks for the tumor registries. However, many of the registries, including National Cancer Institute’s Surveillance, did not successfully capture the contralateral events6. Studies heavily relied on manual chart review, which is both time consuming and labor intensive, thus not feasible for large cohort study7. Automated methods have been proposed to extract breast contralateral and recurrence events8-10. However, these studies did not distinguish breast cancer recurrence with contralateral breast cancer events, which significantly limited further cohort studies. Strauss et al. used the morphology codes and anatomic sites to detect contralateral breast cancer events11. However, the work required that the pathology reports are well documented in standard formats, which in reality is not true and requires special care from Natural Language Processing systems to unify the cross-institutional variations in pathology reports12,13. In addition, defining rules to retrieve information from
the copious pathology reports can be labor intensive. Furthermore, if the report did not state which side of breast was examined, the rule based system will have difficulty in calling a contralateral event. Efforts have been also devoted to apply claims data for contralateral event detection\textsuperscript{14,15}. However, claims data are believed to have limited validity for inferring cancer recurrence events\textsuperscript{16}.

Motivated by the limitation from previous studies, we proposed a method to extract features from the common narrative text in progress notes, together with the numbers of pathology reports for each side of breast cancer, to detect contralateral breast cancer events. We experimented with Support Vector Machine (SVM) and quantitatively assessed the probability of a breast contralateral event.

**Study Cohort**

The Northwestern Medicine Enterprise Data Warehouse (NMEDW) is a joint initiative across the Northwestern University Feinberg School of Medicine and Northwestern Memorial HealthCare\textsuperscript{17}. The Lynn Sage database in NWEDW was searched for women who underwent breast conservation surgery for Ductal Carcinoma in Situ (DCIS) or primary invasive breast cancer. We identified 1063 women who underwent breast conservation surgery for a new diagnosis of stage $0$ to stage $3$ breast cancer. Three co-authors (SE, AR, KK) performed chart review for these patients, and identified 33 contralateral events among these 1063 women. Study procedures were approved by the hospital’s Institutional Review Board (IRB).

**Method**

We first randomly split the 1063 subjects into a training set and a held-out test set according to a $7:3$ ratio. In the training dataset, progress notes from 15 women with contralateral breast cancer were extracted and reviewed. The sentences or partial sentences indicating the occurrence of contralateral breast cancer and cancer diagnoses related events were retrieved and summarized in Table 1. These partial sentences were then tagged by MetaMap, which is a nature language processing (NLP) tool to map the biomedical text to the Unified Medical Language System (UMLS) Metathesaurus\textsuperscript{18}. The concept unique identifier (CUI) corresponding to each concept is obtained by parsing the MetaMap outputs. To reduce the noise, CUIs that are not related to breast cancer event is manually filtered and discarded, such as the CUIs of ‘with’, ‘has’, ‘seen’, and etc. were filtered. After filtering the CUIs, 42 CUIs were retained and these CUIs together represent the descriptions for contralateral breast cancer events. We refer to these 42 CUIs as a positive CUI dictionary. These 42 CUIs appear in Appendix A.

After obtaining the positive CUI dictionary, a number of pre-processing steps were performed on the progress notes. Such as removing duplicate copies, dividing the notes to sentences, and removing non-English symbols. Negation and uncertain sentences containing the words of ‘no’, ‘risk’, ‘concern’, ‘worry’, ‘unremarkable’, ‘rule out’, ‘deny’, ‘evaluation’, and their different inflections (e.g., tenses of verbs), were excluded. Following these pre-processing steps, the remaining sentences were tagged using MetaMap. Once we got the MetaMap output, the CUIs with negations were excluded. In addition, those CUIs that are not in the positive dictionary were excluded. The retained CUIs were used as features in our model. However, using single CUI as feature may not be informative enough for us to detect some of the contralateral events. For example, the sentence “Patient was first seen for right breast cancer who now has new left breast dcis.” If we look at each individual CUI, we won’t be able to conclude the contralateral event. We need the CUIs of ‘right breast cancer’ and ‘new left breast dcis’ to reach the conclusion. To this end, a complete combination of the CUIs in the same sentence would be able to help us discriminate contralateral events. Following this observation, additional features were generated by combining CUIs that were in the same sentence. In the above example, the feature combinations of (left, right), (new, left), (left, right, breast cancer) etc. were generated. Clearly, the feature of (left, right, breast cancer) offered clues for contralateral events. Using the sentence “Patient was first seen for right breast cancer who now has new left breast dcis” as example. CUIs ‘C0007124’ (Non-infiltrating Intraductal Carcinoma), ‘C0006142’ (Malignant neoplasm of breast), ‘C0444532’ (Right sided), ‘C0222601’ (Left breast), ‘C0205314’ (New) were generated. With a complete combination of these CUIs, we obtained 31 new features. For example, one of the new feature is {‘C0444532’ (Right sided); ‘C0205314’ (New); ‘C0222601’ (Left breast); ‘C0007124’ (Non-infiltrating Intraductal Carcinoma)} and we can use it to infer breast contralateral event.

Following the pre-processing of the progress notes, additional features were derived based on the number of pathology reports. For each sample, the numbers of pathology reports generated for left and right breast cancer were separately counted and used as two additional features. Intuitively, if a patient has contralateral breast cancer event, then the patient should have at least one pathology report for each side. One additional binary feature indicating whether the patient has pathology reports for both sides were derived. Ideally, every patient with contralateral event should have
pathology reports for both sides. In our experiment, checking whether the word ‘left’ or ‘right’ is contained in the report, we were able to derive such features.

These generated features were used to train a support vector machine (SVM) model for further contralateral event detection. We chose SVM because of its widely-acknowledged generalizability. To obtain a reasonable feature sample ratio and remove the redundant features, Chi-square test was applied to select features before training the model. Only top 50% features were retained for subsequent modeling.

Five-fold cross-validation was applied on the training dataset to tune parameters for the model, which were then evaluated on the held-out test data. In our experiments, we trained four baseline classifiers on different feature types. Baseline 1 is the proposed model without the additional information from the number of pathology reports, referred to as combined MetaMap. Baseline 2 uses only the numbers of pathology reports, referred to as pathology report count. Baseline 3 uses only concepts in the positive dictionary without their combination, referred as Positive Dictionary without Combination. Baseline 4 uses bag of words as features, referred as Bag of Words. To generate the features for bag of words, TfidfVectorizer class in scikit-learn was used to convert the raw documents to a matrix of TF-IDF features.

An overview of the workflow employed in this study is shown in Figure 1.
Results

Among the 1063 subjects, the average numbers of pathology reports are 3.79 with 95% Confidence Interval of ± 0.19 for left side and 3.27 with 95% Confidence Interval of ± 0.19 for right side. If a subject has pathology reports for both sides, the new feature was labeled as 1. In the training data, among the 21 subjects with contralateral breast cancer, 21 (100%) have pathology reports on both sides. Among the 724 subjects without contralateral event, 259 (35.77%) subjects have pathology reports generated for both sides.

In total, 1282 features were generated in the baseline 1 of combined MetaMap, which used all information from progress notes but not from pathology reports. Three features were generated in baseline 2 by using the three features derived from the numbers of pathology reports. A total of 42 features were used in baseline 3 by using positive dictionary without combination. In baseline 4, we used bag of words and 55192 features were generated.

Table 2 shows the feature numbers and cross-validation area under curve (AUC) scores of our proposed model in comparison with the other four baselines. To account for performance variability due to different split of folds, the five-fold cross-validation was repeated 10 times and the standard deviation was obtained. It is clear that combined MetaMap outperforms the positive dictionary without combination and also the bag of words. We compared proposed model with combined MetaMap using Student’s t-test (α=0.05). The difference is statistically significant with P_value = 0.00027. We see improvements on AUC score in our proposed model compared to all other four baselines. In the cross-validation, the AUC score of our proposed model is 0.93 with standard deviation equals 0.02.

Table 3 shows the feature number and AUC scores on the model for prediction in comparison with the four other methods in held-out test. The AUC score is 0.89, which outperforms all four baseline methods by a large margin.

Using the trained model upon the training set, we obtained the coefficient for each feature. The top ranked six features appeared in Table 4.

Discussion

In this study of detecting contralateral breast cancer events from progress notes and counts of pathology reports, the AUC score for our proposed model is 0.93 (±0.02) in cross-validation and is 0.89 for held-out test. The model is able to retrieve contralateral breast cancer events by using the combination of narrative text in progress notes and the additional features derived from the numbers of pathology reports. The proposed model outperformed all four baseline methods, demonstrating that different features offer different levels of information. For the *combined MetaMap* feature
only, the AUC is low because some progress notes do not necessarily contain the concepts that exist in the positive CUI dictionary. On the contrary, all patients with contralateral event have pathology reports for both sides of breast cancer. In addition, many patients without contralateral breast cancer event also have pathology reports for both sides, indicating that this feature will help improve recall but may lower precision. Putting these two types of features together has the potential to address the limitations of each other and increase the chance of identifying contralateral events. It is acknowledged that we have seen some jargons in the progress notes. However, considering that one patient’s progress notes are often written by multiple clinicians, we still have a high chance to find well-formatted sentences in the progress notes. In the positive feature study, the derived variable ‘Pathology Report for Both Side Indicator’ ranked as second feature, indicating that the variable we have created is an efficient one. In addition, the top ranked features hinted us a story that if new carcinoma presents in right or left breast, or if Noninfiltrating Intraductal Carcinoma presents twice in one sentence together with breast or entire breast, the patient then have a high chance to have contralateral breast cancer. Obviously, ‘bilateral breast cancer’ is another indicator to be used to find the events. These semi-structured features may provide alternative perspectives that are useful in capturing contralateral recurrence. In the future, we plan to identify more semi-structured features to complement CUI-based features, where tensor modeling may provide useful tools for integrating different types of clinical features10.

In an error analysis, one of the patient with contralateral event was not identified because of concept positions in the power set. In the patient’s progress note, one sentence appears as: “this is a 61-year-old woman with right breast cancer newly diagnosed”. The power set derived was \{right side; breast cancer; newly diagnosed\}. However, in the model we have trained, we only have a position-sensitive feature of \{newly diagnosed; right side; breast cancer\}. The derived power set was not recognized and the event was not identified. In the future, instead of using position-sensitive power set, we plan to use graph based representation to capture the relations between medical concepts (CUIs) with more accuracy20,21. In another case, we saw: “including stage 2 l breast ca, dcis r breast” in the progress notes. However, the ‘left’ and ‘right’ are both abbreviated to ‘l’ and ‘r’. Our model is not yet complicated enough to recognize these abbreviations.

Conclusion

Using self-defined rule-based system, one can possibly identify the numbers of pathology reports for each side of breast cancer as supplementary features. We expect this study to generalize well across medical institutions. The easiness of replication can reduce the time-consuming manual effort to identify contralateral breast cancer events for cancer registries. Moreover, instead of binary classification, this model can provide the abstractors with the continuous probability score as confidence. This study can also be applied to retrieve other breast cancer events such as local recurrence, distant recurrence as long as the positive CUI dictionary is defined.

</table>
Towards Supporting Patient Decision-making In Online Diabetes Communities

Jing Zhang MS, Rebecca Marmor MD, Jina Huh PhD
University of California San Diego, San Diego, CA

Abstract
As of 2014, 29.1 million people in the US have diabetes. Patients with diabetes have evolving information needs around complex lifestyle and medical decisions. As their conditions progress, patients need to sporadically make decisions by understanding alternatives and comparing options. These moments along the decision-making process present a valuable opportunity to support their information needs. An increasing number of patients visit online diabetes communities to fulfill their information needs. To understand how patients attempt to fulfill the information needs around decision-making in online communities, we reviewed 801 posts from an online diabetes community and included 79 posts for in-depth content analysis. The findings revealed motivations for posters’ inquiries related to decision-making including the changes in disease state, increased self-awareness, and conflict of information received. Medication and food were the among the most popular topics discussed as part of their decision-making inquiries. Additionally, We present insights for automatically identifying those decision-making inquiries to efficiently support information needs presented in online health communities.

Introduction
Diabetes is a chronic, typically incurable condition; patients must constantly manage and receive care throughout their lifetimes. The burden of self-management falls on the patients. People with diabetes make decisions every day that affect their health 1, such as food and exercise choices and consequently express high desires for gaining medical knowledge 2. Upon diagnosis, patients with diabetes must absorb information, change habits, and adopt new behaviors 3. As patients achieve control of their diabetes, new issues come up and they need to readjust their routines and behavior 4. Prior research has found that there is a lack of information provided to patients after their initial diagnosis 2,5–7. Patients are left with questions regarding lifestyle modifications and other required changes 6.

Online health communities (OHCs) are a critical source of information for patients with diabetes given the vast amount of anecdotal information available 8,9. Researchers are developing collective sense-making models 10, text classification methods 11,12, and visual decision-making techniques 13 to help patients make use of OHC content. The challenge here is that, as patients gather needed information and manage their diseases over time, the kinds of inquiries patients make also evolve over time.

According to the decision-making literature, the decision-making process includes establishing objectives, gathering information, developing and comparing alternatives, making the decision, implementing a plan of action, and reflecting on the decision 14,15. These inquiries manifest in OHCs as patient post questions pertaining to decision-making, specifically, as they compare alternatives. OHCs are filled with collective knowledge that has a great potential to support the evolving information needs of patients and their decision-making. Though current research is investigating ways to make use of OHC content, how to support those patients’ decision-making is understudied.

In this paper, we investigate patients’ information needs, specifically the decision-making inquiries in OHCs. We performed content analysis of the inquiries that the comparing stage of the patient decision-making process. Our study presents insights for automatically identifying these decision-making inquiries and opportunities to better support decision-making in online health communities.

Background
Decision-making challenges in diabetes management
In the US alone, in 2014, 29.1 million people were diagnosed with diabetes 16, a 12% increase from 26 million in 2010. Out of the total population with diabetes, 28% do not realize they have diabetes. Additionally, 86 million Americans have pre-diabetes—this data translates to the fact that more than 1 in 3 Americans have at least pre-diabetes 17. Diabetes management relies heavily on self-care 1 and has a substantial and increasing impact on the quality of life of Americans. The majority of people who suffer from chronic illnesses such as diabetes fail to receive appropriate or effective chronic illness management from primary care providers 18. To bridge this gap, patients with chronic illnesses need to become educated partners in their care 19.

According to Corbin and Strauss’s chronic illness trajectory framework, eight phases along the illness trajectory were proposed to explain the evolving nature of patients’ and families’ needs, with “trajectory” referring to the course of a
chronic disease in its different stages and phases. As such, chronic illness changes over time, with the person moving from one phase of illness to the next when there is a transition in the disease state. As patients transition out of stable phases along the chronic illness trajectory, they experience increased self-awareness and the seeking of empowerment, through the process of learning, making choices, and identifying changes needed.

During this transitional stage, patients will have intensified information needs and face complex decision-making challenges surrounding lifestyle and medical choices. For example, as patients with diabetes’ conditions develop, they require support through the progress from lifestyle changes to the use of medication and finally onto insulin. As they transition to each phase, they inquire and compare their options to decide on the next course of action. Consequently, during this time, it is especially important to provide informational support to aid informed decision-making, a process that involves various resources and understanding pros and cons of different options.

**Patient decision-making**

The decision-making process is a complex construct, where researchers continue to debate the level of rationality involved in the process. For instance, normative theories of decision-making (e.g., subjective expected utility theory) assumes patients consider decisions rationally and evaluate the risks and benefits of all available interventions. On the other hand, descriptive theories of decision-making (e.g., prospect theory) describes how cognitive biases can cause people to deviate from the rational ideal. The Dual-Process Theory of decision-making states people make decisions either intuitively or rationally where the latter results in less cognitive bias.

While decision-making theories highlight the various factors that influence people’s decision-making behavior, the decision-making process models share common steps leading to making a decision. These common steps include: establishing objectives, gathering information, and comparing alternatives. We are specially interested in the comparison process because it is indicative of decision-making and can be expressed explicitly through comparative terms in the natural language. Thus decision-making inquiry in our study will be characterized by comparison making. This type of inquiry provides a critical window of opportunity to support patient decision-making by informing them of options and about the risks, benefits, and consequences of the options. Decision-making inquiries help the quality of patients’ decisions to be improved. Current studies on patient decision-making, however, focused largely on supporting shared-decision-making between the patient and the clinician during the clinical encounter. Research on understanding patients with diabetes’ decision-making about self-management in everyday settings should be further investigated.

**Informational and emotional support in OHCs**

OHCs are a critical source of information for patients with chronic diseases, and extensive research has been performed on the two main types of social support OHCs offer—emotional and informational support. Researchers identified the critical role of emotional support over informational support in OHCs with regards to community commitment and member satisfaction. Biyani et al. used machine learning methods to identify the emotional and informational support in OHCs and found that influential members provide more emotional support as compared to regular members. Similarly, ‘Caretakers’ personas in OHCs who are long time posters provide emotional support to others. Introne et al. also found that the small, densely connected core members of OHC generate the majority of support for others. Vlahovic et al. looked at support matching and satisfaction, and their findings indicated receiving emotional or informational support predicted increased satisfaction of the support receivers.

Although emotional support is being highlighted as a critical role in OHCs, we know little about how patients with diabetes attempt to make decisions using information from OHCs. Mamykina et al. showed much of diabetes self-management involves the need to make quick decisions under uncertain conditions, such as making nutritional choices, deciding on the best time to exercise, and deciding whether or not to take over-the-counter medication. As a consequence, people come to make sense of these uncertain conditions through discussions with others in OHCs. And the collective sensemaking is achieved by constructing shared meaning through deep discussions, back and forth negotiation of perspectives and conflict resolution in opinions.

The importance of informational support is further highlighted as Budak and Agrawal found informational support more frequently than emotional support in educational Twitter chats. OHC users expressed less satisfaction when they sought informational support but received emotional support, and they expressed more satisfaction when they sought and received the informational support they needed. To improve support elicitation and receiving, Wang et al. presented the conceptual model of social support elicitation and provision, in which they concluded that question asking was effective in eliciting informational support. Moreover, researchers are developing ways to help patients make use of OHC content, such as text classification methods and visual decision-making techniques. However,
the challenge here is that, as patients manage their diseases over time, their information needs in OHCs are complex and change over time as well [40].

To better support patients’ information needs in OHCs, we need to understand how their needs evolve overtime. Massimi et al. 41 surveyed across multiple communities across patients’ health trajectory and concluded that the success of OHCs should not be restricted to growth and active participation and that leaving OHCs should be considered a natural part of the community’s lifecycle. One critical perspective in this finding is the importance of understanding the community’s lifecycle together with individual members’ evolving needs. Zhang, et al. found that the sentiment of posts significant increase over time 42. Wang, et al.’s 33 work further demonstrated that relationships exist between the type of inquiries and the timing of OHC participation in that receiving emotional support strengthens community commitment. On the other hand, informational support satisfied members’ short-term information needs.

Thus, prior research suggests information support benefits members’ changing and specific needs. However, we have limited knowledge of the context surround these needs. Our hypothesis is that OHCs present patient information needs regarding decision making. In this paper, we plan to investigate these needs through decision-making inquiries, and characterize those decision-making inquiries so we can better support information needs in OHCs.

**Methods**

We chose an active, publicly available online diabetes community (anonymized for privacy of the community members) as a data source to examine our research questions. The choice was based on the overall data size (are there enough activities observed in the community) and the public nature of the data. All messages posted to the community were open to public, where all posts can be read publicly and anyone can post using anonymous IDs.

We used a Java program to extract the community’s posts, which included: title, author name, body content, whether the post is a thread initiating post or a reply, and posting date of each post. The extracted posts were saved to a local database program. Since we were interested in the members’ inquiries (e.g., questions) we excluded replies. Thus, in our dataset, we had 2,359 unique posters’ 4,055 thread initiating posts posted between 2009 and 2013. The Institutional Review Board at our university’s Human Research Protections Program determined this project to be exempt.

To extract posts containing decision-making inquiries, we first employed LIWC (Linguistic Inquiry and Word Count) 43 to automatically detect sentiments that represent decision-making. LIWC is psycholinguistic tool that calculates the frequency with which words in a given text match their dictionary of sentiments. These sentiments represent linguistic and psychological constructs such as pronouns, tense, positive emotion, confidence, and fear 43. LIWC is widely validated and tested by researchers from psychology 44, social sciences 45, social computing 46,47, and medicine 48,49 in predicting sentiments for automated analysis of large text. According to our definition, decision-making inquiries are characterized by comparison making, which will be expressed through language with comparative terms. Building on this, we applied LIWC to all thread initiating posts and ranked them based on the “compare” sentiment.

Annotator 1 (First author--A1) first independently analyzed the top 50 posts from the ranked order based on the LIWC score. Out of the 50 posts, 14 posts contained what A1 considered as comparison of alternatives as identified in the decision-making literature 14,15. A1 shared the results with A2 (last author) to iteratively refine the codebook on identifying decision-making inquiries. As a result, for the posts to be included in the content analysis, the posts would have to meet the following criteria, building on the common steps leading to decision-making, which include gathering information and developing and evaluating alternatives 14,15:

1. **Relevance**: Posts have to be about diabetes care (e.g., self-care as well as care for family and friends) For example: “I tried some oatmeal this morning and it was like eating warm, soft cardboard. YUCK! Can u all make some suggestions as to how to make it more palatable??” This post is an example of patients trying out food that works for their taste. It is coded as relevant because diet and food is a main part of diabetes management.

2. **Comparison of alternatives**: The posts have to explicitly compare specific entities in the case of relative comparison (i.e. What is better? A or B?), or inquire superlative comparison (e.g. What is the best?). Alternatively, posts that express comparison in the form of similarities, differences, or choices making (A or B, A instead of B) are also included.

3. **Decision-making intent**: The posts have to reflect decision-making intent. An example of not having a decision-making intent is as follows: “What do you all think which one is harder/worse to have type 1 or 2 and why? Please provide as much detail as possible. And which type has more complications than the other or are they both pretty equal?” This post solicits member discussion comparing experiences between type 1 and type 2 diabetes but do not entail decision-making, thus this post is excluded for analysis.
After developing the codebook, A1 continued to code a total of 801 posts that started a thread, which accounts for approximately 30% of all posts with the “compare” sentiment score larger than “0” (2803 posts).

Results
Out of the 801 posts reviewed, 79 (~10%) met our criteria pertaining to decision-making for diabetes care. Note that we employed a strict, conservative approach to weeding out ambiguous posts that hinder us to establish streamlined process of automatically identifying relevant inquiries. In the excluded posts, 34 (4.70%) were irrelevant to clinical aspects of diabetes care, 13 (1.80%) did not infer further actionable strategies, and 675 (93.49%) did not contain explicit comparison of alternatives. This finding shows that the future step in our research is to further identify aspects of diabetes care, 13 (1.80%) did not infer further actionable strategies, and 675 (93.49%) did not contain OHCs that can inform clean rules for automatic detection of decision-making inquiries. We will next elaborate on our findings on the topic of decision-making, how posters express such inquiries, the triggers and motivations behind those inquiries. In describing these inquiries, we aim to better understand patients with diabetes’ information needs pertaining decision-making.

The topics of decision-making inquiries
Our content analysis informed the subject matters OHC posters needed to gather information and make decisions upon. We found that the inquiries encompassed a range of topics specific to diabetes care, from oral medication, to insulin pumps, to sweeteners. The complete list and the breakdown from the analysis is shown in Figure 1.

![Figure 1. The common topics of decision-making inquiries](image)

Medication was the most common topic of comparison. One in three inquiries talked about medication. Medication included oral medication and insulin treatment. Posters were concerned about medication efficacy, side effects, costs, and when is the best time to take the medications. Questions posters asked surrounding medication were as general as asking if one oral medication is better than another (example post #1). Questions regarding medications could also be specific, where they went into a detailed narrative of personal history and responses to a medication and then asked for advice from peers with knowledge or in similar situation (example post #2).

Example post #1: “Do you think one oral medication is better than another?” (P8)

Example post #2: “I have been prescribed using glipizide... I have been noticing that my blood sugar went up instead of it going down as my healthcare workers told me it should... Does anyone have similar experience with glipizide? Are the other good alternative medications in place of glipizide? Thanks”(P52)

Food followed medication as the second most common topic in decision-making inquiries. As an important part of diabetes weight management, posters expressed various needs to learn about their food options. Newly diagnosed patients were eager to learn what kinds of foods to avoid, as illustrated in this example: “... I have been diagnosed with diabetes. I need to begin a Diabetic Diet right away and I am unsure as to what food would be best for me to eat? What foods would be best for me to purchase from the grocery store... ”(P54) More seasoned patients tried to
optimize their self-care routine by finding out the best foods for blood sugar control “I want to know what food group will help best to keep my sugar level down.” (P31)

Following medication and food, posters inquired about tools, devices used to aid with diabetes self-care, such as logbook and test kit. They were also interested in action plans as to how to proceed when problems came up. Additionally, drinks and sweeteners (sugar/sugar substitute) have been discussed moderately since they are so embedded in one’s daily life and can have an impact on the management of their blood sugar.

How posters express decision-making
We were interested in how posters expressed decision-making (Figure 2). We first divided the inquiries to the categories that might have differing expressions: “soliciting opinions” and “soliciting experiences.” The post would be considered “soliciting opinions” if it asked for opinions, views, or advice. Opinion-soliciting posts comprised the majority of the posts we identified as decision-making (68 out of 79, 86%). These posts tended to not be geared towards a specific group of people. For example, one poster asked: “Which one is the milder oral medication for a diabetic. Glucophage or Actos? Which will be the first one to try?” (P4)

![INQUIRY TYPE](image1)

![COMPARISON TYPE](image2)

**Figure 2.** Inquiry type and comparison type

In the remaining 14% (11 out of 79) of the posts, the posters explicitly asked if others have had similar experience. These posts typically involved a narrative of a specific context of the poster and ended with phrases such as “has anyone used...” “has anyone had experience...”. These experience-soliciting posts tended to be more specific in asking questions, and the posts were targeted towards the portion of posters with similar experience. This pattern is unsurprising since, without concrete contextual information from the poster, it is hard for other posters to self-identify and match their experiences to the poster’s.

After we identified the inquiry categories in these posts, we also uncovered how the idea of comparing alternatives was expressed through the use of language, as illustrated in what we term “comparison types.” Comparison was most frequently expressed with “comparative” terms such as “better”, “more ...” or “as ... as.” An example post would be: “Which one is the milder oral medication for a diabetic. Glucophage or Actos?...” (P4) Posts that encompassed the idea of comparing and contrasting differences and similarities also fell into this category. Subjects of comparison were explicitly stated in these posts as seen in the example of Glucophage vs. Actos.

The subjects of comparison were not as explicitly stated in the “superlative” comparison type. The superlative comparison is characterized by the posts that inquire about “the best” option. An example is as follows; “I have high fasting bg, typically around 115. All other readings are normal. Which medicine would be most suitable for this?” (P53) In this post, no specific medicine was discussed. It invites posters to bring forth suggestions. Due to the lack of explicit comparison topics, this type of posts tended to provide more contextual information, such as the condition of the poster, or the goal the poster wants to achieve.

**Triggers of decision-making**
Patients with diabetes reconstruct life with illness through the process of learning, making choices, and identifying changes needed. This process was reflected through their decision-making inquiries in this OHC, triggered by various conditions, events, or changes along their illness trajectories. These triggers were important to identify because they indicated when in the illness trajectory patients needed information to support decision-making. The triggers also contextualized the motivations behind making the inquiries. We found that the changes in disease states, increased
self-awareness, contradiction in information, and forming a goal or an outcome were the triggers identified from the decision-making posts.

(1) Changes in disease states
Our analysis revealed that posters posted decision-making inquiries when changes in disease states happened or when posters anticipated changes will happen. Examples included when posters learned that they were pre-diabetic with high fasting blood sugar, when posters were recently diagnosed with diabetes and wanted to learn about their required dietary changes, or when posters anticipated beginning insulin treatment. These changes in disease states might necessitate posters to look into their treatment options, or alternatives to their current treatment plans.

(2) Increase in self-awareness
Patients experience an increase in self-awareness along with the changes in disease state 22. However, sometimes changes in the disease states do not need to be present for the self-awareness to emerge. An example of the increase in self-awareness as a trigger in our data was when a poster learned of his family history of diabetes and asked about preventative measures. The increase in self-awareness led the posters to seek information to educate themselves: “I am trying to eat right…I like one kind of bread that is 10 grams of fiber for two slices and same calories as one slice of regular bread. But some contain more whole grain and less fiber. Which is better?”(P9) Being aware that there might be best practices for managing different aspects of diabetes led posters to make decision-making inquiries. Examples included learning how to use a new device, how to manage diabetes with insulin, or even how to obtain the best information. Because few things only have one correct way, learning the ‘how’ involved comparing different methods to find which one was the ‘best’ for the poster.

(3) Contradiction in information
Patients today receive information from various channels. Information can come from physicians, diabetes educators, peer patients, or internet searches. When faced with various sources of information, contradiction is likely to occur. Posters in this OHC posed decision-making inquiries in the midst of information contradiction they faced during this health information seeking process. An example was when the posters were attempting to understand the controversial issue of fruit intake; They inquired to decide whether or not they could eat fruit, and if so, what kinds of fruits. Contradiction also happened when posters’ expectations and experiences did not match. For example, a poster who took ‘glipizide’ for his blood sugar expected his blood sugar to go down with the medication, but instead it went up. This experience led to frustration and the poster’s desire for getting the answers to why the discrepancy happened and what the best practice going forward should be.

(4) Forming specific goal or outcome
When patients do not receive adequate or useful information through conventional channels, they fill their information gap with information culled from OHCs 36. An example showed a poster becoming frustrated with the inability of physicians to prescribe pain medications that worked: “I felt it was going to be a waste of time (with the doctors)...”(P12) As a consequence, the poster turned to OHCs to actively inquire options from other members to manage pain: “Is pot better than the near worthless and addictive Vicoden I have?”(P12)

We also found that posters made decision-making inquiries when they had a specific goal in mind, such as inquiring about options with the most or most desired properties, such as accuracy and reputability, when it comes to devices, or efficacy and safety, when it comes to medications. For instance, a poster is well aware of the current medication’s side effect and kept him/herself educated on the alternatives and formulated an inquiry that demonstrated knowledge and objective: “I read about using Alpha Lipoic to treat neuropathy...I would like to use it instead of Neurontin since I don’t like Neurontin’s side effects. Can I just use the generic kind you find in Walmart, or do I need to get it at a specialty source (like GNC)?”(P38)

Discussion
Our findings filled a gap in understanding the context that gives rise to posters’ decision-making inquiries in online diabetes communities. This context includes the topics discussed for decision-making and posters’ values and preferences for their options. As Sepucha et al, pointed out, the quality of the decision-making process can be improved by helping patients feel informed about the options, as well as the risks, benefits, and consequences of the options 24. Guided by this measurement construct for patient decision aids, we can build a patient-driven, aggregated knowledge base of diabetes management. Recent research looked into developing a problem-solving knowledge base for diabetes self-management 50. We should utilize existing and on-going peer patients’ contributions on OHCs that our posters attempted to gain.
The knowledge of how OHC posters express inquiries pertaining to decision-making in OHCs provided valuable insight for automatically identifying decision-making needs. Identification of such moments has practical implications for supporting decision-making, which will be detailed in the next section.

Technical Implications
Based on our findings we suggest several technical implications, including methods for detecting decision-making inquiries and providing informational support to decision-making inquiries.

(1) Detecting decision-making inquiries
In this study, the decision-making inquiries were identified through a two-step process including ranking by filtering through LIWC features with “compare” sentiment and manual coding. Manual coding distinguished posts relevant to diabetes care, containing comparison and decision-making intent. Our findings informed the following indicators as potential predictors for decision-making inquiries: changes in disease states, increase in self-awareness, information prone to contradiction, and goal- or outcome-oriented languages. However the qualitative indicators need to be fleshed out further in order to transform them into a measurable indicator. This presents a research opportunity for NLP, social computing, and machine learning researchers. Our next step would be to develop these indicators into measurable outcomes and test the predictability on a different diabetes community and to different disease type communities.

Once the identification happens, we can funnel these OHC members to aggregated solutions and knowledge uniquely available in OHCs as discussed below.

(2) Providing informational support to decision-making
We learned that changes in disease states and in self-awareness were some of the triggers for decision-making. We can utilize this knowledge to construct an illness information roadmap along the diabetes illness trajectory. This information road map can help patients situate their conditions and information needs in context. Disease progression and the subjects relevant to a specific disease stage will be identified and included in the road map.

For instance, sugar substitute helps patients with diabetes limit their sugar intake 51 and our findings showed choosing a suitable sugar substitute is among the top five topics of inquiry. The topics can be matched to patients and provide tailored information gathering mechanism. The information on sugar or sugar substitute should then be presented in ways that the patients can easily perform their comparison process on. For instance, when patients come into OHCs trying to decide on sugar substitute, they could be presented with aggregated information on the options people have discussed, as well as their pros and cons. Since the mechanism of comparison is central in human decision-making 52, we can externalize this process by presenting options from previously generated content in an easy-to-compare format.

With a roadmap, patients have access to transparent illness progression information and can anticipate future events and topics. As a result, the uncertainty and anxiety facing patients will be reduced, patients would feel more in control and confident in their knowledge of the condition, and feel more resourceful in managing it.

One limitation of this work is that we applied strict criteria to capture the decision-making inquiries limiting to posts expressing comparison making. Future studies can broaden the scope to include broader instances of the decision-making inquiries. However, the findings contributed to establishing rules we can build on in understanding decision-making takes place in online health communities. Another limitation is that we studied one OHC. Since different OHCs will have different cultures, including patient inquiries, disease characteristics and interaction dynamics, future work could benefit from including a diverse sample of OHCs covering conditions beyond diabetes. Since different forms of social media platforms are emerging with new capabilities for patients to connect with each other and exchange questions and answers, future study should also compare and validate our findings with different platforms in which patient information exchange occurs. Furthermore, our data was limited to what the patients reported on an OHC— we cannot assess the results of their decision-making process in their offline practice. Such limitation is a common one, however, for studying people’s behavior in online communities. Future work should involve triangulating sources not only from OHCs but also their offline behaviors through sensors, surveys, and interviews.

Conclusion
In this paper, we discussed the findings from a diabetes online community’s posts to help us understand patient information needs surrounding everyday decision-making. The knowledge generated through this study shed light on patients’ experience and challenges in the self-management of diabetes. Understanding the implications of the findings will guide us in providing better support for patient decision-making. Our study contributes to understanding decision-making inquiries patients make in OHCs and inform how clinicians, administrators, healthcare institutions, and researchers should approach supporting patients’ everyday decision-making process.

Can SNOMED CT Changes Be Used as a Surrogate Standard for Evaluating the Performance of Its Auditing Methods?

Guo-Qiang Zhang, PhD1,2, Yan Huang,1,2 Licong Cui, PhD2
1 Institute for Biomedical Informatics, University of Kentucky, Lexington, KY
2 Department of Computer Science, University of Kentucky, Lexington, KY

Abstract. We introduce RGT, Retrospective Ground-Truthing, as a surrogate reference standard for evaluating the performance of automated Ontology Quality Assurance (OQA) methods. The key idea of RGT is to use cumulative SNOMED CT changes derived from its regular longitudinal distributions by the official SNOMED CT editorial board as a partial, surrogate reference standard. The contributions of this paper are twofold: (1) to construct an RGT reference set for SNOMED CT relational changes; and (2) to perform a comparative evaluation of the performances of lattice, non-lattice, and randomized relational error detection methods using the standard precision, recall, and geometric measures. An RGT relational-change reference set of 32, 241 IS-A changes were constructed from 5 U.S. editions of SNOMED CT from September 2014 to September 2016, with reversals and changes due to deletion or addition of new concepts excluded. 68, 849 independent non-lattice fragments, 118, 587 independent lattice fragments, and 446, 603 relations were extracted from the SNOMED CT March 2014 distribution. Comparative performance analysis of smaller (less than 15) lattice vs. non-lattice fragments was also given to approach the more realistic setting in which such methods may be applied. Among the 32, 241 IS-A changes, independent non-lattice fragments covered 52.8% changes with 26.4% precision with a G-score of 0.373. Even though this G-score is significantly lower in comparison to those in information retrieval, it breaks new ground in that such evaluations have never performed before in the highly discovery-oriented setting of OQA.

Introduction

Large, comprehensive terminological systems such as SNOMED CT [1] continue to evolve over time, with ontology quality assurance (OQA) an indispensable part of the terminology lifecycle [2]. OQA approaches typically involve the implementation of computational tools that translate ontological principles into specific rules and patterns [3]. Ontological systems are then audited using such tools to infer and flag out substructures violating such rules and patterns, pointing to potential errors to be corrected in the next release after validation and review.

Finding errors in existing ontologies is a creative discovery process. Because of the highly discovery-oriented nature of OQA, the performance measure of precision (i.e., the percentage of true errors among the candidates that have been examined) for auditing methods is neither an initial consideration nor as glorious to quantify, unlike the setting for information retrieval [4]. Similarly, recall, the percentage of errors discovered among all true errors (“the ground truth”), is impossible to measure because of the lack of ground truth: a complete, validated error list is impossible to construct, again because of the highly discovery-oriented nature of the task.

Nevertheless, reference standards, or benchmarking data sets with validated results, have played critical roles for advancing disciplines such as image analysis (e.g., Face Recognition Technology [5] and Wilt Dataset [6]) and information retrieval (e.g., The Text Retrieval Conference series (http://trec.nist.gov)), and would be an important resource for OQA. Despite the fact that it is impossible to obtain precision and recall measures for OQA methods in absolute terms, it may still be meaningful to investigate such measures relative to some “partial ground truth.”

The goals of this paper are twofold: to develop reference sets for evaluating the performance of OQA methods for SNOMED CT, and to demonstrate how such reference sets may be applied to evaluate the performance of lattice vs. non-lattice-based methods with randomized review as a background benchmark. We propose RGT, Retrospective Ground-Truthing, as a surrogate reference standard for evaluating the performance of automated OQA methods. The key idea of RGT is to leverage the cumulative SNOMED CT changes derived from its regular longitudinal distributions by the official SNOMED CT editorial board as a partial, surrogate reference standard. Three performance measures are proposed: RGT recall, RGT precision and RGT geometric mean (G-measure), formulated by adapting the standard measures using RGT relational changes derived from SNOMED CT U.S. distributions as the reference set.

We demonstrate the feasibility of this approach by constructing an RGT reference set for SNOMED CT relational changes and performing a comparative evaluation of the performances of lattice, non-lattice, and randomized relational error detection methods using the proposed RGT measures. A RGT relational-change reference of 32, 241 IS-A changes were constructed from 5 versions of SNOMED CT from September 2014 to September 2016, with reversals and changes due to deletion or addition of new concepts excluded. 68, 849 independent non-lattice fragments, 118, 587 independent lattice fragments, and 446, 603 relations were extracted from the U.S. version 20140301. Com-
parative performance analysis of smaller (less than 15) lattice vs. non-lattice fragments were also given to approach the more realistic setting in which such methods may be applied. Among the 32,241 IS-A changes, independent non-lattice fragments covered 52.8% changes with 26.4% precision with a G-score of 0.373. Our results show that the non-lattice auditing method had significantly better overall performance for detecting incorrect and missing IS-A relations. With independent further work in the accurate identification of specific relational errors contained in individual fragments [7], non-lattice auditing method could prove to be a powerful, versatile approach to OQA.

1 Background

The Evolution of SNOMED CT. SNOMED CT [8] is the most comprehensive, multilingual clinical healthcare terminology in the world, developed by SNOMED International, the trading name of the International Health Terminology Standard Development Organization (IHTSDO). It provides a consistent representation of clinical content in electronic health records and has been used in more than fifty countries. It contains over 300,000 active concepts with unique numeric identifiers (SNOMED ID, or ID in short), organized into 19 hierarchies including Clinical Finding and Body Structure. To connect such concepts, over 1,500,000 relations, including IS-A (subtype) relationships and attribute relationships (e.g. associated morphology and finding site) [9], are constructed and maintained. Release Format 2 (RF2) [10] is used to support reference set creation.

For each version of SNOMED CT, RF2 provides a snapshot folder containing such items as: all active content (concepts, description, and relationships); a “delta” folder which includes identified new and changed content from previous snapshot version; and a “full” folder with the history of all content. Each relationship consists of numeric attributes, such as effectiveTime (date of change), active (“0” for not active, “1” for active), sourceId (the source concept of a relation), destinationId (the target concept of a relation), relationshipGroup, and typeId (relationship type).

Ochs et al. [11] captured editing operations and created an easily understandable SNOMED CT “delta” set that included added relations and removed relations. An inactive relation in the “delta” with type IS-A can be treated as an IS-A relation deletion or an IS-A relation error in the prior version. Similarly, an active relation in the “delta” with type IS-A can be treated as an IS-A relation insertion or a missing IS-A relation in the prior version.

To illustrate, Fig. 1 displays a fragment in the SNOMED CT version 20140301 (left), which was changed in version 20160901 (right) with an IS-A deletion (dashed red line) and an IS-A addition (solid red line).

![Figure 1: An example of SNOMED CT IS-A changes. A fragment in the SNOMED CT 20140301 release (left) was changed in the 20160901 release (right), with an IS-A deletion (dotted red) and an IS-A addition (solid red).](image)

Non-lattice Auditing. We review several related notions for non-lattice auditing (see more details in [12, 13]). The concepts and the IS-A relationship between concepts in an ontology such as SNOMED CT can be viewed as a partially ordered set (poset) \( L \) with a reflexive, transitive relationship \( \leq \). That is, \( L \) is the set of concepts, and \( \leq \) is the IS-A relationship. A concept (or element) \( u \) is called an upper bound of a subset \( X \subseteq L \) if for each \( x \in X \) we have \( x \leq u \). A concept \( m \) is called a minimal upper bound of a subset \( X \subseteq L \), if \( m \) is an upper bound of \( X \), and for any \( n \leq m \) such that \( x \leq n \) for each \( x \in X \), we have \( m = n \). We use \( \text{mub}(X) \) to denote the set of minimal upper bounds of \( X \).

Dually, an element \( l \in L \) is called a lower bound of a subset \( X \subseteq L \), if for each \( x \in X \) we have \( x \geq l \). An element \( m \) is called a maximal lower bound of a subset \( X \subseteq L \), if \( m \) is a lower bound of \( X \), and for any \( n \geq m \) such that \( x \geq n \) for each \( x \in X \), we have \( m = n \). We use \( \text{mlb}(X) \) to denote the set of maximal lower bounds of \( X \).

A lattice pair is a pair of concepts that have a unique maximal lower bound (when the pair has any shared lower bound). For example, on the left of Fig. 2 (an induced subgraph of SNOMED CT, in the sense that all corresponding relations
in SNOMED CT must be included in the subgraph when the nodes are included), the two concepts (in green) “Brain stem infarction” and “Cerebellar infarction” form a lattice pair: this pair has a unique minimal upper bound “Posterior cerebral circulation infarction” (in pink) and unique maximal lower bound “Claude’s syndrome” (in crimson). Thus this concept pair is a lattice pair. This fragment is called a lattice fragment.

A non-lattice pair \((a, b)\) is defined as a pair of concepts that have at least two maximal lower bounds, that is, the size of \(\text{mlb}\{a, b\}\) is greater than 1. For example, on the right of Fig. 2 (another induced subgraph of SNOMED CT), the concept pair “Acute nervous system disorder” and “Cerebral infarction” has two (hence not unique) maximal lower bounds: ‘Vascular dementia of acute onset’ and “Acute lacunar infarction.” Thus this concept pair is a non-lattice pair. This fragment (including the maximal lower bounds) is called a non-lattice fragment.

The Lattice-based Structural Auditing (LaSA) principle (a.k.a. non-lattice auditing [14]) provides a mathematically grounded, error-agnostic method for auditing biomedical ontologies. LaSA focuses on the order structure induced by the hierarchical relationship (IS-A) and requires that such a structure forms a lattice: every concept pair should not have more than one maximal lower bound. It extracts non-lattice pairs and generates non-lattice fragments, consisting of concepts in-between a maximal shared descendant and a member of the non-lattice pair. Non-lattice fragments are in conflict with the Fundamental Theorem of Formal Concept Analysis [15], which states that concept hierarchies derived from the duality of intension and extension always have their order structure being a (complete) lattice. In recent work, Cui et al. [7] provide a new method for mining non-lattice lexical patterns for detecting missing concepts and hierarchical relations in SNOMED CT. Evaluation using a random selected 100 fragments by experts, showed that non-lattice fragments have a high frequency of containing missing IS-A relationships.

2 Methods

We first construct a partial reference set focusing on two types of relational errors derived from the “delta” of SNOMED CT releases: incorrect IS-A relations represented by IS-A deletions, and missing IS-A relations as captured by IS-A insertions. We then perform a comparative evaluation of lattice, non-lattice, and randomized relational auditing methods using the standard precision, recall, and geometric measures.

2.1 Constructing RGT

We use 5 versions (U.S. version 20140301 - U.S. version 20160901) of SNOMED CT for capturing relational changes (change numbers are shown in the second column in Table 1). We focus on erroneous and missing relations on shared concepts, so newly added relations that involve newly added concepts are ignored. An IS-A relational change (or IS-A change in short) with the same source and target concepts may have different “modualId,” which may cause a repeated count. Moreover, IS-A relations may be reversed back to a prior version as a part of the changes in later versions [16]. For example, relation “Streptococcal tonsillitis (ID 41582007) IS-A Tonsillitis (ID 90176007)” is deleted in the July 2014 version and added in the January 2016 version. To construct a robust reference set of relational changes, we perform three preprocessing steps:

- Extracting only IS-A changes;
- Removing duplicated counts and reversed changes; and
2.2 Extracting Independent Lattice and Non-lattice Fragments

We first extract all lattice and non-lattice fragments for the U.S. version 20140301 of SNOMED CT using our MapReduce pipeline [12], which consists of two MapReduce phases to extract non-lattice fragments from large partially ordered ontological structures. The resulting fragments are not “independent” in the sense that one fragment may be contained in another, making further error detection intertwined, as well as violating the independent sampling assumption for statistical analysis. However, given a large collection of fragments, obtaining a reduced “independent” collection with exhaustive pairwise comparison is computationally prohibitive. To address this issue, we formulate the notion of independence as follows. For (induced and connected) fragments \( f_1 = (C_1, R_1) \) and \( f_2 = (C_2, R_2) \) where \( C_1 \) and \( C_2 \) are sets of concepts and \( R_1 \) and \( R_2 \) are sets of relations,

- we say that \( f_2 \) is a subfragment of \( f_1 \) if \( R_2 \subseteq R_1 \); and
- we say that \( f_1 \) and \( f_2 \) are independent \( f \) neither of them is a subfragment of the other.

For example, the non-lattice fragment in Fig. 3 shows the non-lattice fragment generated by the non-lattice pair “Pelvic injury” (ID 282771003) and “Closed fracture of neck of femur” (ID 35982003) has a non-lattice subfragment generated by the non-lattice pair “Pelvic injury” (ID 282771003) and “Closed fracture of neck of femur” (ID 35982003).

In general, a collection of fragments is called independent if each pair of fragments from the collection is independent.

Formally, for a non-lattice pair \((a, b)\) and their maximal lower bounds \(mlb\{a, b\}\), the non-lattice fragment determined by the pair \((a, b)\) is defined as a subgraph containing the concepts between the pair \((a, b)\) and any concept in \(mlb\{a, b\}\). For a lattice pair \((c, d)\), their only maximal lower bound is the unique element in \(mlb\{c, d\}\), and their only maximal upper bound is the unique element in \(mub\{c, d\}\), the lattice fragment determined by the pair \((c, d)\) is defined as a subgraph containing the concepts between the pair \((c, d)\) and the concept \(mub\{c, d\}\), combining the concepts between the pair \((a, b)\) and the concept \(mub\{a, b\}\). The MapReduce pipeline in [12] can be used to exhaustively detect non-lattice and lattice pairs. We further compute independent fragments using the generating pairs.

By definition, comparing all relations between every pair of fragments is required for constructing a dependent collection of non-lattice fragments. To reduce the computational cost involved, we propose an algorithm to detect all possible non-lattice subfragments for each given non-lattice fragment. Lattice fragment dependency can be computed in a similar way.

Let \(P\) be the set of all non-lattice pairs, and \(F\) be the set of all non-lattice fragments for a given SNOMED CT version. Every non-lattice fragment \(f_{(a,b)} \in F\) is generated by some non-lattice pair \((a, b) \in P\). Then \(f_{(x,y)}\) is subfragment of \(f_{(a,b)}\) if

- \((x, y) \neq (a, b), (x, y) \in P, \{x, y\} \subseteq f_{(a,b)}\); and
- for any relation \((u, v) \in f_{(x,y)}, we have \((u, v) \in f_{(a,b)}\).

The second condition is required because a non-lattice pair may generate a non-lattice fragment without itself being a part of the fragment. For instance, the non-lattice fragment in Fig. 4 shows an independent non-lattice fragment generated by the non-lattice pair “Nonvenomous insect bite with infection” (ID 10461000) and “Infected insect bite of upper limb” (ID 283347003). This fragment contains another non-lattice pair “Nonvenomous insect bite of trunk with infection” (ID 19108007) and “Infected insect bite of upper limb” (ID 283347003), although this pair does not generate a subfragment of the displayed fragment.

2.3 Performance Measures

To the best of our knowledge, there are no existing measures for comparing distinct OQA methods. We introduce RGT recall, RGT precision, and RGT geometric mean to measure the performance of OQA methods, motivated by the precision and recall measures commonly used in information retrieval.
We consider an OQA method $M$ as a group of fragments (in general terms as induced subgraphs). Each fragment may potentially capture some ontological errors that involve concepts as nodes and IS-A relations as edges. A fragment $f$ is a graph consisting of a set of IS-A relations. The size of $f$ is defined as the number of concepts involved in it.

We can view a benchmark of validated changes (i.e., ground truth) as a tuple $E = (E_0, E_1)$, where $E_0$ is the set of validated relational errors (where a relation deletion is indicated), and $E_1$ is the set of validated missing relations (where a relation insertion is indicated).

To evaluate the performance of $M$ against $E$, we can break the RGT measure of precision and recall into two categories: measures with respect to deletion, and measures with respect to insertion:

- The deletion recall is defined as the ratio
  $$\frac{|\{r \in E_0 \mid \exists f \in M, r \in f\}|}{|E_0|};$$

- The deletion precision is defined as the ratio
  $$\frac{|\{f \in M \mid \exists r \in f, r \in E_0\}|}{|M|};$$

- The insertion recall is defined as the ratio
  $$\frac{|\{r \in E_1 \mid \exists f \in M, r \in f\}|}{|E_1|};$$

- The insertion precision is defined as the ratio
  $$\frac{|\{f \in M \mid \exists r \in f, r \in E_1\}|}{|M|}.$$

Note that while RGT recall is defined as a ratio of the number of relations, RGT precision is defined as a ratio of the numbers of fragments. One can combine precision and recall to obtain the geometric mean measure (G-measure) $\sqrt{\text{recall} \times \text{precision}}$. The G-measure shows a combined performance of precision and recall. The higher the G-measure, the greater the agreement between an OQA method and the SNOMED CT changes.
3 Results

Relational changes in SNOMED CT U.S. versions ranged from 19,753 in the 20160901 release to 64,676 in the 20160301 release (Table 1). All the changes were calculated based on the released “delta” set for each version. There has been a total of cumulative 263,994 relational changes from the 20140301 release to the 20160901 release, after removing relation reversals and duplicates. Therefore, the cumulative change is not a simple summation of the numbers in all prior changes.

Table 1: SNOMED CT change statistics from U.S. version 20140901 to U.S. version 20160901.

We compared five auditing methods according to our formulation of each method as a collection of fragments. Non-lattice auditing consists of all non-lattice fragments and lattice auditing consists of all lattice fragments. Similarly, independent non-lattice auditing consists of all independent non-lattice fragments and independent lattice auditing consists of all independent lattice fragments. Additionally, single-edge auditing consists of all fragments made of a single relation (edge). This corresponds to randomized edge examination.

We used 20140301 release of SNOMED CT to generate non-lattice fragments, lattice fragments, and single-edge fragments. We also extracted all independent fragments from lattice and non-lattice fragments. To calculate the deletion recall using the RGT formulation, we collected the number of SNOMED CT IS-A deletions discovered through methods (numerator) and the number of 5 versions SNOMED CT IS-A deletion cumulation (denominator). The result is shown in Fig. 5 where the y axis is the numerator and the x axis is the denominator. The 5 numbers of cumulative IS-A deletion $E_0\text{ from 20140901 release to 20160901 release (4,799; 8,965; 13,844; 19,968; and 20,744) were computed in the same way as the last row in Table 1. For each of the 5 methods, the slope is the deletion recall, and the larger the slope, the better deletion recall the method has. The line of best fitting for each method is linear, which indicates that the deletion recall is stable with different numbers of SNOMED CT IS-A deletion for all methods. In other words, deletion recall for each method is almost a constant, e.g., the slope for single-edge is always 1 because
its deletion recall is 100%. Such a feature indicates that deletion recall is a robust measure for OQA method evaluation. With such a feature, we may predict that the IS-A relations deletion recall relative to the ground truth for a method may be close to its deletion recall relative to SNOMED CT IS-A deletion.

We also divide lattice and non-lattice fragments into large sized groups and small sized groups for detailed comparison. We consider larger fragments those fragments with sizes larger or equal to 15, and small fragments those fragments with sizes smaller than 15. The second column in Table 2 presents the numbers of non-lattice and lattice fragments in each group obtained in SNOMED CT U.S. version 20140301, which is the denominator in the formulation of precision. The third column is the numbers of fragment hits (enumerator), the number of changes detected by the methods using cumulative SNOMED CT changes.

Table 2: List of non-lattice and lattice fragments number and hits obtained in SNOMED CT version March 2014.

Fig. 6 displays the results for deletion recall and deletion precision. Fig. 7 displays the results for insertion recall and insertion precision. Table 3 displays the results for the G-measure for IS-A deletion, IS-A insertion, and the changes with respect to each method.

The first three rows of Table 3 show that non-lattice auditing performs better than lattice auditing, which is much better than single-edge using G-measure. From Fig. 6 and Fig. 7, we can find the reason that non-lattice has a higher G-measure is non-lattice has higher deletion recall and insertion recall (79.9% and 53.4%) than lattice while they perform similarly in deletion precision and insertion precision, this means non-lattice auditing has better coverage on incorrect IS-A relational errors and missing IS-A relational errors.

Among all methods, independent non-lattice auditing performed the best on discovering incorrect IS-A relations with a 68.4% deletion recall and a 26.2% deletion precision. Only 68,849 independent non-lattice fragments (about 11% of all non-lattice fragments) exist in SNOMED CT version 20140301, and 62,001 (90%) of them are small sizes (≤15) so that they are amendable for human inspection. Our result indicates that independent non-lattice fragments could play significant role for detecting incorrect IS-A relations for SNOMED CT. However, independent non-lattice fragments failed to perform well on discovering missing IS-A relations, while non-lattice auditing returns the best G-measure in
Figure 7: Insertion recall (left) and insertion precision (right) for each method. The methods are non-lattice (NL), lattice (L), single-edge (SE), independent non-lattice (INL), independent lattice (IL), independent non-lattice with fragments size $\leq 15$ (INLS), independent non-lattice with fragments size $>15$ (INLL), independent lattice with fragments size $\leq 15$ (ILS), independent lattice with fragments size $>15$ (ILL).

missing IS-A relation detection. We noticed that a missing relations is often needed to connect a concept inside an independent non-lattice fragment and another concept outside the independent non-lattice fragment. By this reason, larger non-lattice fragments with sub-fragments are able to catch such missing relationships. The scenario can also lead to undesirable insertion discovering result for independent non-lattice because missing relationships are only detected between concepts inside a fragment.

Table 3: List of G-measures for various methods that detect SNOMED CT changes.

4 Discussion

Small G-scores. Compared with traditional information retrieval methods, the G-scores calculated in this paper are relatively low, even for the higher-performing non-lattice approaches. This should not be a concern for two reasons. One is that SNOMED CT change is continuing with each new release, and we are always dealing with parital ground truth. In lack of the existence of available complete ground truth set, the performances for any OQA methods would suffer. The second reason is that detecting ontology errors or defects is a highly discovery-oriented, and sometimes not even well-defined process. For the first time, this paper introduced a framework to provide the feasibility to calculate G-scores to enable the comparison of distinct OQA methods (but the comparative evaluation of some existing OQA methods may remain infeasible).

Comparison of methods between fragment sizes. By comparing methods with larger fragments sizes and smaller fragments sizes, methods with larger fragments always show better RGT precision than the methods with smaller fragments. It is intuitive that larger fragments have more concepts and relationships so that they have more possibility to contain errors. On the contrary, methods with smaller size fragments present better scores on RGT recall relative to deletion and insertion, which means SNOMED CT IS-A relationship changes are aggregated on small sizes of fragments.

Comparison of populations between methods. Independent non-lattice auditing performed best among the three evaluated methods, with merely 68,849 fragments. To demonstrate the statistical significance, we computed test
statistic Z-scores on precision between non-lattice and lattice (35.5); independent non-lattice and independent lattice (46.8); independent non-lattice and single-edge (201.2); and independent lattice and single-edge (149.3). Independent non-lattice auditing departs the most in outcome from larger population sets consisting of individual IS-A relations.

**Balance of RGT precision and recall.** Our setup for ontology auditing methods to capture quality issues is analogous to capturing fishes using fishing nets. A single method provides a collection of fishing nets. The fishes are the cumulative changes approved by the SNOMED CT editorial panel that have been officially reflected the releases. The nets are the SNOMED CT subsets or fragments determined by a particular method. To illustrate the possibility in the extremes, a method may provide a single net, which is the entire graph of SNOMED CT (100% recall, 100% precision against RGT reference set). But this is useless since no progress is made in making “the haystack” smaller. Another method may provide the finest possible net, which consists of single IS-A relations. This is also useless since it is equivalent to random examination, because of the largest possible numbers of “fishing nets” used. A more useful method should balance the number of “nets” as well as the sizes of the “nets.” We believe this is achieved using independent non-lattice fragments with sizes not exceeding 15.

**SNOMED CT changes vs. the ground truth of relational errors.** The entirety of the ground truth of ontology errors is unknowable because the lack of a complete and validated error list is the inherent nature of the task for OQA. SNOMED CT changes is the most trustworthy error list since it has been generated by the world’s most authoritative group - the SNOMED International Editorial Panel. However, there exist change reversals [16] that need to be accounted for, as is the case in this study.

**Limitations of non-lattice auditing.** Non-lattice auditing [14] is founded on the theory of formal concept analysis. This paper demonstrates a significant difference between the G-scores of lattice vs non-lattice based methods in their ability in capturing official SNOMED CT relational changes. However, knowing a non-lattice fragment contains a relational error and identifying this specific error remains two different matters, as each fragment still contains multiple relations. To address this issue, we developed data mining techniques [7] leveraging structural and lexical information for automated detection of relational errors in non-lattice fragments. Further development of data mining techniques combining a rich variety of information sources represent provide additional research opportunities in this area.

**Changes in the number of non-lattice fragments between versions.** The number of non-lattice fragments can be a significant measure to evaluate the quality of SNOMED CT. We computed the numbers of non-lattice fragments for 4 pairs of versions using shared common concepts between versions: 581,327 (version 20140301) and 575,927 (version 20140901), 562,819 (version 20140901) and 574,028 (version 20150301), 596,015 (version 20150301) and 587,263 (version 20150901), 610,785 (version 20150901) and 604,221 (version 20160301). We did not include the latest version in the comparison because of the sudden drop in the number of relational changes. 3 of 4 pairs showed a decrease of the number of non-lattice fragments. This may suggest that quality assurance work between these versions actually reduced the number of non-lattice fragments. However, the reasons for the unexpected increase in the 20150301 release may need further investigation.

**SNOMED CT versions used for RGT.** We used the latest five versions of SNOMED CT (the March 2017 version was released too late to be included in this study) for feasibility demonstration of our method. This choice was purely a matter of convenience and did not result from methodological or computational limitations of our approach. In fact, it would be desirable to use all the available SNOMED CT versions (in Release Format 1 as well as Release Format 2), with an appropriate starting release as the time-point for computing the fragments. One might only want to go so far to reach a point of relatively stable version (with the sizes of delta sets within a reasonable range). All the performance measures would only improve, as the RGT reference set will become larger. We also noted an abnormality in the sudden drop of relational changes in the 20160901 release, which needs further investigation.

**5 Conclusion**

This paper introduced an innovative notion of RGT reference set for SNOMED CT relational changes and performed a comparative evaluation of the performances of lattice, non-lattice, and randomized relational error detection methods using the newly introduced precision, recall, and geometric measures. An RGT relational-change reference set of 32,241 IS-A changes were constructed from 5 versions of SNOMED CT from September 2014 to September 2016, with reversals and changes due to deletion or addition of new concepts excluded. 68,849 independent non-lattice fragments, 118,587 independent lattice fragments were extracted from the SNOMED CT March 2014 distribution. Comparative performance analysis of smaller (less than 15) lattice vs. non-lattice fragments were also given to reflect the more realistic setting in which such methods may be applied. Among the 32,241 IS-A changes, independent non-lattice fragments covered 52.8% changes with 26.4% precision and a G-score of 0.373, showing non-lattice auditing...
as a superior approach than lattice auditing, confirming a theoretical predication implicitly given in [7, 14].

Acknowledgment

We thank Shiqiang Tao and Wei Zhu for their contribution to the development of tools used in this paper for non-lattice visualization. This research was supported in part by University of Kentucky Center for Clinical and Translational Science (Clinical and Translational Science Award UL1TR001998) and National Science Foundation under MRI award No.1626364.

Abstract

Patient portal and personal health record adoption and usage rates have been suboptimal. A systematic review of the literature was performed to capture all published studies that specifically addressed barriers, facilitators, and solutions to optimal patient portal and personal health record enrollment and use. Consistent themes emerged from the review. Patient attitudes were critical as either barrier or facilitator. Institutional buy-in, information technology support, and aggressive tailored marketing were important facilitators. Interface redesign was a popular solution. Quantitative studies identified many barriers to optimal patient portal and personal health record enrollment and use, and qualitative and mixed methods research revealed thoughtful explanations for why they existed. Our study demonstrated the value of qualitative and mixed research methodologies in understanding the adoption of consumer health technologies. Results from the systematic review should be used to guide the design and implementation of future patient portals and personal health records, and ultimately, close the digital divide.

Introduction

The successful treatment of many chronic diseases, like diabetes mellitus, has long been facilitated by strong patient investiture in his or her own healthcare. Empowered and well-informed patients who have access to their personal health data—such as their HbA1c trend over time—may be persuaded to make sound behavioral modifications that correlate with their disease progression. Patient portals and personal health records (PHRs) typically provide patients with access to their laboratory and imaging results, alternative modes of communication with their providers, and many other benefits.

Despite the availability of patient portals and PHRs for nearly a decade, the adoption rate and use of both consumer health technologies among patients have been low. Researchers are becoming increasingly attentive to the barriers that prevent certain members of the population from using patient portals and PHRs. Factors related to socioeconomic status, race, age, or health condition should not influence the penetrance of patient portals and PHRs into society to the extent that they currently do. These technologies need to be embraced across the population to be optimally effective, otherwise disparities in the quality of and access to care will increase.

Given the growing body of literature on the topics of patient portal and PHR adoption and use, in addition to regulatory pressures on healthcare organizations to increase patient enrollment, the need has arisen for a critical analysis of the current literature to best understand how to pursue subsequent research and policy endeavors in a meaningful way. In this study, we aim to systematically review the literature to identify publications that specifically address barriers, facilitators, and solutions to successful enrollment and use of patient portals and PHRs.

Methods

Overview & Scope

Patient portals are secure online tools that can stand alone or be tethered to a healthcare organization’s health record, through which patients can access their personal health information from anywhere with an internet connection. PHRs are online applications that are owned and managed by patients or their proxies and allow for patient input of information for greater control of patients’ own health information management. While the two consumer health technologies serve different functions for patients in terms of ownership, the factors that hinder or facilitate their enrollment and use are fairly equivalent. Moreover, patient portals and PHRs at times are used interchangeably in
the literature. Therefore, we conducted our systematic review to address barriers and facilitators of adoption and use of both patient portals and PHRs, rather than try to determine whether authors meant one versus the other based on terminology and context. In this study, any reference to patient portals is meant to be synonymous with a reference to PHRs, unless explicitly indicated.

Our review included studies that identified barriers, facilitators, and/or solutions. The reason for delving into all three rather than focus on one was to gain an in-depth understanding of what exactly has been studied in the literature and what else remains to be studied. For the scope of this review, the following traditional definitions were used:

- **Barrier**: a law, rule, problem, etc., that makes something difficult or impossible. 5
- **Facilitator**: one that helps to bring about an outcome by providing indirect or unobtrusive assistance, guidance, or supervision. 6
- **Solution**: an answer to a problem. 7

For the purposes of this study, the term “solution” included proposed or implemented methods to address enrollment or usability barriers, even if further study was still required. As such, “solutions” should be distinguished from “facilitators,” which have been studied and proven via evidence to help bring about improvements in patient portal enrollment and use.

Selections for analysis were made from quantitative, qualitative, or mixed methods studies published in scientific journals, peer-reviewed conference proceedings, and reputable sources identified by domain experts. Purely descriptive studies of patient portals or of individual characteristics (e.g., age, gender, race) were excluded from analysis.

**Literature Search**

The search strategy, including the Medical Subject Heading (MeSH) terms and keywords, was developed and performed under the guidance of a health science librarian (DS). The search was performed using MEDLINE® via Ovid as the database. This particular database was chosen for the level of granularity authors could employ in the search strategy compared to other databases. The search query used was [“Patient access to records” (MeSH) OR “patient participation” (MeSH) OR “health records, personal” (MeSH) OR “patient portal” (keyword) OR “web portal” (keyword) OR “patient health record” (keyword)] AND [“health services accessibility” (MeSH) OR “health knowledge, attitudes, practice” (MeSH) OR “patient acceptance of health care” (MeSH) OR “user-computer interface” (MeSH) OR “implementation barrier” (keyword) OR “usability” (keyword) OR “human factors” (keyword) OR “barriers to access” (keyword) OR “facilitators to access” (keyword) OR “provider access” (keyword) OR “caregiver access” (keyword)]. All searches were limited to human studies and published in English between the years 2000 and 2017 with full text availability. Reference mining was performed on key articles and from content experts. Prior systematic reviews were used to identify original studies.

**Screening & Data Extraction**

Three authors (JZ, EA, & BS) screened seven hundred twenty titles and abstracts for eligibility. Selected full-text articles were read in their entirety to determine final inclusion or exclusion (Figure 1). Initial screening and data extraction were performed together to facilitate inter-rater reliability. Subsequent screening and data extraction occurred independently. The workload was distributed evenly among authors at each screening iteration. Any discrepancies that occurred were discussed and resolved through consensus-building.

**Analysis**

At least two authors reviewed each article. Authors independently took notes on barriers, facilitators, and solutions mentioned in the selected full-text articles and recorded their findings in a shared data shell. Recurrent themes were identified and used to code the extracted data (Table 1).

**Results**

Seven hundred-twenty citations from MEDLINE® via Ovid were identified by the literature search. Forty-one were identified as potentially eligible after screening through titles and abstracts. Fifteen articles met eligibility after full-text review. Seventeen additional articles that met eligibility criteria but were not found via the initial literature
search were identified by reference mining. Thirty-two articles were ultimately included in the review (Table 2). Of the included articles, eight were quantitative, nineteen were qualitative, and five were mixed methods studies. Several of the captured themes were represented across studies (Figure 2).

**Barriers**

Thirteen studies identified attitude or culture as a barrier to effective enrollment and use of patient portals. Patients either felt overtly negative toward the patient portal (e.g., self-tracking was explicitly perceived as extra work, distrust of the healthcare system as a whole was a cultural norm among certain populations and patient portals were viewed as unwelcome extensions of healthcare) or were satisfied with the status quo (e.g., concern that embracing patient portals would erode the personal patient-physician relationship).

Six articles acknowledged mixed or negative attitudes among providers as barriers. Providers felt conflicted over whose responsibility it was to promote the patient portal and saw the patient portal as extra work added to an already long list of burdensome clinical responsibilities.

Thirteen studies mentioned interface challenges. Problems ranged from unintuitive design elements that created navigation difficulties to the use of text or language at a reading comprehension level too high for most users. In fact, most non-users had not completed high school, which exacerbated their ability to fully comprehend the complexities of their various comorbidities. Nine studies specifically made a point to underscore that no amount of patient portal training could help patients who were functionally illiterate at baseline. Many non-users also had poor digital literacy or lacked computer or internet access. Among these were patients who felt uncomfortable using public resources to access private health information online, e.g., at a public library.

In six of the studies, patients either had not been fully educated about the extent of functionalities offered by the patient portal and felt that the features they knew about were not worth the hassle of continued use, or had not even been informed about the patient portal’s existence prior to the study. Technical or logistical difficulties with the enrollment process (e.g., difficult navigation, lack of information technology support) prevented interested patients from completing registration in fifteen studies.

Privacy concerns were captured as barriers in five studies. People did not have adequate assurance that their personal data were secure on the internet. Others desired extra security after logging into the patient portal or PHR to hide the display of sensitive information. This finding was notable among senior patients who often required the assistance of family or friends to help them navigate the patient portal or PHR or to use it on their behalf via proxy access.

Cost concerns were addressed in two of the studies. Certain users chose to not explore different patient portal features out of concern they might be charged. These same users expressed willingness to pay for extra features in the portal (e.g., after-hours secure messaging with their physician) so long as prices were made transparent.

**Facilitators**

Ten studies identified successful registration as a facilitator to continued patient portal use. Institutions with support staff—i.e., informational technology personnel, nurses, and even doctors—who dedicated time to walk patients through the patient portal and show them the various capabilities on one or more trial runs were successful at committing patients to enroll. Patients who had family members help them enroll were also successful. Twelve studies described the benefits of training. Many patients were interested but felt uncomfortable navigating the patient portal. Training engendered familiarity with the interface and enabled ongoing use of the patient portal.

Patients and providers were likely to use the patient portal if they perceived the patient portal to be more beneficial than existing options (e.g., secure messaging versus calling). This was largely dependent on prior use of the patient portal as well as provider buy-in. To convince patients to enroll, providers had to promote the patient portal in the legitimate context of a clinical visit and provide assurance that the patient portal would supplement, not replace, the existing patient-physician relationship. Providers were particularly effective advocates of the patient portal or personal health record among senior and minority patients. Five studies described how
Figure 1. Flow diagram of article selection and elimination.

Table 1. Two examples of how similarities between extracted data about barriers, facilitators, and solutions (notes made by JZ, EA, BS) were codified by theme (rightmost column).

Patients with chronic illnesses often relied on the patient portal to request prescription refills or to prepare for their next clinic visit.⁴,¹⁵,²⁵-²⁶,³⁷

Six studies identified iterative feedback loops as critical facilitators. Patient portals that went through multiple rounds of usability testing and relied on user feedback prior to modifications often found greater success in patient adoption and use.¹¹,¹³,¹⁶,¹⁸,³¹,³⁸ Being able to make timely evidence-based improvements was also key to steadily increasing user enrollment and maintaining continued use by patients.

**Solutions**
Eight studies promoted policy changes at the public and institutional level to stimulate increased computer and internet access, and to emphasize the impact of the digital divide as a public health concern. 4,13,24,28,30,34-35,37 Eleven studies proposed training and support for patients on digital basics and on the patient portal. In two studies, authors advocated for the continuation of traditional health information resources in print form.14,24 Authors from thirteen studies advocated for more aggressive tailored marketing strategies toward disadvantaged populations. The key was to indiscriminately highlight all advantages of the patient portal, and not solely emphasize its potential as a self-management tool. Self-management was often viewed more as burden than benefit among disadvantaged, chronically ill patients.4,13-16,18-19,24,26-29,32 Transparency about patient portal capabilities, security features, and costs of services was also encouraged.

Redesigns in patient portal interfaces were mentioned in seventeen studies.4,8-10,12,15-18,24-25,28,30,32,34-35,38 Authors advocated for standardization in the creation of future patient portals. Easy-to-use, easy-to-navigate interfaces and simpler language were all encouraged to attract patients across socioeconomic groups. Six studies indicated the need for more consumer health informatics research.10,12,26,29,33-34

Discussion

Patient portals and PHRs were conceived as revolutionary and transformative patient engagement tools, but the reality has been disappointing given low enrollment and usage equitably across populations. Efforts have been made in recent years by researchers to understand the factors that contribute to the success or failure of consumer health technology adoption. Our systematic review evaluated all publications since 2000 that specifically addressed barriers, facilitators, and solutions to optimal patient portal and PHR enrollment and use. Popular themes were identified.

Negative attitudes by patients posed one of the most common barriers. Negative attitudes ranged from outright refusal to engage with the technology, to apathy or ambivalence. Without the provision of a clinically relevant context to the data displayed, patient-accessible laboratory work or imaging results came across to patients as meaningless, confusing, and in the worst-case scenario, even detrimental. On the other hand, patients’ perception of the patient portals’ value increased after the patient portals’ capabilities were showcased and demonstrated, particularly when done so by their providers. For instance, patients who were older or had multiple comorbid conditions represented users who saw great value in having an online resource to keep track of their many medications and provider recommendations. Moving forward, healthcare organizations will need to make greater efforts to recruit providers in the promotion of consumer health technologies without these efforts being seen as yet another clinical documentation burden.

Toward that end, marketing and outreach need to occur indiscriminately, while being sensitive to the likelihood that users from different socioeconomic statuses and cultures may have different expectations of the patient portal. These solutions reflect the bare minimum requests by researchers to prevent the digital divide from widening. The onus falls on informatics societies, such as the American Medical Informatics Association, to not only raise the bar for consumer health technologies by establishing and promoting gold standard guidelines for the design and implementation of patient portals and PHRs, but to also hold vendors and healthcare organizations accountable.

Having a governing body oversee standardization of patient portals and PHRs is more important than ever, especially since our systematic review has revealed that the other most common barrier to patient portal and PHR registration and use is the lack of a user-friendly interface. While providing staffing and resources to help patients interact with the patient portal interface has proven beneficial, particularly in alleviating stress or anxiety associated with patient portal enrollment and navigation for “digital immigrants (individuals who do not or cannot access computers and the internet on a regular basis, e.g. the poor and the elderly),” the reality remains unchanged that many interfaces are long overdue for a facelift.

Future Directions

Consumer health informatics is a growing discipline. Our review of the literature has provided patient portal and PHR vendors and the institutions that purchase them a succinct summary of all available evidence-based strategies to recruit and retain patient portal and PHR users. Ongoing research, particularly in the domain of human factors and usability testing, would be beneficial for the continued optimization of consumer health technology adoption. 39-40

Conclusion

We conducted a systematic review and identified several themes in barriers and facilitators of patient portal and PHR adoption and use. Common barriers were negative attitudes by patients and interface problems. Frequently reported facilitators were perceptions of benefit and the provision of patient portal and PHR training. Interface redesign and improved marketing and outreach were popular solutions. More research is needed in human factors and usability testing to understand how to engage and motivate patients toward improved health outcomes. Sufficient penetration of patient portals and PHRs into patients’ routine healthcare practices will provide researchers and providers the opportunity to harness the intellect, energies, and care of patients to achieve mutual healthcare goals.

Abstract
Quality reporting that relies on coded administrative data alone may not completely and accurately depict providers' performance. To assess this concern with a test case, we developed and evaluated a natural language processing (NLP) approach to identify falls risk screenings documented in clinical notes of patients without coded falls risk screening data. Extracting information from 1,558 clinical notes (mainly progress notes) from 144 eligible patients, we generated a lexicon of 38 keywords relevant to falls risk screening. 26 terms for pre-negation, and 35 terms for post-negation. The NLP algorithm identified 62 (out of the 144) patients who falls risk screening documented only in clinical notes and not coded. Manual review confirmed 59 patients as true positives and 77 patients as true negatives. Our NLP approach scored 0.92 for precision, 0.95 for recall, and 0.93 for F-measure. These results support the concept of utilizing NLP to enhance healthcare quality reporting.

Background
Falls are a leading cause of injury in the elderly population and a significant morbidity and mortality risk factor. Approximately 35-40% of generally healthy people over 65 fall at least once each year.1 The risk of falling increases proportionately with age. At 80 years, over 50% of seniors fall annually.2 Over 20% of falls cause a serious injury such as hip fracture or brain trauma.3,4 In 2012-2013, 55% of all deaths due to unintentional injury among the elderly came from falling.5 The estimated direct medical costs for fall injuries in the U.S. alone are $31 billion annually.6 Clinical screening of fall risk can significantly prevent falls.7,8 However, less than half of the elderly patients who fall discuss the fall with their health care providers.9 In 2001, The American Geriatrics Society and British Geriatrics Society (AGS/BGS) published a clinical practice guideline on falls prevention and management in older persons. The AGS/BGS guideline specifies that, at least annually, providers should ask all elderly patients if they had a fall or had no fall during the prior year.10 Moreover, falls risk screening is a core quality measurement required by the Centers for the Medicare and Medicaid Services (CMS) payment incentive program under the Affordable Care Act (ACA).11 Primary Care Providers (PCP) can receive reimbursement for falls risk screening through voluntary participation in the Physician Quality Reporting System (PQRS).12 In 2015, the Medicare Access and CHIP Reauthorization ACT (MACRA) became law, offering value-based alternative payments for reimbursing physician services through a Merit based Incentive Payment System (MIPS).13 In performance year 2017, falls risk screening remains a high priority measure in MIPS.14 Both PQRS and MIPS require reporting the percentage of patients aged 65 years and older who had a risk screening for falls within the prior 12 months. They both use a set of CPT or HCPCS codes to define the denominator and numerator for this quality measurement. However, coded data alone may not completely or accurately reflect clinical activities that providers performed during their practice. Clinical narratives, such as visit notes, admission notes, progress notes, consultation notes, and nursing notes contain important information and are increasingly available in electronic form. However, obtaining structured information from free-text clinical narratives is a major challenge. Natural language processing (NLP) is a technology that uses computer-based linguistics and machine learning approaches to extract and classify information automatically from free-text data.15 NLP offers an opportunity to identify clinical information from narrative documents and holds the promise of enhancing data availability and quality for diagnostic, patient safety, clinical decision support, and quality performance reporting.16-19 In this study, we developed an NLP approach to identify documented falls risk screening in clinical notes of patients lacking discretely coded falls risk screening. We also formally evaluated the NLP algorithm performance against a gold standard (i.e. domain expert manual review). We hypothesized that this NLP approach could correctly identify more falls risk screening in electronic health records (EHR) than the quality metrics based on by administrative codes. Confirmation of this hypothesis would support using NLP approaches to enhance current quality reporting systems.
**Methods**

**Data resource and NLP software**

The primary study setting was the Medical University of South Carolina (MUSC). MUSC is an academic medical science center with inpatient, outpatient, and emergency facilities serving Charleston, South Carolina, and surrounding areas. MUSC has had the EpicCare EHR system (Epic Systems Corp., Verona, WI) in place for outpatient care since 2012 and for inpatient care since 2014. A Research Data Warehouse (RDW) copies the Epic data warehouse and serves as the data repository for clinical research. This study tests the feasibility of identifying mentions of falls risk screenings in clinical notes using NLP for the defined patient population. Clinical narratives collected during 2015 for MUSC Medicare outpatients are available for analyses, including progress notes and consult notes. This study was approved by the MUSC data access committee. We used commercial NLP software (Linguamatics I2E version 4.4, Cambridge, United Kingdom) licensed by MUSC to index, parse, and query each clinical note for this project. Linguamatics I2E (I2E) applies concept-based indexing techniques to electronically identify key words/phrases from text documents and map them to concepts in the UMLS Metathesaurus. Then, I2E queries retrieve information for reports meeting a user-defined set of criteria through a user-friendly interface to define syntactic and semantic representations.

**Measurement of falls risk screening**

For performance year 2015, MUSC used screening for future falls risk (CMS193v3) to report the percentage of Medicare patients 65 years of age and older who were screened for falls risk during the measurement period. The numerator is the number of patients who were screened for future falls risk at least once during the measurement period. Two CPT codes, 3288F and 1100F, are required on the claim form to submit this numerator option. The denominator is the number of patients from the initial Medicare outpatient population. Exceptions for the denominator are documented medical reasons not to screen for falls risk, including the patient being non-ambulatory or wheelchair bound. We developed an NLP algorithm and conducted a performance evaluation based on CMS193v3.

**Development of the lexicon for falls risk screening**

In practice, providers record clinical findings and activities as narratives for each patient encounter, including symptoms, health histories, physical exam results, consultation services, and care plans. In these clinical narratives, NLP can identify mentions of falls risk screening that providers performed during the encounter. A domain expert, a nurse analyst with extensive quality measure experience, manually reviewed 144 patient charts and generated an initial list of terms that were commonly used to represent falls risk screening. These initial terms included “fall,” AMPAC (Activity Measure for Post Acute Care), and ADLs (Activities of Daily Living measures) plus mention of fall. Without domain expert engagement, the NLP informatics team then developed a draft full terminology set based on this initial list. We also generated modifiers (e.g. “evaluation,” “associated symptoms,” “risk screen,” “history of,” etc.). I2E provides default detection of pre- and post-negation, a collection of regular terms that are negative mentions (e.g. “no,” deny,” “negative”). However, the I2E default clinical negation detection is not sufficient to exclude a “false” falls risk screening in clinical notes. In fact, when a patient is identified as “no fall” or “denied falls” in clinical notes, a falls risk screening had likely been conducted during the encounter. Therefore, we considered such negative mentions of falling as true cases of falls risk screening. Another area of ambiguity included words associated with “falling” that might represent lab value decreases (e.g., “hgb fall,” “bone density fall,” “ejection fraction fall”), vital sign reductions (e.g., “weight fall,” “BP fall”), seasons (e.g., “last fall,” “in the fall”), problems (e.g., “fell on ice,” “fall with fracture”), or others (e.g., “fall asleep”, “drain fall”, “fell out”). In context these terms are not relevant to a fall screening and were reconsidered as valid negations for this study. We also included in our negation criteria terms that reliably indicate a non-ambulatory patient (e.g., “wheelchair bound”, “bed bound”) because a non-ambulatory patient is excluded from the denominator for CMS falls risk screening measures. For each term, we utilized the I2E morphologic variants functions and I2E built-in ontology to generate a set of spelling variants, acronyms, and abbreviations; we then queried these terms against clinical notes to extract any relevant lexical representations to form an enhanced and refined list. The domain expert and the NLP informatics team came to consensus agreement, creating the final lexicon. A final lexicon list was imported to the I2E customized macros, which allows for reuse and refining.

**Development of NLP algorithms to identify falls risk screenings**

We developed a set of NLP queries to identify falls risk screening mentions in clinical notes (progress notes and consults notes), using the following criteria: A) mentions of falls by the lexicon; and B) excluding fall mentions with negations. These NLP queries were designed to capture semantic information, syntactic patterns, and clinical negations in order to translate a documented falls risk screening to structured data elements including: 1) patient MRN;
2) falls risk screening; 3) note create date; 4) note updated date; 5) author type; 6) note ID; and 7) type of clinical note. We used I2E 4.4 to index, query, flag, and count the number of query hits within each type of clinical note. We used all clinical notes for 144 patients to develop an NLP algorithm for each variable, evaluated the results of the NLP queries independently and in combination against the gold standard of expert chart review. These NLP and chart review evaluations were done independently by a domain expert, who was blinded to the patient source. Discrepancies between query results and the manual expert review led the informatics team to iteratively refine and develop the I2E query algorithms until sensitivity and specificity could not be further improved or could not reach predefined thresholds. A multiple I2E query combining these 7 queries was established to produce a structured output table to store information extracted by the 7 queries.

**NLP algorithm performance evaluation**

For clinical notes from all 144 patients, we compared the results generated from the I2E multiple query to the results from the gold standard. A domain expert further validated the results for both positive and negative cases of NLP-detected falls risk screening by manual chart review. The average times for falls risk screening case identification by both the I2E multiple query and manual review of clinical notes were reported and compared. Furthermore, we calculated three standard performance measures for the NLP algorithm: the precision, recall, and $F$-measure. Precision (exactness) is the proportion of true positives to the total number of algorithm-identified cases; in contrast, recall (completeness) is the proportion of true positives that are retrieved by algorithms. $F$-measure is a weighted harmonic mean of precision and recall ($F$-measure $=2 \times \frac{\text{precision} \times \text{recall}}{\text{precision} + \text{recall}}$); an $F$-measure reaches its best value at 1 and worst at 0. Finally, for all false positives and negatives generated by the NLP algorithms, the reasons for false classification were manually determined and summarized to improve the algorithm.

**Results**

**Falls risk screening lexicon**

Using the Epic Medical Shared Savings Program (MSSP) abstraction assistant tool, we identified 144 patients who were Medicare outpatient beneficiaries and had no discrete fall screening results recorded during 2015. The I2E multiple query processed 1,588 documents (1,575 progress notes and 13 consult notes) from these 144 unique patients within 0.5 seconds comparing with 10 hours by manual review. The average number of document per patient was 11 (max: 106; minimum: 2). We developed a set of I2E queries to search the initial key words ("fall," "ADLs," "AMPC," etc.) against these 1,588 documents. After iterative evaluations between the keywords hit and the original documents, we developed a lexicon of falls risk screening and negations. The final lexicon presented wide variations (Table 1). A total of 38 terms associated with falls risk screening resulted in 397 hits in 223 documents from 93 unique patients. The leading keywords were "fall" and its morphologic variants (236 hits, 67.4%), "fall risk" (42 hits, 11.7%), and "denies any falls/no falls/ Denies falling/no recent falls" (22 hits, 6.2%). Among 26 pre-negations, the leading terms were "fracture fall," "this fall," and "in the fall." Among 35 post-negations, the leading terms were "fall at," "fall in," "fall on," and "fall of [a year]". The most common note in which these instances occurred was a progress note, and the most common author types were physician, physical therapist, and physician assistant (Figure 1).

NLP algorithm performance

The multiple I2E query combining seven I2E queries produced a structured output table which extracted a patient MRN, note ID, keywords for falls risk screen, the sentences where keywords hit, note type, author type, and note creation date. It also provided a link to the original document, which the NLP developer and domain expert could review during the development and evaluation phases (Figure 2). Among 144 patients, I2E query identified 93 patients with a likely mention of falls risk screening from 223 documents. Applying both pre- and post-negations, NLP identified 62 patients (40.2%) with falls risk screening from 118 documents. The domain expert’s manual review identified 64 patients who had falls risk screening and 80 patients who did not have a falls risk screening. The I2E algorithm and manual review identified, in common, 59 patients who had falls risk screenings and 77 patients who had no falls risk screening. Three non-ambulatory patients were identified by both NLP and manual review. The I2E query for falls risk screening had a precision of 0.92, recall of 0.95, and an F-measure 0.93 (Figure 3). A major reason for false negatives and false positives was that our NLP approach could not clearly distinguish a fall event as the reason of a clinical visit from a falls risk screening in some clinical notes (Table 2).

**Discussion**

Using Lingumatics I2E, we developed an NLP lexicon and algorithms to detect mentions of falls risk screening in clinical notes (mostly progress notes) automatically for patients who had no coded falls risk screening reported to PQRS through Epic MSSP. Our NLP algorithms sufficiently extracted and aggregated necessary quality outcomes for falls risk screening and achieved high performance as evaluated with our gold standard. Our study results confirmed that NLP can enhance current quality reporting approaches for falls risk screening. The potential value of NLP enhancements for quality regulatory reporting is extremely high for measures such as annual falls risk screening. Nevertheless, we strongly caution against the use of current NLP technology and algorithms as we have utilized here for official measure reporting. However, automated NLP assessments could be used periodically throughout a quality measure reporting period to help gauge individual and group provider performance and encourage needed discrete documentation. Moreover, some regulatory quality metrics do allow manual abstraction; for example, limited and official chart review could confirm a positive NLP result for falls risk screening within clinical notes that had not been coded. That might well result in significantly better and more accurate provider group performance on the regulatory measure.

Information about falls risk screening is commonly documented in clinical notes, and completely and accurately extracting mentions of falls risk screening from clinical narratives using NLP is an achievable although challenging goal. To the best of our knowledge, this is the first report of NLP–based extraction for quality reporting on falls risk screening. Other studies have focused on falls detection, with variable accuracy. For example, Toyabe reported a high accuracy (F-measure: 0.91) NLP approach to identify inpatient injuries from image order entries; he also noted that his NLP algorithm for identifying inpatient falls in progress notes only achieved an F-measure of 0.12 because of the high number of false-positive cases.\(^{23}\) Elsewhere, Shiner et al. reported about an NLP algorithm to detect falls in progress notes with modest accuracy (specificity: 0.80; sensitivity: 0.44), as evaluated by manual review.\(^{24}\) While these studies were designed to detect a “fall incident,” our NLP algorithms were designed to detect a “falls risk screening” event from clinical notes, an NLP task posing more challenges. Initially, we used terms related to “fall risk” and “fall screening” to probe a falls risk screening; however, in clinical practice, providers may not use these terms to document falls risk screening even when they have actually performed it. For example, providers may document screening with the following statements: “Patient has no fall in the past year” or “no fall.” Providers may also document clinical information relevant to falls as “there have been some falls, memory loss,” or “fall or dizzy when standing.” Prior types of NLP algorithms would not likely detect these cases nor do typical coding procedures. Therefore, we used the term “fall” as the major search term in order to mimic a common way that providers document a conversation about falls with patients. Before applying negations, a hit of “fall” is much more frequent than hit of “fall risk” (236 vs. 42 mentions in our corpus).
We applied negation detections to classify a mention of “fall” into either a positive case or a negative case of falls risk screening. At the same time, it was important to keep in mind that the term “fall” may have other linguistic meanings that would cause false positives for “falls risk screening” identification. For example, a description of a “fall event” (“fall on wall,” “fall with broken arm”); a season of the year (“last fall,” “fall 2014”); or “fell” as a typo for “feel.” We established a set of pre-negation and post-negation detection rules in order to eliminate false positives; however, these negations also introduced false negatives. For quality reporting, we expect a highly specific (avoiding false positive) NLP algorithm by sacrificing sensitivity. After iterative evaluation and refinement, our final I2E algorithm achieved 0.92 precision and 0.95 recall, which indicated that our NLP approach could effectively identify falls risk screening in clinical notes of patients who had no coded falls risk screening recorded in their EHR.

Our NLP approach accurately identified 59 patients without coded falls risk screening (out of 144) who had a falls risk screening documented in their clinical notes. These patients were previously misclassified as having no falls risk screening performed by their PCPs. This result indicates that quality reporting based on administrative coded data alone may not accurately measure the quality of care providers performed. After years of PQRS implementation, CMS noted that potential data quality issues exist among reporting systems, such as missing data elements and inaccurate or incomplete quality measure calculations. CMS also highlighted that completeness and accuracy of data are critical to the accurate calculation of a quality performance score.23 Researchers have suggested multimodal approaches rather than relying on a single data resource to capture clinical events.26, 27 Recently, quality reporting studies, including colonoscopy quality metrics, postoperative complications identification, and advanced adenoma detection, demonstrated that the NLP-based approach offers a powerful alternative to either unreliable administrative data or labor-intensive manual chart reviews.28-30 In order to reduce non-reporting issues for measuring falls risk screening, one potential strategy is to incorporate NLP-extracted information on quality indicators that exist in the clinical notes as the supplemental data source for current quality reporting systems.

Limitations
Four major limitations are identified for this study. First, the study population (negatives by coded data) only included 144 patients, and we estimate that relatively small number of patients could be identified as cases of falls risk screening; therefore, we did not split the clinical notes into a training and testing set. In order to obtain the NLP performance for the testing set, we plan to include 2014-2016 data and randomly sample a training and testing set to reevaluate our NLP algorithm. Second, we only used clinical notes from patients who had no administrative coded data recorded for falls risk screening to develop our lexicon and NLP algorithms. Indeed, providers may document a falls risk screening differently in clinical notes for patients who had coded falls risk screening. On the other hand, providers may possibly not document a falls risk screening in clinical notes at all because these screening activities are assumed to be reported through a coded form. In fact, MUSC also uses the Morse Fall Scale to assess falls risk for hospitalized patients; and this information is usually not documented in clinical notes. Therefore, our NLP approach would not reliably identify patients who had been assessed with the Morse Fall Scale. A further study focusing on NLP strategies identifying falls risk screening for cases confirmed by coded data may help refine the lexicon and NLP algorithms. Finally, this study was designed for the context of MUSC quality reporting purposes. Our lexicon and NLP algorithms may not be generalizeable to other institutions without customization and evaluation. However, the concept of NLP-based approaches to enhance PRQS reporting may well be applicable to other healthcare settings.

Conclusions
Information about falls risk screening can commonly be found in clinical notes of patients lacking such screening recorded by coding systems for quality reporting purposes. For PQRS quality reporting, we developed an NLP approach that automatically and effectively identified and extracted information about falls risk screening found in clinical notes. The results support the concept that using both structured coded data and clinical narratives for quality reporting is superior to the current reporting approach based on administrative coded data alone. Future work will focus on replicating the study findings using a larger sample and developing NLP-based identification strategies for other quality matrix. NLP augmentation of current regulatory quality measure assessment methodologies may result in improved care and more accurate quality reporting.

Abstract

The completeness of a medical terminology system consists of two parts: complete content coverage and complete semantics. In this paper, we focus on semantic completeness and present a scalable approach, called Spark-MCA, for evaluating the semantic completeness of SNOMED CT. We formulate the SNOMED CT contents into an FCA-based formal context, in which SNOMED CT concepts are used for extents, while their attributes are used as intents. We applied Spark-MCA to the 201403 US edition of SNOMED CT to exhaustively compute all the formal concepts and sub concept relationships in about 2 hours with 96 processors using an Amazon Web Service cluster. We found a total of 799,868 formal concepts, within which 500,583 are not contained in the 201403 release. We compared these concepts with the cumulative addition of 22,687 concepts from the 5 “delta” files from the 201403 release to the 201609 release. 3,231 matches were found between those suggested by FCA and those from cumulative concept addition by the SNOMED CT Editorial Panel. This result provides encouraging evidence that our approach could be useful for enhancing the semantic completeness of SNOMED CT.

Introduction

Ontologies (a.k.a. terminology systems) serve as a knowledge source in many biomedical applications including information extraction, information retrieval, data integration, data management, and clinical decision support. The quality of an ontology is a key property that determines its usability. As evidenced by their fast paced evolution (e.g., SNOMED International releases a new version almost every 6 months), ontological systems are often incomplete and under-specified. Therefore, one quality issue is semantic completeness. For example, in SNOMED CT, the concept Structure of muscle acting on metatarsophalangeal joint (with identifier 707861009) was not present in the 201403 release but was added in the 201603 release. To study semantic completeness, Jiang and Chute used Formal Concept Analysis (FCA) as a tool to construct contexts from normal form presentations in SNOMED CT and analyzed the resulting lattice hierarchy for unlabeled nodes. These unlabeled nodes signify semantically incomplete areas in SNOMED CT which can serve as candidate pool of new concepts for inclusion in SNOMED CT.

Given their size and complexity, performing such an FCA-based semantic completeness analysis for large ontologies is computationally as well as methodologically challenging. In fact, constructing concept lattices from formal contexts is believed to be a PSPACE-complete problem. Hence, performing formal concept analysis on large biomedical ontologies in their entirety, such as on SNOMED CT with over 300,000 concepts and 1,360,000 relations, was considered impractical. Because of the computational challenge, Jiang and Chute had to randomly select only 10% of the contexts from the subbranches of two largest domains of SNOMED CT to perform an FCA-based analysis. Although such a limited sample size may serve to demonstrate feasibility, an exhaustive analysis would be needed to achieve the full potential of the approach.

Most existing algorithms for computing formal concepts are not scalable to very large contexts. The process of generating formal concept hierarchies and constructing concept lattices from large contexts, after formal concepts are identified, is an additional computationally costly step. Due to such challenges, no scalable approaches have been proposed to exhaustively audit the semantic completeness of large biomedical ontologies using FCA, even with the aid of cloud computing technology. To address the computational challenge involved in constructing concept lattices from large contexts, we propose Spark-MCA, a Spark-based Multistage algorithm for Concept Analysis. Spark-MCA implements our proposed new FCA-based algorithms within the Apache Spark distributed cloud computing framework to provide a scalable approach for exhaustively analyzing the semantic completeness of large biomedical ontologies.

Another challenge that impedes the quality assurance of semantic completeness is the lack of reference standards.
Because of the inherent discovery-oriented nature and associated challenges involved in quality assurance work for ontological systems, there is an inevitable lack of “reference standards.” In semantic completeness auditing, case studies are commonly used for validating proof-of-concept. However, for large scale ontological systems, case studies may not be sufficient. We adopt RGT, Retrospective Ground-Truthing, as a surrogate reference standard for evaluating the performance of auditing methods for semantic completeness. The key idea of RGT is to extract the cumulative concept changes during the evolution of a developing ontology. In this study, for the purpose of evaluating semantic completeness, we focused on the addition and deletion of concepts. We used the cumulative inserted concepts in “delta” files of SNOMED CT between two releases, 201403 and 201609, as the RGT to evaluate the performance of Spark-MCA.

The contributions of this paper are: (1) the introduction of Spark-MCA, scalable distributed algorithms for exhaustively evaluating the semantic completeness within feasible computational times; (2) the application of RGT for validating the performance of FCA-based semantic completeness auditing method. Our results show that Spark-MCA provides a cloud-computing feasible approach for evaluating the semantic completeness of SNOMED CT using formal concept analysis.

1 Background

SNOMED CT Release Cycle. Developed and maintained by SNOMED International, SNOMED CT is the premier comprehensive clinical terminology for healthcare-related industries worldwide. As required by the meaningful use provisions of the Health Information Technology for Economic and Clinical Health (HITECH) Act, SNOMED CT is suited for use in clinical documentation in electronic health records (EHR). Clinical data coded in SNOMED CT can be used for multiple purposes. For example, providers can send SNOMED CT encoded data securely during transitions of care to other providers or upon discharge, or share data with patients themselves. This decreases barriers to the electronic exchange of critical patient information and positively impact patient safety.

SNOMED CT adopted description logic (DL) to formally represent concept meanings and relationships. A normal form of concept expression is a structured combination of subtype relationships (i.e. is-a) and attribute relationships (e.g., associated morphology, causative agent, finding site, part of). For example, the definition of Shunt of cerebral ventricle to extracranial site is shown in Figure 1 using such a normal form.

![Figure 1: SNOMED CT concept expression for Shunt of cerebral ventricle to extracranial site.](image)

Each SNOMED CT release comes with a “delta” file, which identifies the individual changes that occurred between releases. Table 1 is a fragment of the “delta” file in the SNOMED CT 201609 release. In the “active” column, an entry 1 denotes that a concept (e.g., 128282005) becomes active from this release (i.e., an addition), while 0 denotes that a concept (e.g., 128570000) becomes inactive from this release (i.e., a deletion). We use this file to retrieve cumulative concept changes between releases as RGT to evaluate our Spark-MCA.

Formal Concept Analysis. Formal concept analysis (FCA) has been advocated as a mechanism to audit the quality of SNOMED CT.\textsuperscript{4,11–13} FCA is a mathematical method for knowledge engineering. It can be used to derive a concept hierarchy or formal ontology from a collection of objects and their attributes.\textsuperscript{14,15} The input data for FCA is a binary relation between a set of objects and a set of attributes. This relation is represented in the form of a formal context, \( I = (X, Y, R) \), where \( X \) is a set of objects, \( Y \) is a set of attributes, and \( R \) is a relation \( R \subseteq X \times Y \). Each formal context \( I = (X, Y, R) \) induces two operators: \( \uparrow : 2^X \to 2^Y \) and \( \downarrow : 2^Y \to 2^X \). The operators are defined, for each \( A \subseteq X \) and \( B \subseteq Y \):

\[
A^\uparrow = \{ y \in Y | \forall x \in A: (x, y) \in R \}, \quad B^\downarrow = \{ x \in X | \forall y \in B: (x, y) \in R \},
\]

where \( A^\uparrow \) is the set of all attributes shared by all objects in \( A \), and \( B^\downarrow \) is the set of all objects sharing all attributes in \( B \). A formal concept is a pair \( (A, B) \) with \( A \subseteq X \) and \( B \subseteq Y \) such that \( A^\uparrow = B \) and \( B^\downarrow = A \). The collection of all such pairs, together with the natural partial order \( (A_1, B_1) \leq (A_2, B_2) \) iff \( A_1 \subseteq A_2 \) \( (B_2 \subseteq B_1) \), form a complete lattice.\textsuperscript{14} The structure of the concept lattice corresponds to the hierarchy of formal concepts and provides generalization and specialization between the concepts, i.e., \((A_1, B_1)\) is more specific than \((A_2, B_2)\) (or \((A_2, B_2)\) is more general).

There are two basic algorithmic strategies for computing formal concepts: (a) forming intersections by joining one attribute at a time, and (b) repeatedly forming pairwise intersections starting from the attribute concepts. Kuznetsov and Obiedkov provided a survey and comparative evaluation of algorithms for FCA.\textsuperscript{16} Bordat\textsuperscript{17} used strategy (a), while Chein\textsuperscript{18} used strategy (b). In this study, we use the idea of Troy, Zhang, Tian’s\textsuperscript{19} multistage algorithm for constructing concept lattices (MCA) and adapt and extend it in order to take advantage of the scalable distributed Spark framework.

We use ontological definitions for constructing a formal context. One can think of ontological concepts as objects, and ontological relationships as attributes in constructing a formal context. For example, with respect to Figure 1 we can use [69483009,Shunt of cerebral ventricle to extracranial site (procedure)] as an object and the other lines as its attribute entries.

Cloud Computing. Apache Spark is an advanced and high-end upgrade to Hadoop, aimed at enhancing scalability and performance using Resilient Distributed Datasets (RDDs) which facilitates in-memory computations on large clusters in a fault-tolerant manner.\textsuperscript{20} While both share the key-value conceptual framework, Spark is generally faster than Hadoop for MapReduce because of the way it processes data. It completes the full data analytic operations in-memory and in near real-time: reading data from the cluster, performing the requisite analytic operations, and writing results to the cluster. The in-memory processing strategy makes Spark more suitable for iterative algorithms. However, designing efficient algorithms in a distributed way requires a different strategy than that for the traditional approach, with more attention paid to data locality, job break-down, and trade-offs between parallelism and communication latency.

2 Method

2.1 Overview

In this paper, we introduce Spark-MCA, a distributed algorithm based on MCA, using the theoretical basis of FCA and adapting it to the Spark framework. Spark-MCA contains two parts: distributed MCA for obtaining all concepts, and distributed big set operation for lattice diagram construction. Spark-MCA takes in the original concepts and relations from SNOMED CT in the format described in the previous section as source formal context and generates the entire concept lattice from this context. We illustrate the main steps of our algorithm in the following subsections with the help of an example dataset extracted from SNOMED CT (Table 2).

We performed two types of evaluation: (1) partial validity, and (2) computational performance. To demonstrate that our Spark-MCA can be used in auditing semantic completeness and the results of our algorithm can provide a viable candidate pool of new concepts in a developing ontological system, we apply RGT by comparing the results of Spark-MCA with the concepts added to SNOMED CT versions. For computational performance, we tested our algorithm for its scalability by comparing the running times for datasets of different sizes. We also evaluated our algorithm on its performance on the same dataset but using different numbers of working computer processors.

2.2 Model SNOMED CT Using the FCA

SNOMED CT uses name-value to describe composite expressions. Take [405813007 | Procedure site - Direct (attribute)] → 35764002 | Brain ventricle structure (body structure)] in Figure 1 as an example. Here, 405813007 | Procedure site - Direct (attribute) is the name part, while 35764002 | Brain ventricle structure (body structure) is the value part. We use two steps to construct a formal concept from such SNOMED CT expressions. First, we include SNOMED CT concepts objects and each of their name-value pair as one attribute. For example, Figure 1 is encoded as 69483009: 116680003 → 88834003; 405813007 → 35764002; 260686004 → 424208002, where we used identifiers for simplicity. Second, to enrich the attributes, we include its ancestors’ attributes by leverage transitive closure of the isa relation (identifier 116680003). With the second step, Figure 1 is encoded as 69483009: 116680003 → 138875005; 405813007 → 35764002; 260686004 → 424208002; 260686004 → 129264002, where 138875005 is the root of the sub-hierarchy and dose not have any ancestors.

2.3 Spark-MCA

Algorithm for Distributed MCA

The distributed part of Spark-MCA is built on top of MCA. The idea behind MCA is to perform multistage intersection operations on each pair of concepts from the initial concept set consisting of all objects, until no more new concept is generated. Each of the stages is independent of the previous ones and does not involve any concepts in the previous stages. For notational preparation, define $S \cap T := \{s \cap t | s \in S, t \in T\}$, where $S$ and $T$ are collections of subsets. With respect to a given formal context $(X, Y, R)$, the MCA algorithm involves the following iterative steps:

$$S_0 := \{X\},$$
$$S_1 := \{\{x\} | x \in X\},$$
$$S_{i+1} := (S_i \cap S_i) - \bigcup_{1 \leq k \leq i} S_k$$

for $i \geq 1$. One important intermediate step for each stage is to remove all existing concepts $\bigcup_{1 \leq k \leq i} S_k$ when forming $S_{i+1}$. This way, only newly generated (and necessary) concepts are kept for subsequent stages, resulting in potentially large savings in computational cost.

The strategy involved in designing a distributed algorithm is to decompose a complex job into a sequence of jobs and to distribute particular parts of the data to be processed on different processing nodes. Our idea is to leverage the independence of stages involved in MCA and design a distributed MCA in the following way: Instead of iteratively performing intersections of object concepts pairs, $(S_i \cap S_i) - \bigcup_{1 \leq k \leq i} S_k$ on a single computer in each stage, we employ the MapReduce paradigm to split the iteration of pairwise intersections into a number of partitions. Each partition is then processed on an independent compute node by a Map function. The outputs from the Map functions are then collected, shuffled, and sent to compute nodes to perform Reduce functions. The output of Reduce functions are split
again to repeat the above steps. While iterations involved in MapReduce become very expensive in a standard Hadoop MapReduce implementation due to the I/O latency between the MapReduce steps, the distributed MCA implemented using the Spark framework can take advantage of in-memory processing to reduce the I/O latency.

Data in Spark are generally represented in the form of MapReduce key-value pairs \(<k, v>\) and stored as resilient distributed datasets (RDDs). Algorithm 1 describes the concept formation phase in Spark-MCA to generate all concepts from a given context. First we initialize the primitive concept set using \(S = \{x | x \in X\}\). Then, each loop in the \(while\) block (lines 3 - 11) performs one pairwise intersection. In each iterative step, we first obtain all pairs of current concepts as the \(keys\) for the input to Map (line 5). Then we split the pairs into a number of partitions and send them to compute node. Every node performs Map tasks of intersection on \(x^{\uparrow}\) and \(x\) (lines 6 and 7). The Reduce tasks collect all \(keys\) of Map’s results as candidate concepts to perform next iteration, and add the outcome to the final result (lines 8 - 10). When no new concepts generated, the algorithm stops and returns the set of cumulated formal concepts \(C\).

Table 3: The newly generated formal concepts in each stage for the formal context in Table 2 using Algorithm 1.

Table 3 shows the result of new formal concepts generated in each stage. Stage 0 generates all primitive concepts represented by intents. Stage 1 outputs two new concepts: C7 and C8. Stage 2 does not output any new concept, and thus the concepts generation phase stops.

Algorithm for Performing Big Set Operations
One criterion for the well-formedness of an ontology is that its hierarchical structure forms a lattice.\(^{11}\) By constructing lattice graphs, we can locate those newly generated concepts in the big picture of the entire ontology and help further inspection of the concept neighbors. With lattice graphs, our result can be a used for other structure-based auditing methods, as well as for visualization.

After all formal concepts are obtained, we have a nature transitively closed relationship with respect to set inclusion. For graph rendering, we need to construct the minimal, irreducible set of subset relations as an irredundant representation of set inclusion (modular transitivity). To do so, we use distributed set operations to construct lattice graphs from the output of the concept concept construction part of MCA (Algorithm 1). We design our lattice construction algorithm by leveraging distributed big set operations using the following strategy adapted from Zhang et al.\(^{13,21}\):

1. get all subset relations of one concept, 
2. remove other relations except for the minimal supersets.

More formally, given a set \(X\) in a collection of subsets \(C\), we use \(\uparrow X\) to denote the set of all common ancestors of \(X\), i.e.,

\[
\uparrow X := \{a \in C | \forall x \in X, x \subseteq a\}.
\]

Thus, \(\uparrow X\) represents the strict upper closure of \(X\). When \(X\) is a singleton, i.e., \(X = \{x\}\), we write \(\uparrow x\) for \(\uparrow \{x\}\). Similarly, we define \(\downarrow X := \{a \in C | \exists x \in X, x \subseteq a\}\). We have,\(^{13,21}\) for any set \(X, Y \subseteq C\),

\[
\downarrow X = \bigcap_{a \in X} \uparrow a, \quad \downarrow Y = \bigcup_{b \in Y} \uparrow b.
\]

Hence, the set of minimal upper bounds of \(X\) can be obtained using the formula \(\uparrow X - \uparrow(\uparrow X)\).
The distributed big set operations involve two MapReduce jobs: Marking Subset Relations (Algorithm 2) and Transitive Reduction (Algorithm 3). The input of Algorithm 2 is the collection of all formal concepts (intents, say) obtained from Algorithm 1. First we initialize a HashSet \( C' \) to store all concepts and distributed to all computational computers (line 2). Then all concepts are split into partitions to perform MapReduce tasks. In each task, we collect the subsets of concept \( c_i \) by iteratively checking each element in \( C' \) to see if it is a subset of \( c_i \) (lines 3-12). The output of Marking Subset Relations is a collection of concept-subsets pairs \((c_i, a_c)\), which will serve as the input of Transitivity Reduction. In Algorithm 3, concept and subsets pairs are first cached in \( CS' \) and sent to all nodes (line 2). Then each MapReduce task removes those subsets that are the subsets of the current concept on each pair. This is achieved by removing the union of the subset list \( S_i \) for each subset \( i \) with concept \( c \) in \( S_c \) (lines 3-10).

Table 4: The list of formal concepts generated from the formal context given in Table 2.

In Spark-MCA, each concept is represented by its intent (and refers neither to the original context, nor to any extent). One can easily incorporate a data structure for looking up the extent of a concept, after all concepts are determined. In this study, we maintain two hash maps: one is \( C \), which, for each concept \( x \in X \), collects all its attributes; similarly, the other is \( A \), which, for each attribute \( y \in Y \), collects all concepts that contain a particular attribute. Hence, the intersection \( \bigcap a_i^+ \), where \( a_i \) is the attribute of concept \( c_i \), contains all extents of a concept. To identify the labels of formal concepts, we compare their attributes with the primitive concepts list. Concepts corresponding to the primitive concepts are naturally labeled, while the others concepts can be treated as a candidate pool of new concepts for enhancing semantic completeness.
2.4 Evaluation Method

SNOMED CT provides a “delta” file, which contains changes of concepts and relations associated with each release. To evaluate the performance of Spark-MCA, we constructed RGT by obtaining concepts that were added in the releases. Obtaining an appropriate set of changes across multiple SNOMED CT releases is not a mere job of performing unions. For the purpose of evaluation, we constructed a reference set involving two steps: (1) extract added concepts (active value: 1) from all 5 “delta” files from 201403 release to 201609 release; (2) remove deleted or revised concepts (active value: 0) from the added concept sets obtained in the first step. These remaining concepts are selected as a RGT for evaluating the result of Spark-MCA. Since the suggested concepts by Spark-MCA have no labels, we matched the corresponding concepts using their attribute sets (intents).

For scalability analysis, we executed Spark-MCA on Amazon Web Services (AWS) with different hardware configurations. For this study, we selected M4, the latest generation of general purpose instances as the main working configuration. The hardware configuration for M4 is as follows: (1) 2.3 GHz Intel Xeon® E5-2686 v4 (Broadwell) processors or 2.4 GHz Intel Xeon® E5-2676 v3 (Haswell) processors, (2) EBS-optimized by default.

3 Results

3.1 Semantic Completeness Analysis

We applied Spark-MCA to the SNOMED CT 201403 release and found a total of 500,583 formal concepts suggested by Spark-MCA that were not included in this release. For evaluation, RGT identified 22,687 concepts as additions based on the 5 “delta” files from 201403 to 201609. A total of 3,231 concepts were found in the intersection of the two groups of concepts. This means that Spark-MCA correctly identified 3,231 concepts as missing concepts in the SNOMED CT 201403 release. Table 5 shows the numbers of identified concepts in representative subhierarchies. In this table, “FCA-New” denotes the number of suggested new concepts by Spark-MCA; “Delta” denotes the cumulative number of concept additions based on the “delta” files; “IS-A Only” denotes the number of concepts in “delta” files with no attributes; “New attributes” denotes the number of concepts in the “delta” files whose definition involved attributes that are not in primitive concept list; and “Matched” denotes the number of concepts in the “delta” files that were also found using Spark-MCA.

Table 5: Comparison of Spark-MCA results and retrospective ground truthing with respect to main subhierarchies.

3.2 Scalability Analysis

Scalability is one of the hallmarks of cloud computing. We performed two scalability tests for our Spark-MCA by analyzing computational time for different subhierarchies of SNOMED CT and for different AWS configurations, respectively. For the first test, we selected 4 largest subhierarchies in SNOMED CT 201403 release: Body structure, Clinical finding, Procedure, and Pharmaceutical biologic product. We performed the test on an AWS cluster with 96 processors. The computational time for each subhierarchy is shown in Table 6. For the second test, we repeatedly ran Spark-MCA on the Body structure subhierarchy with different configurations by increasing the number of processors in the AWS cluster. Figure 3 shows the time taken for computing concepts, and Figure 4 shows the time taken for concept lattice graphs. We found a linear decrease of the computational time when the number of computation processors ranged from 1 to 30. When the number of processors approached 100, the computational time tends to cease to decrease, indicating a threshold at which additional processors would not be helpful.
3.3 Evaluation

We applied a Precision-Recall metric to the comparison of our results and RGT. Table 7 shows the $P_1$, $R_1$, and $R_2$ scores in terms of subhierarchies (see the table caption for the definitions of the scores). The $P_1$ values are not so good and we did not calculate the precision by removing concepts in “delta” with no attributes or new attributes. In any case, this would not cause a big difference because of the large number of results from Spark-MCA. For smaller “delta” files, precision may not be so significant. From Table 7 we can see that in the 3 largest hierarchies, Body structure, Clinical finding, and Procedure, our Spark-MCA can identify 47.5%, 18.0%, and 30.2% of all newly added concepts, respectively. If we removed those concepts without attributes or with new attributes, the proportions become even larger. This indicates that Spark-MCA could be a reliable approach for addressing semantic completeness.

<td>0</td>
</tr>
</tbody>
</table>

Table 7: $P_1$: ratio of Spark-MCA resulting concepts that can be found in the “delta” files. $R_1$: ratio of delta concepts that can be identified by Spark-MCA, including all concepts from “delta.” $R_2$: ratio of delta concepts that can be identified by Spark-MCA, removing concepts in “delta” with no attributes or new attributes.

From Table 6, we can see that larger formal contexts required more computational time using our algorithm. However, we point out that because of the density and complexity, we cannot assume that a context with more objects and attributes would necessarily take more computational time. For example, the Clinical finding subhierarchy had more objects (concepts) and attributes, but it needed less computational time than did the Procedure subhierarchy. For Procedure, the process was completed in about 1.5 hours on 96 processors, which might also be completed in days using a sequential approach. From Tables 3 and 4, we can see that as the number of processors increase, the time taken for processing the same dataset declined significantly in the range of 1 to 30 computer processors. Due to the shuffle stage in Spark, the total computational time became stable as the number of processors increase. In conclusion, our computational experiments did demonstrate the scalability of our Spark-MCA algorithm.
4 Discussion

Limitation of Spark-MCA. Although our results showed Spark-MCA to be a practical method in evaluating semantic completeness, there remain a number of limitations. First, Spark-MCA cannot find those added concepts in “delta” involving newly added attributes. For example, Difficulty swimming (714997002) is added with a new attribute 363714003—Interprets (attribute) = 714992008—Ability to swim (observable entity) in the 201603 release, but Spark-MCA did not include it. Other types of lexical or structure auditing methods can be useful supplements to Spark-MCA in auditing semantic completeness. Second, it is less useful to apply the FCA approach to terminological systems with very minimal semantic definitions (e.g., limited to one type of relationship). Subhierarchies in SNOMED CT involving only the isa relation where Spark-MCA suggested no new concepts, even though these were present in the delta files (numbers given in parenthesis indicate additions in the delta files) are: Environment or geographical location (125), Observable entity (418), Organism (1,118), Physical force (0), Physical object (631), Qualifier value (649), Record artifact (32), Model Component (69), Social context (33), Special Concept (0), Substance (2,420).

SNOMED CT versions used for RGT. We used the latest five versions of SNOMED CT (the March 2017 version was released too late to be included in this study) for the feasibility demonstration of our method. This choice was purely a matter of convenience and did not result from methodological or computational limitations of our approach. In fact, it would be desirable to use all the available SNOMED CT versions (in Release Format 1 as well as Release Format 2), with an appropriate starting release as the time-point for computing the formal concepts. All the performance measures would only improve, and the RGT reference set would become larger.

Limitation of RGT. To understand why some concepts suggested by Spark-MCA were not included in SNOMED CT, and some were, we need domain experts assessment and case study to improve gain insights. Such insights may help enhance the method further.

Comparison with related results. We examined the example subhierarchy (hypophysectomy) provided in Jiang and Chute's work. We found our results to be in agreement. However, because Jiang and Chute did not provide details about all their findings, we could not perform a more thorough comparison.

Sensitivity of the FCA-based model. FCA-based approach is in general known to be sensitive to the density and complexity of the input formal context. Even though Spark-MCA performed reasonably well for SNOMED CT, we did not perform similar computational experiments on other terminology systems.

5 Conclusion

In this study, we introduced Spark-MCA, a scalable approach for evaluating the semantic completeness of SNOMED CT using an FCA-based method on top of the Spark cloud-computing framework. We formulated SNOMED CT into a formal context in FCA and then used Spark-MCA to exhaustively compute the formal concepts of the context as well as the associated subset relations. We the applied Retrospective Ground-Truthing to assess the performance of Spark-MCA. Our results show that Spark-MCA provides a cloud-computing feasible approach for evaluating the semantic completeness of SNOMED CT using formal concept analysis.

6 Acknowledgment

User-Centered Design and Usability Assessment of an EHR Integrated Automated SOFA Calculator App

Christopher A. Aakre, MD, Jaben E. Kitson, Man Li, Vitaly Herasevich, MD, PhD
Mayo Clinic, Rochester, Minnesota

Abstract
Sepsis is a frequently encountered, life-threatening condition with significant in-hospital mortality. A recent change to the clinical definition of sepsis introduced the need for frequent recalculation and comparison of the Sequential Organ Failure Assessment (SOFA) score. Automation can overcome this clerical burden. We describe the user-centered user-interface design and usability assessment of an EHR-integrated app for a previously validated near real-time automated SOFA scoring algorithm that meets clinicians’ needs.

Introduction
In March 2016, the Third International Consensus Definitions for Sepsis and Septic Shock (SEPSIS-3) redefined sepsis to include a change in SOFA score ≥ 2 points over baseline. Subsequently, the SOFA score must be frequently recalculated to identify sepsis—increasing clerical burden. In response to the increased task-load, Mayo Clinic has developed and validated an automated SOFA score calculator algorithm. In this work, we describe a user-centered design process for the creation of an “app” that integrates this automated SOFA score calculator algorithm into our local critical care EHR.

Methods
We utilized an agile development process to create a user interface (UX) for an automated SOFA score calculator integrated into our local critical care EHR. Clinician stakeholders were interviewed to determine (1) essential and (2) nice to have features and how to display each SOFA component. UX prototyping was performed using Pencil, an open source graphical user interface prototyping tool, and modified iteratively with feedback from prospective end-users until consensus was attained. The final UX’s usability was assessed with the Computer Systems Usability Questionnaire by clinician end-users with real world usage of the app over a two-month period in the medical intensive care unit.

Results
Among the 12/50 (24%) usability survey respondents, our user-centered UX design process resulted in > 75% favorability of survey items in the domains of system usability, information quality, and interface quality.

Conclusion
By engaging end-user stakeholders throughout the UX design process, we successfully created a user-centered UX for an automated SOFA score calculator app integrated into our local critical care EHR. Emerging interoperable platforms may allow for rapid creation and distribution of clinical decision support algorithms and calculators as apps. App developers will need to consider UX usability and user-centered design during creation of these tools.

Figure. Percent of responses categorized as favorable, unfavorable, or neutral within each domain from the post-implementation Computer Usability Scale Questionnaire (Respondents = 12).
Cranky Comments: Detecting Clinical Decision Support Malfunctions Through Free-Text Override Reasons

Skye Aaron1, Adam Wright, PhD1,2,3

1Brigham & Women’s Hospital, Boston, MA; 2Harvard Medical School, Boston, MA; 3Partners HealthCare, Boston, MA

Introduction: Electronic health record (EHR) systems often provide a free-text area for clinicians to enter an override reason when overriding a clinical decision support (CDS) alert. Override reasons may be used for auditing purposes but typically are not systematically shown to other providers or to EHR technical support. Nonetheless, it has been found that a significant fraction of override reasons are addressed to a recipient who will never be shown the comment.1 Free-text override reasons have previously been studied to categorize types of reasons provided, to determine the clinical appropriateness of alert overrides, and to investigate whether override reasons contain clinically useful information.1 However, no study has used override reasons as a method of detecting alerts that do not function as intended. There is growing evidence that most institutions with CDS will, at some point, have alerts implemented in their EHR that are operating incorrectly, and these malfunctions may go undetected for long periods of time.2 This project investigates the usefulness of free-text override reasons to detect alert malfunctions and prototypes techniques to automatically detect malfunctions by analyzing free-text override reasons.

Methods: Free-text override reasons were collected for all best practice alerts (BPAs), excluding medication alerts, that fired from 5/2015-3/2017 at Partners HealthCare System. BPAs were flagged for review using four detection methods: (1) total number of alert overrides with free-text override reasons; (2) frequency of words that express frustration (as selected by a human reviewer); (3) a high ratio of negative to positive comments as categorized by a Naïve Bayes classifier trained on pre-labeled movie reviews; and (4) similarity of comments within a BPA based on the cosine similarity measure. For each of the detection methods, a human evaluator then reviewed the top 10 flagged BPAs and categorized them as “likely broken,” “likely not broken,” and “unclear.” Flagged BPAs categorized by the human evaluator as “likely broken” were further investigated using the rule logic and data from patient charts to determine whether the alert was malfunctioning and could be fixed.

Results: There were 36,210 free-text override reasons submitted for 151 unique BPAs during the time period. Each of the detection methods yielded BPAs the reviewer classified as “likely broken”: 3 of the top 10 for method 1, 8 of the top 10 for method 2, 6 of the top 10 for method 3, and 6 of the top 10 for method 4. Additionally, all four methods uncovered alerts that were working as designed but could be improved using advice in the override reasons. Table 1 shows three rule malfunctions discovered by the detection methods, along with sample override reasons.

Table 1. Rules that are likely broken based on user-provided override reasons.

<table>
<thead>
<tr>
<th>Rule description</th>
<th>Sample override reasons suggesting a rule is broken</th>
</tr>
</thead>
<tbody>
<tr>
<td>Patient is due for a Cyclosporine Level</td>
<td>“stupid reminder-N/A for ophthalmic CyA” “why?” “inaccurate warning patient on topical restasis does not need level”</td>
</tr>
<tr>
<td>Patient is at risk for developing DKA. Please order long-acting insulin.</td>
<td>“I ALREADY GAVE INSULIN!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!” “he hed [sic] it already - so why do you bother me with this advisory you idiots” “wrong!!! She gets them per GI!! Stop these stupid warnings that are inaccurate”</td>
</tr>
<tr>
<td>Patient is taking digoxin and potassium level is less than 3.0</td>
<td>“please fix this advisory! K+ is the same as potassium” “serum K+ is potassium level- pease [sic] FIX THIS!!!” “Inaccurate warning. K+ is 4.4 today.”</td>
</tr>
</tbody>
</table>

Discussion: Free-text override reasons were useful for discovering BPA malfunctions. Several BPA malfunctions that were discovered have been fixed, and more will be investigated. Although the sentiment analysis method using positive and negative movie reviews is preliminary, it nonetheless uncovered six BPAs that were likely to be broken. Next steps for this project will refine the human evaluation of flagged alerts and improve the application of sentiment analysis by using context-specific training data as well as other types of classifiers.

Conclusion: Free-text override reasons can be used to detect CDS alert malfunctions and to identify alerts that are functioning as designed but could be tailored or improved.

Characterizing a Learning Curve for Annotating Data for Training and Validation of Natural Language Processing Systems

Glenn L. Abastillas, MA RN¹, Spencer D. Morris, MS², Jessica A. Boten, MPH², Tumenbayar Tumurchudur, MA¹, Kinjal Vora, MD-MPA³, Paul A. Fearn, PhD²

¹Information Management Systems, Incorporated, Rockville, MD; ²National Cancer Institute, Rockville, MD; ³Vasta Global, New York City, NY

Background
The National Cancer Institute’s (NCI) Surveillance, Epidemiology, and End Results (SEER) Program provides cancer statistics representing 28% of the US population. To accelerate population-based research to improve patient outcomes in cancer, the NCI is developing a natural language processing (NLP) pipeline to extract structured information from unstructured pathology reports in SEER data. NLP systems often need a large set of human-annotated data for training and testing of algorithms and systems, which is resource-intensive and time-consuming to produce¹,². There is no standardized method used to forecast effort needed for annotation, which would be useful for efficient allocation of resources to NLP projects. We aim to characterize a learning curve (LC) on our data for developing such a method informed by learning curve research from both manufacturing and informatics industries.

Methods
We analyzed 100 de-identified pathology report documents annotated by a pair of two-person annotator-reviewer teams for elements relevant to biomarkers of interest. Annotators extracted information in the form of highlighted text and codified data (annotations) from each document. Reviewers performed quality checks on their annotations per iteration. We analyzed the empirical cumulative distribution (ECD) of documents completed against time required for completion and compared the ECD difference subset by all annotator and reviewer pairs (n = 4).

Results & Discussion
The ECD in Figure 1 highlights a difference in the LC depending on annotator-reviewer team configuration. There is a significant difference in LCs depending on the reviewer who checked annotations (p < 0.05; p = 0.001) rather than the annotator who produced them (p > 0.05; p ≈ 0.92). This may indicate that the review process matters greatly in completing quality annotations. We intend to analyze more incoming data to further develop our analysis and LC.

![Figure 1](image)

Figure 1 Each panel represents our current LC model according to each pair of reviewers (R1 and R2) and annotators (A1 and A2). The color lines represent documents with reviewer-identified revisions (teal) and without (pink). Easier learned tasks tend to have a curve approaching the top-left of the chart. Harder learned tasks tend to have a curve approaching the bottom-right.

Extraction of Patient Temporal Patterns and Clusters from Clinical Data

Samir E. Abdelrahman1, Julio C. Facelli1, Bruce E. Bray1,2, Rashmee U. Shah2, Guilherme Del Fiol1
Department of Biomedical Informatics1 and Division of Cardiovascular Medicine2, School of Medicine, The University of Utah

Introduction: Descriptive data mining techniques, such as temporal pattern mining and clustering analysis, may provide clinicians with deeper understanding of the associations and/or correlations among clinical variables that may predict patient outcomes. Temporal patterns and clustering of patient data evolve due to changes in the patient’s clinical status and proper analytical techniques for their analysis should be informative and give stable results over time. Here we report the application of our Frequency pattern mining, Clustering, and Graph database (FCG) method1 to extract temporally stable and accurate patterns and clusters of patients, as described by clinical and demographic variables measured in an Intensive Care Unit (ICU) setting. The accuracy of patterns and clusters is measured by their ability to correctly discriminate between positive (not-survival) and negative (survival) cases at any given time.

Methods: We developed a temporal descriptive framework with two steps: data preprocessing and tree pruning and clustering using FCG. In the data-preprocessing step, all numeric values were categorized into hourly “low”, “normal”, or “high” levels, using standard reference values. If a patient has multiple readings for the same variable within the hour, we considered the last reading as representative of the patient status in that hour. In the FCG step, the data is represented as a regulated hierarchical tree of frequencies. The tree is cut at a certain level node to remove the patterns of all the preceding nodes, which are deemed as non-informative. Then the clustering analysis is conducted for the pattern’s successive nodes. A graph database was used, as it can provide a permanent storage to support retrieving data for visualizing multiple trees/clusters in a scalable manner.

We analyzed data from each hour of the first 48 hours of ICU patients admitted to a cardiac service, using their mortality outcome as the dependent variable. We extracted demographic information and 100 clinical indicators1 such as vital signs and laboratory tests for 1,000 patients that were randomly selected from the Medical Information Mart for Intensive Care (MIMIC III) database with mortality rate = 30%. The data-preprocessing step produced 480,000 values for each patient. The FCG default values were utilized such that the minimum numbers of readings found in the patient records data was used for defining the cut tree levels and one iteration was performed for merging the clusters of each pattern in that hour. We tested four different tree cut levels (i.e. pattern lengths) of 1, 2, 3, and 4 patterns for which we tested the accuracy of the clusters for each hour. For each cluster, we used the F-measure of the negative cases and the cluster purity (i.e., its ability of cluster to present the most positive or negative cases) (p < 0.05)1 as measures of the performance of the method.

Results: Fig.1 shows the mean accuracies and their standard deviations for every cut-off level during the 48-hour period. The standard deviations represent the stability over the whole timeframe of that cut-off level.

Discussion: Although, we used the framework default values, the analysis produced stable results of the average 48-timeframe accuracies for all cut-off levels considered here. However, the accuracy of the results increase significantly with increasing cut-off levels. However, the best cut-off level depends on the user input threshold.

Conclusion: The proposed framework provides stable and more accurate results with increasing retrieval features as the cut-off level increases. Since the patterns and clusters are accurate overtime with respect to patient outcome, this approach may be useful for clinical decision support in the ICU. We are currently using different strategies to present time variabilities of patient readings. Further algorithmic enhancements will be developed.

Dissemination of HIV, HCV and STD Clinical Evidence to Primary Care Providers – An Analysis of User Profiles and Course Evaluations of a Statewide Online Clinical Education Program

Meredith Abrams, MPH; Dongwen Wang, PhD
Arizona State University, Scottsdale, AZ

Introduction

Rapid advances in HIV, HCV, and STD research have generated important clinical evidence. Timely and effective dissemination of such evidence to primary care clinicians is essential for translating the latest research findings into the daily care of patients. With the wide use of information technology, continuing professional development courses are increasingly offered online. The New York State (NYS) HIV-HCV-STD Clinical Education Initiative (CEI) online training program has developed hundreds of multimedia learning modules, online CME/CNE courses, interactive case simulation tools, and other internet-based resources since its launch in 2009. These resources have been disseminated to tens of thousands healthcare providers from 170+ countries. This study analyzes the profiles of clinicians participating in the CEI online CME/CNE course during the study period. For each parameter of the user profile and seven categories of training topics, we performed univariate analyses with chi-square test to identify the potentially significant factors for positive course evaluations.

Methods

We compiled CEI online training user profiles and course evaluation data from November 2014 through October 2015. We collected clinicians’ personal and professional background such as demographics, education level, primary professional discipline, practice years, employment setting, employment location, caseload, and clinical services provided. We measured course evaluation through clinicians’ self-reported data on usefulness/relevance of information, ease of comprehension, knowledge of the trainer, appropriateness of format, knowledge level before and after training, intention to utilize the learned knowledge, and plan to change clinical practice. We included in the analyses only those clinicians with complete user profiles and passed at least one online CME/CNE course during the study period. We recorded significant differences in knowledge increase by: (1) training topic (p<0.01); (2) race (p<0.01); (3) education level (p<0.01); (4) discipline (p<0.01); (5) employment setting and location (p<0.01); (6) HIV, STD, and HCV caseloads (p<0.01); and (7) most HIV, HCV, and STD services (p<0.01). We recorded significant differences in knowledge increase by: (1) training topic (p<0.01); (2) race (p<0.01); (3) discipline (p<0.01); (4) practice years (p<0.01); (5) employment setting and location (p<0.01); (6) HIV, STD, and HCV caseloads (p<0.01); and (7) most HIV, HCV, and STD services (p<0.01). We recorded significant differences in intention to change practice by: (1) course topic (p<0.01); (2) race (p<0.01); (3) ethnicity (p<0.01); (4) education level (p<0.01); (5) discipline (p<0.01); (6) practice years (p<0.01); (7) employment setting (p<0.01); (8) HIV, HCV, and STD caseload (p<0.01); and (9) most HIV, HCV, and STD services (p<0.01).

Conclusion

Clinicians had very positive evaluations of the CEI online courses. We have identified potential factors for positive impact to knowledge increase, intention to use knowledge, and plan to change clinical practice. Future development of online CME/CNE courses may need to incorporate these factors for more effective knowledge dissemination.
A Resource for Clinical Semantic Textual Similarity

Naveed Afzal, PhD, Yanshan Wang, PhD, Feichen Shen, PhD, Liwei Wang, MD, PhD, Hongfang Liu, PhD
Department of Health Sciences Research, Mayo Clinic, Rochester, MN

Introduction
There is a growing need for automated methods to better synthesize patient data from electronic health records (EHRs) and reduce the cognitive burden in clinical decision-making process for providers. Patient data can be scattered in several heterogeneous sources. Tools that can aggregate data from diverse sources and minimize data redundancy, organize and present the data in a user-friendly way to reduce the cognitive burden are desired. One necessary task for extracting and consolidating information is to recognize semantically similar text snippets, a natural language processing (NLP) task known as semantic textual similarity (STS), which computes the semantic similarity between text snippets. In the general English domain, the SemEval STS share tasks have been organized since 2012 to develop automated methods for the task. Clinical text contains highly domain-specific terminologies and thus specific NLP tools and resources tailored to the clinical domain are needed for analysis, interpretation and management of clinical text. In this study, we describe our effort to create an STS resource consisting of sentence pairs from clinical notes with semantic similarity assigned by clinical experts.

Methods
The construction of a dataset by gathering naturally occurring pairs of sentences with different degree of semantic equivalence itself is a very challenging task. We selected unique sentences from 3 million de-identified clinical notes of patients receiving their primary care at Mayo Clinic. For sentence pair’s selection, we used various surface lexical similarity measures that enable us to find sentence pairs sharing some level of surface similarity. We used three surface level similarity measures: sequence-matching algorithm, cosine similarity and Levenshtein distance. All methods assign a score between 0 to 1 where 0 indicates no similarity and 1 otherwise. We average these three scores to get the final surface similarity score for a sentence pair. We experimented with different score ranges and empirically selected all sentence pairs where the average score was greater or equal to 0.45. In order to build sentence pair’s dataset that would reflect a uniform distribution of similarity ranges, we randomly selected equal number of sentence pairs from five scales of surface similarity range [0.45 – 0.95] from the dataset. We sampled 1,250 pairs and filtered sentence pairs that contain personal health information and that left us with 1068 sentence pairs. After the sentence pair selection phase, two clinical experts, each with many years of experience, were asked to annotate each sentence pair on the basis of their semantic equivalence using a scale of 0-5 (low to high similarity) using the provided guidelines and examples. A similarity score of 0 denotes complete semantic dissimilarity between two sentences. A similarity score of 1 shows that two sentences are not equivalent but are topically related to each other, while similarity score of 2 indicates that two sentences agree on some details mentioned in them. The similarity score of 3 implies that there are some differences in important details described in two sentences while a score of 4 represents that the differing details are not important. The score of 5 represents that two sentences are completely similar. The final similarity score for each sentence pair was obtained by averaging both annotators’ similarity score.

Results
Given a sentence pair, an STS system would need to return a similarity score. For a baseline system, we produced final score by averaging aforementioned surface similarity measures for each sentence pair. The system performance was evaluated using the Pearson correlation coefficient between the system output scores and the average human scores; we obtained a Pearson correlation coefficient score of 0.68 for baseline system.

Conclusion
The ability to organize concepts on the basis of their similarity or relatedness to each other is an essential step in the human mind and in many NLP applications. In this study, we have illustrated our effort to address a gap in existing resources for the study of STS in clinical domain. We selected sentence pairs from clinical domain using various surface-based similarity measures and each pair was annotated on the basis of their semantic similarity by human annotators. The use of STS can significantly reduce excessive redundant information that results in information overload, cognitive burden and difficulties in effective decision-making process at point-of-care.
Introduction
Lack of timely follow up on abnormal test results is common and linked to missed or delayed diagnosis, resulting in negative patient outcomes and increased malpractice\(^1\). To examine the safety culture surrounding test result follow up, we used qualitative and quantitative patient safety data in the ambulatory setting. We inspected how patients and providers estimated the frequency for providing timely test results; how patient satisfaction with their provider correlated with their provider’s response time to test result messages; and qualitative themes in patient complaints and safety reports filed by clinic staff. While this data has been used individually for quality improvement, we believe that examining these metrics together offer valuable insight into test result management culture.

Methods
Data was requested for outpatient clinics affiliated with Brigham Health, a tertiary academic medical center. To examine how providers estimated their frequency for providing timely test results, we analyzed data aggregated on the clinic level from Agency for Healthcare Research and Quality Surveys on Patient Safety Culture (AHRQ SOPS) from 2012 (1,482 surveys) and 2014 (1,739 surveys). To examine how patients perceive the timeliness of returned results and their satisfaction with their provider, we utilized data from the Consumer Assessment of Healthcare Providers and Systems (CAHPS) Clinician and Group Survey for patients who had an office visit between 12/1/15 – 5/31/16 (8,707 surveys returned), aggregated on the clinician level. Additionally, provider response times to test message results was calculated for messages received between 6/1/15 – 8/26/16. Providers were matched to CAHPS survey responses via provider ID. Patient complaint data pertaining to test results categories from the Brigham Health Patient Family Relations department from 1/1/11 to 4/30/16 (2,083 cases), and safety reports filed by Brigham employees between 1/1/11 to 9/18/16 (6,381 reports) were analyzed for narrative trends.

Results
Preliminary analysis of SOPS data showed a weighted average score of 0.88+/-.14 in 2012 and 0.83+/-.12 in 2014 for Brigham clinics for a question asking about critical abnormal result follow up\(^2\). The SOPS score indicates the proportion of returned surveys with a favorable response. Analysis of CAHPS data on how frequently a patient perceives that the provider’s office follows up on test results showed that 73.8% were returned with the patient marking “Always”\(^3\). We also correlated the percentile rank of individual providers with the median amount of time the provider took to respond to high priority messages. With a cut-off of 20 messages and 20 returned surveys, we found that as response time decreased, satisfaction increased (p=0.0073). We isolated 144 complaint cases and 737 safety reports that were caused by delayed test results. The most common narrative trend for patient complaints was breakdown in communication between provider or clinic and patient. The most common issue for safety reports was delivery or transportation of collected samples.

Discussion/Conclusion
We investigated the culture of test result follow-up using tools typically used to examine patient satisfaction and experience and staff culture. Pairing together CAHPS, a survey tool that measures patients’ perception of perceived care, and SOPS, a survey tool that examines employees’ perception of given care, allowed us to gather quantitative data on test result follow-up culture. Patients and staff perceived test result follow-up similarly, with the average practice scoring around 0.8 and 74% of patients saying that they always receive prompt follow-up. Similarly, we found a slight correlation between how long providers take to respond to message and how satisfied the patient is with their care. Additionally, while examining patient complaints and staff safety reports, we saw similar narrative trends. Using these four sources of data allowed us to examine multiple perspectives in follow-up culture and to identify possible explanations for inappropriate follow-up. We hope to further explore these data sources to identify solutions to inappropriate follow-up.

Introduction

Much of the recent advancements in medicine have been driven by data-centric approaches that utilize big data sets to derive knowledge for informing treatment options. As the direction of this progress continues, one of the limiting factors will be the availability of large-scale repositories that contain heterogeneous patient data. Because of the sensitivity of releasing PII, many data sets continue to be housed behind firewalls and are not easily accessible by most researchers. This greatly limits their utility because potential users typically lack the time and resources needed to successfully overcome the various hurdles for gaining access. The work described in this poster is being done under the auspices of the APOLLO (Applied Proteogenomics Organizational Learning and Outcomes) Network, a collaboration between the NCI, the DoD, and the VA for studying the proteogenomic pathways that impact disease. In support of this effort, the VA has been actively engaged in establishing regulatory and technical workflows that facilitate the release of de-identified patient clinical, imaging, and genomic data from various sources to partner institutions, specifically the Genomic Data Commons (GDC) and The Cancer Imaging Archives (TCIA) of the NCI. We believe that the lessons learned and the various artifacts produced from our efforts to release this data will prove useful to other researchers and decision-makers who desire to make their own data available to the broader community.

Methodology

Transferring VA data to external repositories consisted of several major tasks: obtaining patient consent to release their data; curating the data from multiple sources both within and external to the VA; de-identifying the data to remove all PII; and obtaining all regulatory approvals for the established processes and workflows. The following sections will describe these steps in more detail.

Patient Consent. Formal consent was obtained from patients through an established protocol for gathering a research cohort based on the VA’s Precision Oncology Program. Patients were given a choice to either have their data released internally within the VA, externally to other repositories, or not released at all.

Data Curation. Clinical data elements were selected from existing protocols and data sets specifically for lung cancer patients. Sources of data elements included ORIEN, MED-C, DoD, GDC, and APOLLO. The VA’s Corporate Data Warehouse was used as the primary source for clinical data. Imaging data consisted mainly of chest CT studies and were obtained from individual PACS systems throughout the VA network. Genomic FASTQ files that resulted from tumor sequencing were obtained directly from the vendors. All three data streams were linked using the patient’s ID.

De-Identification. Clinical data values contained no PII and dates were de-identified using the TCGA’s date obfuscation method. Software from TCIA was used to scrub all PII from the DICOM headers of images. The genomic FASTQ files contained no PII within its content and thus did not require additional de-identification.

Regulatory. Several regulatory requirements were satisfied to ensure proper protection of veterans’ privacy, including signing data use and transfer agreements with the NCI, subject matter expert certification and information security approvals for the de-identification processes, and risk analyses for using electronic submission portals.

Conclusion

Our experience in releasing VA patient data has shown that challenges are more often regulatory than technical. Our hope is that the increasing reliance on rich data sets for researchers to advance clinical care and the desire of patients themselves to share their own data will drive positive change in healthcare privacy policy and help establish protocols and workflows that facilitate the sharing of medical data.
Bladder cancer is among the most common forms of cancer, with nearly 17,000 deaths projected this year [1], and is the fourth leading cancer in men [2]. We developed a natural language processing (NLP) application that focused on (a) the severity of pathology findings and (b) the existence of finding mentions in pathology reports.

Methods

Using Department of Veterans Affairs (VA) electronic medical records, we identified 12,874 patients with bladder cancer diagnosed between 01/01/2005 – 12/31/2012 and created an initial set of 1,476,063 documents. Based on frequency of documents, we identified and filtered on surgical pathology reports created within 30 days before and up to 120 days following the cancer diagnosis that contained at least one of the following keywords: “ureteral”, “urethral”, or “bladder”. This resulted in 11,030 documents for 7,490 patients. 600 documents were then randomly selected and annotated by two urologists for 7 variables: histology, grade, carcinoma in situ (CIS), invasion type, invasion depth, muscle in specimen, and stage. The differences were adjudicated through a series of discussions and the assistance of a third urologist. We then split the annotated set of 600 documents into three parts: 300 (50%) of documents as a training set, 150 (25%) of documents as a development set, and 150 (25%) of documents were set aside for final validation.

Using the training and development sets of annotations, we built an NLP pipeline for the Apache Unstructured Information Management Architecture Asynchronous Scaleout (UIMA AS) [3], utilizing the libraries and tools contained in the Leo framework [4]. We implemented three modules in the pipeline: a regular expression module to detect mentions of each of the 7 variables, negation pattern matching, and term filtering to exclude negated text. Instances of the variables found in the text were aggregated to the most severe finding. For example, if a single document was found to have two specimens; one with no cancer and one with a histological urothelial classification, the output would have a single record for urothelial.

Results

After processing the test set of 150 documents, the hierarchical application performance was validated (Table 1). An error analysis of the final testing set showed a small number of random errors consisting of words and pattern combinations that were not previously seen in the training set and consequently, not captured in the testing set. There were no systematic errors that affected multiple separate documents.

Discussion

NLP applications such as this, which focus on severity of cancer data in patient reports can collectively produce significant results. Categorical output may vary, according to precision, recall, and accuracy.

Introduction
The increase in resistance of pathogens to antibiotic medication has become a major public health concern. Surveillance of changes in antibiotics resistance is imperative to inform clinicians on the appropriate use of existing medication for treatment, as well as guide the development of new antimicrobial agents1. Pseudomonas aeruginosa is an increasingly multi-drug resistant pathogen with a high rate of mortality in critically ill patients. Surveillance must be carried out to monitor any changes in susceptibility to common antibiotics2. Common medications for treating P. aeruginosa infections include gentamicin from the aminoglycoside antibiotics class, Imipenem, a carbapen antibiotic, and Ciprofloxacin from the quinolone class. The research question of the present study addressed whether changes in resistance of P. aeruginosa to these three antibiotic medications occurred during the period from 2006 to 2012 using laboratory data obtained from teaching hospital facilities.

Materials and Methods
We obtained laboratory test results from the Cerner Health Facts database collected from inpatient teaching hospitals. Sample sizes for the three antibiotics were: gentamicin = 512, Imipenem = 514, ciprofloxacin = 506. The study researched differences in resistance of Pseudomonas aeruginosa between 2006 and 2012. We used three hierarchical binomial logistic regression analyses to isolate effects uniquely associated with time on resistance, while controlling for gender. Time, coded as years, was treated as a categorical variable using 2006 as the reference category. We dichotomized resistance (susceptible vs. resistant). Resistance statuses originally coded as intermediate were classified as resistant. Gender used males as the reference category. To isolate and control for effects associated with gender, it was added in a first block. Years, the variable under investigation, was added in a second block. The three statistical analyses used SPSS version 24 (experimentwise $\alpha = .05$) and excluded year 2009 due to insufficient data.

Results and Discussion
The logistic regression analyses did not indicate any significant changes in resistance in the years following 2006 at the $\alpha = .05$ experimentwise error rate. The overall model was not significant for any of the three medications (Gentamicin: $\chi^2 = 6.97, p = .32$; Ciprofloxacin: $\chi^2 = 3.50 p = .74$; Imipenem: $\chi^2 = 4.04, p = .67$). Years did not significantly predict resistance for any of the individual medications as shown in table 1.

*2006 is the reference category for year; Male is the reference category for gender

Conclusion
The study revealed no evidence that P. aeruginosa resistance to Gentamicin, Ciproflaxin, and Imipenem changed significantly between 2006 and 2012. Thus, it does not indicate an urgent need to replace or modify these medications. Further studies with other antibiotics and larger sample sizes can use logistic regression to analyze trends in resistance.

Harmonizing User-defined Phenotypic Variables using Latent Semantic Analysis (LSA) to Improve Data Discoverability in dbGaP

Liz Amos, MLIS, Satyajeet Raje, PhD, Masato Kimura, PhD, Preeti Gokal Kochar, PhD, Victoria Wilder, MLS, Ben Busby, PhD

U.S. National Library of Medicine, National Institutes of Health, Bethesda, MD, USA

Background
The NLM Database of Genotypes and Phenotypes (dbGaP) provides a rich source of studies with genotypes, phenotypes and associations between them1. As part of the submission process, dbGaP requires researchers to submit a data dictionary of study variables including their short descriptions. A recent study2 highlights the need to harmonize these user submitted variables to allow researchers to effectively find studies that share the same or similar variables in dbGaP. The study documents a manual effort to map variables in dbGaP to a standardized set of measures, viz. the PhenX toolkit. However, the rapidly expanding size of dbGaP variable dictionary (200,000+ variables by early 2017) renders sustaining such manual post-coordinated efforts infeasible. In this project, we attempt to (semi-)automate the harmonization of variables in dbGaP using the user-submitted variables.

Methods
A. Measuring conformity in original study. The original study provides PhenX IDs (by RTI International) and LOINC codes (by NCBI staff) for 20635 variables in dbGaP. To assess conformance within the original mapping, we perform a pairwise comparative analysis of the PhenX and LOINC mappings for all variables.

B. Clustering variables using LSA. We use Latent Semantic Analysis (LSA) to compute a pairwise similarity score between the 20635 variables in the original study (using the gensim python library3). We leverage the user submitted variable descriptions as textual input. We cluster together variables based on the calculated similarity score (threshold of 0.8 was empirically chosen). Thus, each variable has a list of “duplicates” identified by LSA. To validate the output of the LSA method, three evaluators manually reviewed 10% (~2000) randomly sampled duplicate variables independently. We also compare the results of our LSA based method with the existing PhenX and LOINC mappings.

Results / Discussion
A. Measuring conformity in original study. The results of the pairwise comparison indicates that the LOINC mapping has a more generalized grouping of variables compared to PhenX (610 unique LOINC codes vs. 1414 unique PhenX IDs). Moreover, LOINC codes conform completely to the PhenX mapping (i.e. all pairs with same PhenX ID have the same LOINC code). It should be noted that LOINC codes were missing for 3556 variables.

B. Clustering variables using LSA. Manual evaluation showed that the LSA method can identify “duplicate” variables with very high accuracy (96% precision when all 3 evaluators agree that a result is valid). The inter-rater agreement among evaluators was also high (kappa = 0.07). However, we observed poor conformance between the LSA derived clusters with existing PhenX ids and LOINC codes for some concepts. This means that the LSA is able to cluster variables that were not originally clustered by the LOINC or PhenX IDs. Further analysis revealed this is mainly due to discrepancies between semantic and syntactic characteristics. For instance, implicit synonymy among terms in a terminology (e.g. “sex” and “gender” have same LOINC code) cannot be clustered by LSA. Further refinement would be needed to account for such conditions.

Conclusion
Initial results using LSA for harmonization of variables in dbGaP shows promising results. We are currently exploring ways to extend our method to map to other standard terminologies, such as SNOMED CT. We are also studying the impact of using harmonized variables to the number and quality of cohorts retrieved from dbGaP.

Decoding the Behavior Change Techniques in Mobile Health Apps

Marcy G. Antonio, PhD (c), MPH, BSc1, Karen L. Courtney, PhD, MSN, BSN, BA1, and Judith T. Matthews, PhD, MPH, RN2

1 University of Victoria, Victoria, British Columbia, Canada; 2 University of Pittsburgh, Pittsburgh, Pennsylvania, United States

Background

It was estimated in 2016 that 165,000 health-related mobile apps would be downloaded 1.7 billion times [9]. Most of these apps are rarely used and have limited evidence of supporting and improving health outcomes [1-3]. Further, the majority of health apps have been developed with little attention to successful techniques for behavior change [2,3]. This study used the Behavior Change Technique Taxonomy (BCTT) developed by Michie et al. [4] to classify behavior change techniques employed in a sample set of mobile health apps, as a first step toward designing evidence-based health apps that are likely to influence users’ behaviors and generate positive health outcomes.

Aim

To develop a codebook based on the BCTT, and to apply this codebook in the identification of behavior change techniques in commercially available health apps.

Methods

The codebook is being developed in two phases. The completed first phase involved incorporating the 93 behavior change techniques (BCTs) defined by the BCTT into a coding framework specific to mobile health apps. The framework includes individual examples of health app features that match with each BCT code, as well as examples of mobile health app interventions that insufficiently align with specific codes. The ongoing second phase entails psychometric assessment of the inter-rater reliability of the codebook. Trained coders are independently identifying the BCTs in 10 randomly selected health apps that focus on chronic disease management. The identified BCTs are being examined for level of agreement to determine areas of the classification scheme that require clarification or revision. Through this iterative process coders will evaluate a series of apps until inter-rater agreement is substantial, as signified by a Kappa coefficient of at least .75.

Results

This poster will present the process for developing the coding framework, training coders, and evaluating the inter-rater reliability of the resulting codebook. It will also provide classification examples from the various mobile health apps, as well as identify their current strengths and limitations in incorporating BCTs.

Conclusion

The BCTT has been useful for identifying the critical techniques present within behavioral change interventions [9]. To date, the majority of the studies that have applied this taxonomy have focused on in-person interventions. This work applies the taxonomy to mobile health applications which offer unique opportunities for delivery of BCTs that may not be possible with in-person interventions. Classification of the behavior change techniques used in mobile health apps will aid in future research on effective mobile health app design aimed at changing behavior and improving health outcomes.

Reference Range Number Lines Preferred by Latino Adults for Display of Clinical and Patient-Reported Outcome Data

Adriana Arcia, PhD, RN¹
¹Columbia University, New York, NY

Introduction
Tailored infographics can be used in patient- or consumer-facing informatics resources to support communication of clinical and patient-reported outcome data but additional research has been needed to identify optimal graphical formats for displaying various types of data. Reference range number lines are a graphical format in which reference ranges (e.g., blood pressure; scoring categories from a depression screening instrument) are marked off in labeled segments along a number line (e.g., Figure 1B). We worked with over 100 Latino adults with varying levels of health literacy. The first study was with residents of northern Manhattan using variables covering a variety of biometric and self-reported outcomes; the second was with family caregivers of dementia patients and focused on variables specific to dementia and caregiving. In each study, the aim was to develop tailorable infographic designs that would be preferred and perceived as easily comprehensible by the target audience. After the design phase, we programmed the designs into a novel system, Electronic Tailored Infographics for Community Engagement, Education, and Empowerment (EnTICE²), to automatically generate tailored infographics based on data provided.

Methods
We used similar methods across two studies. First, we identified multiple graphical formats (e.g., reference range number line, illustrated table) appropriate for the display of each variable. Next, we created one or more infographic designs for each format such that we prepared multiple designs for every variable. Then, we conducted participatory design sessions (N = 27) in both English and Spanish with small groups from the intended audiences to solicit preferences between designs and suggestions for their improvement. Infographic designs preferred by participants were iteratively refined between sessions until participants expressed satisfaction and had no further substantive changes.

Results
Participants across languages, target group, and literacy level consistently preferred designs that included reference range number lines over other graphical formats. In the first study, participants suggested combining the number lines for body mass index (BMI) and waist circumference with illustrations of body silhouettes. In the second study, refinements to designs that incorporated reference range number lines were focused on a) the imagery used to anchor the reference ranges, b) word choice for the text labels, and c) improvements to numerical scaling.

Conclusion
Reference range number lines are acceptable to and perceived as easily comprehensible by Latino adults with varying levels of health literacy. Although intended to meet the needs of a particular population, the strong preference for this graphical format across in-group differences suggests the format may have broad appeal. Therefore, it should be tested in additional groups to determine if it can be appropriately adopted as a standard patient-facing format for the display of values for which reference ranges apply.

Figures 1A & 1B. A score for the Kessler Psychological Distress instrument is displayed at left (1A) in an illustrated tabular format and at right (1B) in a reference range number line format (final version). Participants preferred the number line format and sun image to the tabular format and blue clouds /rainbow image. Score ranges were shifted from 6-30 to 1-25 because participants found the original scaling confusing.
Introduction
The Health Information Technology for Economic and Clinical Health (HITECH) Act earmarked $30 billion to incentivize the meaningful use of EHR and technology. One of the core pillars of the HITECH Act is engagement of patients and families in their health. The Centers for Medicare and Medicaid (CMS) meaningful-use requirement recommends that hospitals use health information technology (HIT) with features that will engage patients in their care. As hospitals work towards meeting these requirements, it has become clear that different hospitals are at different stages in their adoption. While some are hesitant and slow to adoption, others have adopted technologies with a wide range of patient engagement features. Therefore, it is important to investigate if a hospital’s financial standing determines the number of features or add-ons they include in their adopted information technologies. This study explores the relationship between hospital financial strength and breadth of patient engagement features offered through HIT.

Method
Data on hospital adoption of patient engagement HIT features were obtained from the AHA IT supplement, and financial data were obtained from the Centers for Medicare and Medicaid (CMS) cost report. Total margin and operating margin were used as measures of financial strength, and a summated scale of the identified patient engagement features (from 0 – 11) was created. Multinomial regression models with a longitudinal panel sample of 1,612 hospitals (2012 – 2013) were used. Only non-governmental acute care hospitals that provided information on the patient engagement features adopted for both years were included. Four categories of hospitals based on the breadth of patient engagement features adopted were identified: high adoption (9 – 11), medium adoption (5 – 8), low adoption (1 – 4), and no adoption. It was hypothesized that hospital financial strength will be positively and significantly associated with breadth of patient engagement features offered to patients (e.g., provide patients with an electronic copy of their discharge instructions and record, provide patient-specific education resources, and view and download their health/medical record). Variables identified from previous studies to be associated with innovation adoption were included in the model as control variables. They are: total number of beds, teaching status, system membership, ownership status, geographic location, competition, per capita income, Medicare discharges per inpatient days, average length of stay, occupancy rate, and FTE per 1000 inpatient day.

Results
From 2012 to 2013, the hospitals included in this study had adopted on average 5.08 out of a total of 11 patient engagement features. This increased from 4.62 features in 2012 to 5.54 features in 2013. Low adoption, medium adoption, and high adoption hospitals offered on average 3.11, 6.38, and 9.60 patient engagement HIT features respectively. This study further revealed that financial strength is important in determining the number of HIT features for patient engagement a hospital will adopt. Hospitals with high adoption had better total margins and operating margins compared to hospitals with no adoption (β= –0.088, p < 0.01) and (β= –0.066, p < 0.05), but only better total margins compared to hospitals with low adoption (β= –0.054, p < 0.01). There was however no significant difference in financial strength between high adoption and medium adoption hospitals.

Conclusion
The HITECH Act encourages the adoption of HIT in anticipation that it will help improve health care quality, reduce health disparities, and promote patient-centered delivery of medical care. This study presents a categorization of hospitals based on the number of patient engagement features offered through their adopted HIT. It also shows an overall positive trend in the number of features hospitals offer to engage patients. Notwithstanding, organizations will often weigh political pressures in light of their economic realities. This study suggests that even with the incentives provided to hospitals, administrators are obligated to consider their financial position in their strategic adoption of technology for patient engagement. While a hospital’s financial standing may not be the only consideration for administrators it is a top priority, and must be fully explored to reduce hindrances to achieving nationwide adoption.

Integrating a patient display into the primary care exam room to improve patient engagement

Onur Asan, PhD1, Paul Iglar, BS1, Jeanne Tyszka, MS,1 and, Rabia Copuroglu, BS1
1Center for Patient Care and Outcomes Research, Division of General Internal Medicine, Medical College of Wisconsin, Milwaukee, WI, USA

Abstract

This study was a mixed method interventional study to improve patient-centered communication and patient engagement with using electronic health records in primary care settings. We set up a double screen monitor in the exam rooms, with one being a patient specific display. We videotaped 24 visits and interviewed all patients as well as 8 physicians after the visits. The findings showed the potential of this approach to improve patient engagement, patient understanding of the data as well as transparency in the visit.

Introduction

The use of electronic health records (EHRs) in primary care has increased dramatically in the last decade. Increasingly, research in primary care focuses on how to use EHRs in a patient-centered way and design more patient centric EHRs in order to enhance patient-clinician communication and patient engagement during the visit. Several studies suggest that the potential pitfalls of EHRs can be avoided if physicians use EHRs as a communication and patient education tool during the visit, including sharing the screen with patients. Screen sharing might help to improve real-time patient-clinician communication; facilitate more accurate documentation, shared decision making, shared understanding, and patient involvement; it could also reduce the patient alienation that results when physicians focus on the computer screen. In this study, we had an intervention of a patient specific screen in the exam room (double screen). With the additional screen, patients were able to see all activities ongoing in the EHRs, and providers were able to share any information with the patient in much easier way. The goal of this study was to understand perception (including perceived usefulness and ease of use) and use of this patient-centered display, from both patients and providers in primary care environment.

Methods

We conducted a mixed method study to understand perceptions of providers and patients as well as their interaction with the double screen monitor in the visit. We videotaped 24 visits and using two videos from different angle. We also interviewed all 24 patients as well as 8 physicians who participated to the study. Purposive convenience sampling method was followed to recruit providers. We used a special tool called Noldus-Observer to code all videos to quantify interaction in the visit. We also used content analysis to identify themes in the interview.

Results

The video analysis showed duration of patients engaged with the second screen as well as total interaction time of doctors with EHR and patient. It was also interesting to observe that patients mostly looked at their screen while provider is typing to see what is typed in. The qualitative piece of the data showed that there is potential of having second screen to improve patient engagement, medication reconciliation, patient understanding of the data and patient trust in providers. Most of the patients liked the 2nd screen and felt more empowered since they could see every EHR related action of providers. Some providers felt that it improved number of questions prompted by patients. It was also reported that providers used patient screen to educate some of the patients with visuals and it was well- received. Most patients felt the second screen was useful, however almost half of the providers did not feel in the same way. We also identified some improvement points. Since the primary EHR screen is clutter, patient screen was also clutter. The size of the monitors are large, so it created some barriers given the desk and layout of the room was small. The future designs should make it more simplified and less clutter and more patient centric. Overall, patients acknowledged their pleasure to have access to their own data and transparency in the visit compared to visits before.

Discussion/Conclusion

More collaborative technologies in health care settings have great potential to support patient-centered care and communication by providing accessible, and actionable health information. The findings of this exploratory study can guide future exam room patient centred EHR redesign and intervention studies.
Healthcare Claims Data - Challenges in Acquisition and Analysis

Bhanu Bahl, Ph.D¹, Daniel Runt, MSMI¹, Nealia Khan, MPH¹, Douglas Macfadden, MS¹

¹The Harvard Clinical and Translational Science Center, Harvard Medical School, Boston, Massachusetts

Introduction

The Prevention and Wellness Trust Fund (PWTF) evaluation is a project established by the Massachusetts Department of Public Health (MDPH) with Harvard Catalyst team to estimate the impact of a variety of evidence-based interventions on both clinical and cost outcomes for the four principal conditions: pediatric asthma, hypertension, tobacco cessation, and falls in older adults. In this regard, the HC informatics team built a HIPAA compliant technical infrastructure for collecting anonymized patient data from a variety of sources, including the Massachusetts All-Payer Claims Database (APCD), Case Mix Index, death registry, and electronic health records through MDPHNet. In this poster we will illustrate the process and challenges encountered in the healthcare claims data capture, data cleaning, data validation, and overall data processing. Several policies and procedures regarding the sharing, transmission, storage, and distribution of data files were put in place including HIPAA complaint data security measures.

Methods

Implemented data governance procedures for secure data transfer, processing, and use as documented in the Data Use Agreement. The research data was treated as Level 4, the University’s second highest security classification, sufficient for identifiable human research. Rules for data validation and cleaning were created. Several SAS procedures were developed for converting raw data files into analysis data sets which included, but were not limited to, derived data fields, handling missing data, data linking, and data aggregation. All the coding scripts were kept within a Git repository. Rules and processes were further optimized after feedback from the statisticians.

Challenges

The delivery of the data was a raw text data dump, with processing to be done using the SAS¹ software, version 9.4. The objective was to locate individual datum in a large dataset, verify their quality, and decide to keep, derive, or discard each element. The size of the datasets, which was several terabytes, as well as the remote configuration – and multiple users accessing the same dataset – each presented performance issues. The rules for grouping ICD 9 codes to define a condition of interest, e.g. elderly falls, posed a challenge in the variant data.

Results and Conclusion

Solutions that lead to efficient processes for data extraction and handling were: well-defined data requirements, creation of small analysis-driven datasets, multiple iterations of data pulls during the streamlining process, and the creation of subsets of data. This streamlined the creation of analysis-specific files which has multiple benefits:

1. Removing end-users from the process of data cleaning and processing, resulted in high confidence analytical datasets, that were easy to use by statisticians
2. Employing this iterative process helped quantify the ratio of data used vs. data received, thereby reducing time spent on the challenge of finding multiple needles in a large haystack
3. Reducing the file size by removing redundant data, reduced computational burden and wait time for users.
4. Implementing the 'small data' approach, resulted in improvement in the quality of data, efficiency in process, and better reproducibility.
5. Optimized Algorithm for data sub-setting, cleaning, merging, and validation
Local Causal Networks Discover Predictive Cytokine Biomarkers of Scleroderma

Ali S. Bakhtiari¹ PhD, Galina S. Bogatkevich² M.D., Ph.D., Alexander V. Alekseyenko¹,³ PhD

¹ Biomedical Informatics Center, Department for Public Health Sciences, ² Division of Rheumatology and Immunology, Department of Medicine, ³ Department of Oral Health Sciences, Medical University of South Carolina, Charleston, South Carolina.

Introduction

Scleroderma is an autoimmune disease with established relationship between immune cytokines and its prognosis (1). The task of linking the cytokines to scleroderma diagnostically is important in simplifying detection of the disease. The purpose of this work is to discover cytokine biomarkers of scleroderma using local causal neighborhood (LCN) learning techniques. LCN methods identify biomarkers in the causal vicinity of the target variable (e.g. scleroderma status), which under broad assumptions results in most parsimonious and highly predictive models.

Materials and Methods

Our study cohort consists of 40 cases of positive scleroderma patients and 24 healthy controls. The study has been approved by Medical University of South Carolina (MUSC) IRB. We measured 29 bronchoalveolar lavage fluid (BAL) cytokines in each of the study subjects. We have log-transformed the raw cytokine measurements and imputed the missing values from their 10 nearest neighbors identified by K-nearest neighbors (KNN) algorithm. Adjustments for sex and race have been performed by fitting a linear regression model to individual cytokine models and extracting the residuals. We have performed univariate Welch t-tests to find the cytokines significantly associated with scleroderma status. Next, we have used the HITON-PC algorithm (2) from causal explorer toolbox (3) to identify the local causal network (LCN) of the scleroderma status. In order to assess the stability of the LCN estimate, we performed 1,000 iterations of cross validation. In each iteration, we have randomly selected 70% of the dataset and obtained the LCN biomarkers identified by HITON-PC. The remaining 30% of the data has been withheld for testing. The frequency of the appearance of the inferred cytokines from the whole dataset in the individual subsampled runs, acts as a metric for the stability of the model. The same 1,000 iterations have been used for predictive analysis. We used the LCN biomarkers as predictors for the logistic regression model of scleroderma status. The performance of each model has been assessed in the testing set using the area under the curve (AUC) of the receiver operating characteristic (ROC) curve.

Results

From the 29 studied cytokines, 8 are significantly associated with scleroderma status (P<0.05). After adjusting for multiple comparison using false discovery rate (FDR) method (4), 3 cytokines remained significant (FDR=0.05). HITON-PC algorithm has identified 2 cytokines to be in the LCN of the scleroderma status. Cross validation analysis of the HITON-PC algorithm have shown that the 2 inferred cytokines are frequently present in the LCN of the subsampled dataset as well. The predictive performance of the LCN biomarker under logistic regression model is estimated to achieve an average classification success rate of 68.46%, mean sensitivity of 65.49% and mean specificity of 73.44%. AUC of ROC curve is 73%.

Conclusion

In this work, we have demonstrated the use of LCN for discovering cytokines biomarkers of scleroderma status. We have shown the merit of using the LCN, by rigorously testing the model’s predictive power.

Patient Generated Health Data Governance at a Cancer Center

Erdeta Bani, MPA\textsuperscript{1}, Rimma Belenkaya, MS, MA\textsuperscript{1}, Olga Strachna, MS\textsuperscript{1},
Daniel Stein MD, PhD\textsuperscript{1}, Peter Stetson, MD, MA\textsuperscript{1}

\textsuperscript{1}Division of Health Informatics, Memorial Sloan Kettering Cancer Center, New York, NY

Introduction
As the number of patient data collection instruments grows, and the sets of questions asked to patients proliferate\textsuperscript{1}, the need for governance becomes critical. ONC has only just begun developing a policy framework to identify best practices, gaps and opportunities for implementation and integration of Patient Generated Health Data (PGHD) into clinical workflows. Internally, health care organizations do not normally have governance around the process for PGHD implementation and integration\textsuperscript{2}. Practical guidelines on how to optimally standardize and systemically govern integration of PGHD into clinical workflow/clinical systems remain a knowledge gap.

Methods
We have implemented a PGHD Governance Program at Memorial Sloan Kettering (MSK) to support the systematic collection and analysis of patient generated data via electronic questionnaires. Governance of the PGHD integration requires collaboration of various stakeholders\textsuperscript{2}. At MSK, PGHD Governance is represented by two interconnected entities: PRO (patient reported outcomes) Working Group and eForms Committee. The PRO Working Group is represented by clinicians, researchers, epidemiologists, biostatisticians and informaticians. The eForms Committee is a larger multidisciplinary taskforce comprised of SMEs in Informatics, Patient & Caregiver Engagement, Nursing Operations, Health Information Management, Biostatistics, Mobile Application Development, and representatives from the PRO Working Group. The role of PRO Working Group is to create a conceptual framework for PRO integration. The role of eForms Committee is to oversee all aspects of implementation of the conceptual framework and apply these principles beyond PRO questionnaires to all PGHD. Thus the eForms Committee ensures standardization of questions/question sets across instruments; optimal patient experience with questionnaires that do not introduce survey fatigue; appropriate secondary uses of PGHD; and monitoring usage and value of electronic instruments over time. We include representatives of the patient's care team in all aspects of PGHD integration.

Results
Our PGHD Governance was launched in January 2016. The eForms Committee developed a workflow for receiving and triaging all PGHD requests. It oversaw enforcement of this workflow, meeting monthly to address new requests, and to evaluate the effectiveness and impact of the PGHD on clinical practice while ensuring data integrity in the legal record. In its first year, the PRO Working Group identified goals for collecting PROs; chose appropriate instruments and adjusted them to serve specific goals and populations; established patient cohort parameters; determined setting and timing for administering assessments; chose scoring methodology; designed reports and analytical methods to interpret results; determined thresholds for care team notifications and escalation rules; and evaluated impact of the PRO intervention on the practice. To date, the collaboration between these two entities has standardized PRO-CTCAE, exercise, smoking and pain question sets in a number of instruments used with new, post-operative, palliative, and survivorship patients. It used analytic dashboards to evaluate use and value of questionnaires such as EORTC-QLQ30. It has converted more than 80 paper questionnaires to electronic ones applying these implementation principles.

Conclusion
Although we are at a very early stage of the PGHD Governance implementation, our approach has already improved our process of electronic PGHD instrument adoption. Including representatives of care teams in all aspects of the governance helped our clinicians understand information collection bottlenecks, improve their workflows and communication with patients and evaluate the impact of the PGHD intervention on the clinical practice. As our PGHD governance program matures, we expect our approach to PGHD governance can be applied more broadly to healthcare institutions, beyond cancer centers, that are looking to tackle this challenge.

The Time is Right for Clinical Data Platforms that Reduce Clinician Time Reviewing Patient Care Data Elements: Emerge as a proof of concept

Denise Barchas RN MSN1, Angela Lipshutz MD MPH1, Kathleen Liu MD PhD1, Kathleen Turner RN1, Charlotte Garwood RN MS2, Kelly Timothy RN MSN1, Amie Lencioni RN1, Michael Gropper MD PhD1, and Hildy Schell-Chaple RN PhD1

Introduction

The electronic health record (EHR) is intended to provide clinicians with secure, instant, and current patient-specific clinical data. Despite this intent, EHR usability and data display is suboptimal and may lead to time wasted for clinicians using the EHR, ultimately affecting patient care delivery1. The purpose of this study was to evaluate the time spent by intensive care unit (ICU) clinicians to locate specific clinical harm prevention intervention elements for venous thromboembolism events (VTE), delirium, ventilator associated events (VAE), central line-associated blood stream infections (CLABSI), ICU-acquired weakness (IAW), and care discordant with goals (GOC). Clinicians were asked to locate and review data in the EHR as if they were performing routine chart review and compare it to time spent reviewing the innovative Emerge platform. The Emerge platform transforms EHR data elements to a separate harms monitor that summarizes essential patient data in a graphical fashion (Figure 1).

Methods

Clinicians were recruited from the adult medical-surgical ICU at a large academic medical center. Participants were asked to locate specific harm prevention care elements in the EHR (EPIC Verona, WI) and also the Emerge platform for a single patient. The primary measure was time spent to review care interventions by harm type and total time for review of all 23 data elements. A Wilcoxon signed-rank test was used to analyze the difference between time spent in the EHR and Emerge platform. An alpha level of less than .05 was considered statistically significant. Analyses were performed using SPSS statistical software, version 23 (SPSS, Inc).

Results

Based on power calculations to detect clinically relevant differences, 23 ICU nurses, nurse practitioners, and fellow physicians participated in this study. There was a significant reduction in total time spent reviewing care elements using the Emerge platform compared to the EHR (Median (IQR) in minutes, 5:00 (4:17, 6:51) vs. 8:41 (6:30, 9:37), p < .001. Less time was spent reviewing all harm data using Emerge compared to the EHR, and significant reductions were found for review of VTE, VAE, and GOC element (Table 1).

<td>8:41 (6:30, 9:37)</td>
<td>5:00 (4:17, 6:51)</td>
<td>&lt;.001</td>
</tr>
</tbody>
</table>

Conclusion

Well-designed innovations that transform data from the EHR and provide an intuitive visual display can reduce clinician time spent reviewing patient data in the EHR to ensure the plan of care is implemented. The time saved for a single patient multiplied by the typical patient load of 16 ICU patients at our hospital equals 56 minutes. The Emerge platform is a model for innovative platforms that can improve efficiency, usability, reduce time facing the computer, and potentially impact safety and quality of care.

Distributed Health Data Networks: Extending the PopMedNet\textsuperscript{TM} Informatics Infrastructure to Extend Existing Query Functionality to New Data Sources

Kimberly Barrett, MPH\textsuperscript{1}, Jessica M. Malenfant, MPH\textsuperscript{1}, Kyle Erickson\textsuperscript{1} Adam Paczuski\textsuperscript{1}, Zachary Wyner\textsuperscript{1}, MPH, Chayim Herzig-Marx, PhD\textsuperscript{1}, Jeffrey S. Brown, PhD\textsuperscript{1}
\textsuperscript{1}Harvard Pilgrim Health Care Institute, Boston, MA

Introduction: Distributed health data networks are increasingly used to conduct clinical and observational research, medical product safety surveillance and to supplement existing public health surveillance activities. Several of these distributed networks utilize the open source platform, PopMedNet\textsuperscript{TM} (PMN), to facilitate research of electronic health data. PopMedNet (PMN) enables distributed analyses through a flexible infrastructure that allows for various methods of querying data such as, modular programs, file distributions, and menu-driven queries (MDQs). Not only does PopMedNet streamline querying data, but it is compatible with multiple distributed networks- The FDA’s Sentinel system, the NIH Health Care Systems Research Collaboratory, PCORI’s PCORnet, National Cancer Institute’s CRNnet, and the Massachusetts Department of Public Health’s MDPHnet are active PMN-based networks. They have different common data models (CDMs), goals, and priorities, but all benefit from the functionality provided by PMN and related software applications.

Methods: This presentation describes the integration of multiple tools to validate that the PMN distributed querying infrastructure can be used for non-PMN data sources.

Menu-Driven Query: The Menu-driven Query (MDQ) query composer interface was developed to support “query terms” that can be shared across networks. The system supports querying filters (referred to as terms) and result grouping options (referred to as stratifications). The MDQ interface is Common Data Model aware, allowing a user to see only the terms and associated value sets applicable to the Common Data Model they are querying. While this is an assumed ability when an investigator is querying within a single network, this change helps extend the collaboration opportunities across networks with different data models.

After distribution, queries are transmitted to the PopMedNet (PMN) DataMart Client in a JSON string, that is then parsed by the PMN model adaptor for that user’s Common Data Model and compiled into a LINQ expression tree that Microsoft Entity Framework 6 translates into SQL queries appropriate for the target database. This process enables data holders to keep data in the relational database management system (RDBMS) of their choice, reducing barriers to participation. With this improvement, it is no longer necessary to develop custom SQL code for each RDBMS. As previously described, the Rapid Data Characterization Tool (RDAT) initially developed for the Sentinel network in PMN was enhanced to allow querying of new terms for age, sex, height and weight distributions which will benefit PCORnet and others. This tool continues to be used by multiple networks. It uses a data characterization data model that is agnostic to the Common Data Models of the individual networks.

Test Case Inserter: As the capabilities of the MDQs expand, a method of verifying the function and analysis is necessary. The Test Case Inserter tool, a purpose-built command line program, enables users to easily insert test data into a relational database management system (RDBMS), such as Oracle or SQL Server without requiring knowledge of SQL programming syntax for each RDBMS. The test data is formatted according to a Common Data Model, and the Test Case Inserter tool then “inserts” all of the test information into a RDBMS. The tool can be configured to read any data model so long as the .csv adheres to a standard format, originally based on the PCORnet data model. Once the data is inserted into the RDBMS, the researcher can run a MDQ against the data. Users are able to the run a PMN query and validate that the results match what is expected according to what they added via the TCI tool.

Results: We can demonstrate that the TCI can be used to accurately update databases that adhere to existing common data models, such as PCORnet as well as ad hoc databases. This process allows us to validate that the new PopMedNet MDQ’s are accurate and consistent across different database flavors and the functionality can be repurposed for multiple data models. One challenge discovered that should be addressed is the requirement to modify the table and column format from all caps to lowercase depending on the workflow step. For TCI, the target database needs to be all caps, but for the PMN queries, the target database needs to be lowercase.

Conclusion: Ongoing and future work will involve using additional data models that have fields that already exist as queryable terms in the menu-driven query interface and explore how we can continue to extend this functionality. Distributed data networks have proven valuable in conducting public health surveillance, research, and evaluation activities. This work has shown how PMN and allied tools can be extended and scaled for use in various work streams and across networks, regardless of data model or technical environments.
Comparative Analysis of Intravenous to Oral Transitions at Two Tertiary Care Hospitals in the U.S. and Switzerland

Patrick E. Beeler MD\textsuperscript{1,2,3}, David W. Bates MD MSc\textsuperscript{1,2}, Jürg Blaser PhD\textsuperscript{3}

\textsuperscript{1}General Internal Medicine, Brigham and Women’s Hospital, Boston, MA, USA; \textsuperscript{2}Harvard Medical School, Boston, MA, USA; \textsuperscript{3}Research Center for Medical Informatics, University Hospital Zurich, Switzerland

Introduction: Early intravenous (IV) to oral (PO) transitions increase the quality of care and decrease costs. Automated reminders successfully promoted earlier IV-to-PO transitions of antibiotics.\textsuperscript{1} Yet, no comprehensive data on IV-to-PO transitions across all drug classes have been published, although such data could inform on opportunities of reasonable transitions. Our objective was to generate knowledge on IV-to-PO transitions performed at two large, comparable hospitals, one in the U.S. and one in Europe, thereby increasing the generalizability and meaning of the results.

Methods: Data were extracted from the clinical data warehouses at the Brigham and Women’s Hospital (BWH; Boston, MA, USA; preliminary data 1/2014-4/2014) and at the University Hospital Zurich (UHZ; Switzerland; 8/2009-4/2014). These leading tertiary care academic medical centers are particularly suitable for comparative studies due to their similar size (859 and 850 beds) and Case Mix Index of 1.47 and 1.54, respectively. Data were processed using SQL. Drugs and free text orders were mapped to the Anatomical Therapeutic Chemical (ATC) Classification System (WHO, Geneva, Switzerland) ensuring international comparability. At the end of an IV therapy the time frame ±36 hours was beginning PO administrations of the same drug agent. This approach allowed for calculating the interquartile range (IQR): half of PO drugs started within -0.5 h to +3.0 h (UHZ) and 0 h to +7.5 h (BWH) after IV discontinuation. By using these IQRs we could identify IV-to-PO transitions among identical and different drug agents. Aggregated lists of IV-to-PO transitions were reviewed to sort out unreasonable drug agent sequences.

Results: Analgesics accounted for the vast majority of IV-to-PO transitions (Table 1). The most frequent transition of an antimicrobial at the University Hospital Zurich was IV amoxicillin/clavulanic acid → PO amoxicillin/clavulanic acid (n=3,844), at the Brigham and Women’s Hospital IV metronidazole → PO metronidazole (n=315).

Table 1. Most frequent IV-to-PO transitions at the two tertiary care hospitals in the U.S. and Switzerland

Discussion: We found major distribution differences of IV-to-PO transitions. No opioid analgesics were among the top transitions at the UHZ, contrasting with the BWH where 6 of the transitions involved opioids. Regarding the opioid epidemic, our study shows ways in IV-to-PO transitions of analgesics towards non-opioids, and early transitions may be supported by automated reminders. Dipyrone’s approval in the U.S. was withdrawn in 1977 due to its association with agranulocytosis, however, this potent analgesic is frequently used at the UHZ. Considering the mortality related to the opioid epidemic, one might argue for a reevaluation of dipyrones applicability in the U.S. In conclusion, comparative analyses of medication orders revealed surprising cultural and pharmacoepidemiological differences.

A Simple and Efficient Method for the Management of Multiple Electronic Health Record-Driven Phenotype Projects

Cosmin A. Bejan, PhD¹, Joshua C. Denny, MD, MS¹²

¹Department of Biomedical Informatics, ²Department of Medicine, Vanderbilt University Medical Center, Nashville, TN

Abstract
Based on our experience of working with the Electronic Health Record (EHR) at Vanderbilt University Medical Center (VUMC), we developed a simple method of good scientific practice for the management of multiple phenotype projects. Our method relies on the Google Sheets application (https://docs.google.com/spreadsheets/) that allows for cooperative editing of documents by multiple investigators at the same time. Our framework proved to be efficient when working with multiple teams of investigators from both inside and outside VUMC.

Background
Researchers in biomedical informatics are often involved in multiple EHR-based phenotype projects that may happen simultaneously or may be in different phases of their development life cycle. Each of such phenotype projects involves one or multiple investigators, requires the design and implementation of one or multiple phenotype algorithms, and usually results in executing dozens of experiments with various configuration parameters.

Method
The office suite made freely available by Google as both web and mobile applications has quickly become popular for its simplicity. These applications, including Google Docs, Sheets, and Slides, allow for an efficient collaboration where users can simultaneously edit documents, can see character-by-character document changes by other users in real time, can track the past edits, and are able to revert the documents through a revision history mechanism. Out of these applications, we adapted Google Sheets to create a practical framework for the management of our phenotype projects. In general, for each project, we created a spreadsheet that we shared with all the investigators participating in the project. A standard document contains one main sheet with all the experiments performed for the corresponding project and multiple auxiliary sheets with information used in these experiments. Figure 1 depicts one of our projects that involves sensitive time searches for the discovery of rare adverse events associated with various medications.[1] For instance, to identify patients who experienced severe allergic reactions such as Stevens-Johnson Syndrome and Toxic Epidermal Necrolysis (SJS/TEN) caused by phenytoin, an investigator added the medication in ‘MED lists’ and SJS/TEN billing codes in ‘ICD lists’. As shown in Figure 1, time constraints for filtering patients with adverse drug reactions occurring after a medication are specified in the main sheet. The configuration of each experiment is automatically processed, the corresponding phenotype algorithm is executed, and the extracted patient cohort is returned to the investigator for further analysis. Additional information sheets integrated in other projects include: 1) annotation guidelines and relevant examples for textual information extraction projects; 2) the evaluation of phenotype algorithms; and 3) SQL queries for cohort size estimations.

Conclusion
We presented a simple and easy to implement method that proved to be efficient for the management of intensive, collaborative phenotype projects. The type of phenotype projects tested with this method ranges from applications that combine structural clinical information to projects mainly based on natural language processing technologies.

Implementation of a Knowledge Base Driven Perioperative Metrics Framework and Governance Program

Rimma Belenkaya, MS, MA1, Olga Strachna, MS1, Christopher Stromblad, PhD1, Kinjal Shah, MPH1, Hyok-Hee Yoo1, Natalia Shapiro1, Alexander Tanchoco1, Marina Kerpelev1, Ilya Sher1, Jonathan Wills1, Shai Ahmed1, Peter Stetson, MD1, Daniel Stein, MD, PhD1.

1Division of Health Informatics, Memorial Sloan Kettering, New York, NY.

Introduction

We have implemented a knowledge base driven enterprise framework for perioperative metrics, developed at Memorial Sloan Kettering to support operational analytics and research in the perioperative domain.

Consistent generation of key perioperative metrics is challenging, due to the lack of consistent definitions, redundant reports produced by multiple teams, multiple underlying data sources and lack of transparency in metric derivations. The framework we developed covers the entire metric life cycle and ensures consistency of metrics generation and reporting across the enterprise, and increases efficiency in providing stakeholders the data and insights they need.

Methods

We created a framework that includes governance, knowledge base, an integrated harmonized data repository, and data visualization components. The governance body oversees all aspects of the metric development from definition and certification, to datamart design and visualization creation, and it addresses any changes in the underlying data or business processes that may affect the metric.

The knowledge base is made up of two components: A Metric Ontology and a Report & Dashboard Catalog. The Metric Ontology captures detailed metric definitions, classification, relationships between the metrics, and links the underlying data sources and metadata. The Report & Dashboard Catalog contains all the perioperative reports, annotated with rich set of attributes. The knowledge base associates metrics with reports. It is based on a semantic extension of MediaWiki utilizing a set of nested templates and forms to collect and display metric attributes. It features ontology-driven search interface and tools for evaluation of report usability.

The integrated data repository built as a star schema, is a single source of data for derivation of the certified metrics. Its dimensions contain metadata defined in the knowledge base. ETL (extract transform and load) processes that populate the datamart are vetted to accurately harmonize data from multiple sources.

Visualization of the data is the ultimate purpose of the framework, helping the stakeholders to answer key questions about perioperative outcomes, quality of care, operations, and efficiency. Our dashboard design process follows human-centered design principles. The dashboard elements are driven by the metadata defined in the knowledge base. These visual elements also link back to the metric definitions completing the framework loop.

Results

Our framework was launched in July 2016. Since then, the knowledge base was populated with 90 perioperative metrics and over 400 perioperative reports. The top priority productivity and efficiency metrics have been revised, defined, and certified. During this process, new metric variants were introduced that enabled different perspectives on perioperative productivity and efficiency. The first version of the data repository was built and populated. Executive and Ambulatory Case Volume dashboards were implemented, and Scheduling Accuracy dashboard is being designed. We are integrating these instruments into the workflows of the key stakeholders. The next critical metrics, utilization and quality and outcome measures, are underway.

Discussion

Our framework has enabled our Department of Surgery to capitalize on existing informatics and analytic resources to support clinical operations and research. The process of metric development is complex and requires appropriate planning, given the need to coordinate a diverse group of stakeholders and to achieve consensus. Also, while the framework reorganizes existing reports, it does not address problems associated with new data and report requests. We plan to address these limitations next by adopting a Semantic Web platform that supports formalized ontology and collaborative process of metric development and implementing process of triaging new data and report requests.
Honoring Patient’s Data Sharing Preferences: Implementation Challenges

Elizabeth Bell, MPH; Diana Guijarro, BA; Imho Jang; Wenhong Zhu, PhD; Tyler Bath, BS; Gwang-No Yun; Masud Rahman; Chao Jiang, MS; Xiaqian Jiang, PhD; Lucila Ohno-Machado, MD, MBA, PhD; Hyoneui Kim, RN, MPH, PhD

Department of Biomedical Informatics, University of California, San Diego, La Jolla, CA

Introduction and Background

iCONCUR (informed CONsent for clinical data and biosample Use for Research) is a web-based consent management system that allows patients to indicate their data sharing preferences in a tiered manner (https://ctriconcur.ucsd.edu). We are currently revising iCONCUR based on the lessons learned from a pilot study and will test it with a larger sample of patients recruited from the two academic health systems. During this study period, the sharing preferences of participating patients will be honored – i.e., data that they do not wish to share will be excluded from the datasets prepared for researchers. The first step to implementing the process of honoring patient’s data sharing preference is to establish mapping between the data items in the data sharing preference taxonomy and the location of the Clinical Data Warehouse (CDW) where the data items are stored. Based on this mapping, the data that patients do not wish to share is automatically filtered out when a clinical dataset is prepared for a researcher (Fig 1). UCSD Medical Center uses Epic EHR system. Clarity is the database of Epic EHR. Research data has been prepared from the CDW that has the same structure of Clarity (i.e., its copy).

Methods

The data sharing preference taxonomy covers with 10 content areas such as socio-demographic, living environment and life style, medical history, family history, medications, test results, procedures, clinical encounters, vital signs and assessment, and sexual and pregnancy history. We first identified where the information related to the data items listed in the data sharing preference taxonomy is documented in Epic EHR. Then we tracked how those data fields of Epic are ETL-ed (Extract-Transfer-Load) into the CDW to pinpoint the data tables and columns needed to link back to the data sharing preference taxonomy.

Results

Nine content areas were mapped to the fields of the EHR and subsequently to those in the CDW. The content area not fully mapped is living environment and lifestyle, which includes drinking, smoking, and recreational drug use histories, as well as diet habit, exercise and activity, stress level, and social engagement. The former 3 items were fully mapped as they were documented in a structured format. However, the latter 4 were left unmapped, as they do not have dedicated structured fields and are mostly documented in free-text notes.

Discussion

We noted a few complex cases where a single data item from the sharing preference taxonomy is mapped to multiple tables and fields in the CDW. For example, medical history item is linked to three tables (problem list, visit diagnosis, medical history) in the CDW, and pregnancy history is to two tables. Currently, the CDW at UCSD is transitioning into a standardized structure following the Observational Medical Outcome Partnership Common Data (OMOP-CDM) Model. This new implementation will streamline the process of honoring patient’s data sharing preferences by simplifying the mapping between the sharing preference taxonomy and the CDW. For example, in the new OMOP-CDM based CDW, medical history is stored in the single table “Condition Occurrence.” An additional challenge that we identified is handling inter-relationships between medical history and the other types of related information (e.g., test results, medication, and therapeutic procedures) that could be used to infer the medical history even if medical history is not shared. We plan to build a smart honoring system that recognizes such relationships and filters out this related information, even if a patient forgets to indicate the removal of such information along with removing medical history.

Self-Service Cohort Discovery across Five Academic Health Centers: Usage and User Evaluations of the University of California Research eXchange

Douglas S. Bell, MD, PhD1, Lisa Dahm, PhD2, Nicholas Anderson, PhD3, Ida Sim, MD, PhD4, Pralav Dessai1, Marianne Zachariah1, Lucila Ohno-Machado, MD, PhD5

1David Geffen School of Medicine at UCLA, Los Angeles, CA; 2University of California, Irvine, Orange, CA; 3University of California, Davis, Davis, CA; 4University of California, San Francisco, San Francisco, CA; 5University of California, San Diego, San Diego, CA

Introduction

The University of California Research eXchange (UC ReX) is a partnership among the five University of California medical campuses, aimed at enabling multi-campus research projects. In late 2013, we launched the UC ReX Data Explorer, an implementation of the SHRINE1 system, to support cohort discovery queries across the federated clinical data warehouses of the five campuses, which contain records from nearly 15 million patients in total.

Methods

We analyzed usage logs after excluding data from project personnel who performed system testing or user training. We programmed the SHRINE web client to randomly pop-up a survey invitation 30 seconds after query results appear, for 5% of queries. The invitation contained a link to a REDCap survey with questions about the specific query results and the user experience. The survey was active from 2/2015 to 5/2016.

Results

The system went into production 10/2/2013. In the 41 months through 2/28/2017, 426 distinct users ran a total of 8317 cohort queries (19.5 queries/user). Patterns of growth in users and usage differed among the five UC sites (Figure 1).

Figure 1. Growth in new users (left panel), and query volumes (right panel) at each of the UC ReX sites.

Users completed the pop-up survey for 60 queries, representing 26% of an estimated 231.5 opportunities (5% of 4630 queries during the time the survey was active). Users rated 75% of query results as clinically “expected” or “believable,” as opposed to “not likely” (17%), or “not possible” (7%). They rated the results as meeting their goals “completely” or “mostly” for 58% of queries, “somewhat” for 40%, and “not at all” for only 1 result (2%). The Data Explorer was rated as “extremely” (33%) or “somewhat” (42%) easy to use in most responses, whereas 10% rated it “somewhat” or “extremely” difficult to use. Ninety percent of users agreed or strongly agreed with the statement that they would recommend the Data Explorer to their follow researchers. User comments were mixed.

Conclusion

Most users of the UC ReX Data Explorer found the system to be useful and usable for self-service cohort discovery across the UC health systems. Investigators are making growing use of the system but the majority of clinical researchers are not using it. Programs to accelerate the uptake of cohort discovery are warranted.

Introduction: Chronic heart failure (CHF) is a prevalent condition among Veterans within the Veteran Affairs (VA) health care system. A high percentage of Veterans are not receiving guideline-directed beta blocker medical therapy. We examined the barriers and facilitators related to evidence based care among primary care providers to inform the design of a clinical reminder in the VA electronic health record that would prompt appropriate ordering and titration of beta blockers in primary care Patient Aligned Care Teams (PACT).

Methods: Semi-structured usability interviews adapted from a cognitive task analysis perspective were used to elicit provider’s mental models of the care process, and the utility and usability of the clinical reminder prototype. Clinicians from PACTs from 2 VA medical centers and related community clinics were recruited for the interviews (4 physicians, 2 nurses, and 3 pharmacists). Providers were asked to participate from both rural and urban settings in two states. Each interview focused on workflow, clinical decision-making, institutional and contextual barriers and clinician’s attitudes toward using guidelines. Our research team reviewed the transcripts to answer the research questions, “Why are CHF patients in the VA being undertreated with respect to guideline recommended beta blocker use?”, and “What are the barriers to beta blocker titration?”, using applied thematic analysis. 3 Analysis was undertaken to identify themes in the narrative using an iterative approach, beginning with identification of basic PARIHS constructs and then development of emergent themes.

Results: Four themes were identified during preliminary analysis. There is: 1) Confusion about who is responsible for completing the reminders; 2) Concern about patient factors in tolerating titration; 3) Concern about patient comorbidities; 4) Concern about incomplete communication between providers and patients.

Conclusions: Our results provide insight to barriers for beta blocker titration within the PACT in VA. Potential changes to the next version of the reminder may include a link to the patient’s problem list and modifications in the titration story related to titrating to maximal tolerated doses given specific patient factors.

Implementation and Adherence Evaluation of Intrusive Alerts for Adjusting Dose to Renal Function

Francisco M. Bernabeu MD1,2,3, María S. Hernández Caffot MD, PhD1,2, Nadime N. Sufan, Pharm.1,2, Fabiana Ellena MD2,3 Bayan V. Khorsandnia MD1,2
1) Departamento de Informática en Salud, 2) Instituto Universitario para las Ciencias Biomédicas de Córdoba (IUCBC), 3) Servicio de Clínica Médica, Hospital Privado Universitario de Córdoba (HPUC); Córdoba, Argentina

Introduction
Medication errors can trigger adverse events associated with increased mortality, excess length of hospitalization, and extra costs1. Among those are the ones related to the dosage, due to lack of adjustments required for different pathological conditions. Within these, renal impairment plays an important role since about 60% of the drugs are excreted in this way2. In the present study we analyze the implementation of a Clinical Decision Support System (CDSS) with an intrusive drug adjustment alert according to the renal function, and evaluate their adherence and the ability to avoid potential adverse drug events.

Material and Methods
A retrospective study was performed at the HPUC, during 6 months (July - December, 2016). A CDSS of maximum allowable dose was implemented for the 248 most frequently prescribed drugs, 94 of which required dose adjustment for renal impairment. The maximum adjusted doses of each drug were obtained according to creatinine clearance. The alert forced the user to make the decision to modify, cancel or, if justified because the patient was on dialysis, critical or terminal state, continue with the dose. All the hospitalized patients with a creatinine clearance less than 60 ml/min were included. Prescriptions carried out in the oncology sector and the pediatric population were excluded. Medication errors due to inadequate adjustment to renal function and the decisions made by the doctor were analyzed. Adherence was considered adequate (AA) when, in response to the alert, the user chose to cancel, modify or continue, as long as the justification was correct, corroborating the information through the review of medical records. If the justification was incorrect, the adhesion was considered inadequate (AI).

Results
We registered 629 renal dose adjustment alerts, 74 (11.7%) modified the dose of the drug (AA) and 155 (24.7%) canceled the prescription (AA). In 400 cases (63.6%) the physician decided to continue, justifying 136 (34%) cases as being on dialysis; 250 (62.5%) as critical patients and 14 (3.5%) as terminal patients. A sub-analysis by group of patients on dialysis showed that 33 justifications were incorrect as they corresponded to non-dialyzable drugs and 13 to patients who were not on dialysis (AI). From critically ill patients, 51 prescriptions were incorrect because they were non-critical drugs and 118 alerts were non-critical patients (AI), only 81 alerts were adequate in this subgroup (AA). 6 out of 14 terminal justifications were correct (AA). A total of 406 out of 629 (64.5%) alerts were considered as AA and 223/629 (35.5%) as AI.

Conclusion
Our CDSS allowed us to avoid 229 drug adverse events (corresponding to modified and canceled alerts) out of 629 maximum dose alerts according to renal function within 6 months. Despite the evidence in favor of the use of advanced CDSS, its adequate adherence continues to be suboptimal, with 64.5% of them in our study showing a high attempt rate of overriding (35.5%).

Development of a large-scale, whole body CT image database

Shamsi Daneshvari Berry, PhD, MS1,2, Heather J.H. Edgar, PhD2

1University of Mississippi Medical Center, Jackson, MS; 2University of New Mexico, Albuquerque, NM

Abstract

Some research questions cannot be answered because the data is simply not available. Such is the case for many projects that require a large, diverse, high quality dataset. A sample of over 11,000 whole body CT images has been created through a National Institute of Justice grant. After determining the metadata to associate with the images, a large scale database of CT scans and associated metadata is currently under development.

Introduction

Often researchers cannot answer the question of interest because the necessary dataset does not exist. In addition, the technological requirements for datasets grows as the sets themselves become larger. This is the case for questions requiring a representative samples of high quality Computed Tomography (CT) images and associated health and lifestyle data. Currently no such dataset exists.

Decedent Database

The Office of the Medical Investigator (OMI) is a state-wide, centralized medical examiner’s office for the entire state of New Mexico. Any individual who dies in the state in a sudden, violent, untimely, or unexpected manner, and any person who is found dead and the cause of death is unknown, is routed to the OMI for a possible autopsy. In 2010, 5,249 deaths were processed by the OMI, 51% of those underwent autopsy, accounting for 35% of the deaths within the state.1,2

The Center for Forensic Imaging at the OMI was awarded a grant from the National Institute of Justice in 2010 to evaluate whether CT scans can supplant or supplement the traditional autopsy. As a result, every decedent that underwent an autopsy received a high resolution, head-to-toe CT scan. To date this work has produced over 11,000 whole-body, 3-D CT images. However, there were no plans for the images after the 2010 National Institute of Justice grant was completed. As there was no appropriate minimum dataset (MDS), a modified Delphi method was implemented to determine the MDS to associate with the images to make them useful to the widest variety of researchers. A list of 59 metadata variables was developed with a high level of consensus by querying experts from a wide variety of domains (anthropology, forensics, informatics, medicine, demography, dentistry, public health, etc.).3 Data will be gathered from the OMI database as well as next of kin interviews.

In 2016, a National Institute of Justice grant was awarded to create this large-scale database and associated website. It has the potential to answer a large number of previously unanswerable questions that could improve health in the living.

Conclusion

The free-access Decedent Database is currently under development. Researchers will have access to this plethora of data and associated images by the end of 2018.

Identification of Patient Subgroups in Metastatic Breast Cancer Patients Based on Somatic Copy Number Alterations: A Bipartite Network Analysis

Suresh K. Bhavnani PhD1, Archana Ayyaswamy MS1, Tianlong Chen BS2, Jeremy L. Warner, MD MS3

1Institute for Translational Sciences, University of Texas Medical Branch, Galveston, TX; 2Dept. of Physics, Univ. of Houston, Houston, TX; 3Dept. of Medicine & BMI, Vanderbilt University, Nashville, TN

Abstract

While somatic copy number alterations (SCNA) in the human genome are known to exhibit complex patterns in cancer patients, less is known about whether they can help to identify patient subgroups critical for the design of targeted interventions in precision medicine. We therefore used a bipartite network analysis and a new network layout method called ExplodeLayout to analyze the heterogeneity within metastatic breast cancer specimens extracted from the GENIE database, with the goal of inferring the underlying mechanisms. The results revealed 5 co-clusters of specimens and SCNAs which were statistically significant, and enabled inference of complex but comprehensible SCNA heterogeneity in metastatic breast cancer.

Introduction

An increasing number of diseases have been shown to have distinct patterns related to copy number variations in the genome. Cancers in particular have a complex combination of somatic gene deletions and amplifications, driving heterogeneity and genomic instability.1 Furthermore, as most amplifications of copy number variation events cause increased gain of function and fitness of the cancer, they result in a poor prognosis. We therefore explored the use of bipartite networks to identify patient subgroups across metastatic breast cancer patients, with the goal of inferring the underlying mechanisms, and designing targeted interventions.

Method and Results

The Genomics, Evidence, Neoplasia, Information, Exchange (GENIE) supported by the AACR is an international data-sharing project that aims to catalyze precision cancer medicine. This database has 18,966 specimens across many cancer types from which we extracted all metastatic breast cancer specimens (n=1,102), of which a subset (n=894) had SCNA data. In order to optimize modularity, we restricted the analysis to the 20 most-commonly amplified genes, resulting in 527 specimens. To analyze heterogeneity in these data, we conducted a bipartite network analysis2 using the following method: 1) conducted a co-cluster modularity2 analysis to identify the number and membership of specimens and genes in co-clusters; 2) calculated the significance of the clustering using 1000 permutations of the network while preserving size and density; 3) used Fruchterman Reingold2 (FR) to lay out the network; and 4) used a new network layout method called the ExplodeLayout3 algorithm designed to separate significant but highly-overlapped clusters to improve comprehension. This algorithm takes as input the network layout from FR, and node cluster membership from the co-cluster modularity, and maps each cluster’s centroid onto equidistant points on an imaginary circle. The algorithm searches for a circle radius such that the ratio of the total non-overlapped area among the clusters, and the total space required for the entire network layout is maximized, resulting in an optimal cluster separation within a compact area. The resulting network was then interpreted by an oncologist to comprehend the patient subgroups and infer their underlying mechanisms.

Before application of the ExplodeLayout algorithm, there was no visually discernible network structure. After the algorithm was applied, as shown in Fig. 1, the analysis revealed 5 clusters with strong clusteredness (co-cluster modularity=0.49), which was significant compared to 1000 permutations of the network (z=37, p<0.001). The results helped to confirm a known breast cancer subtype (ERBB2 a.k.a. HER2-amplified breast cancer) and to identify new molecularly-defined subtypes. Two clusters (pink and gray) are driven by ampiclon events (11q13 and 8q24, respectively). The green cluster is driven by amplification of the 1q chromosome arm, and represents a group of cancers dependent on the anti-apoptotic gene MCL1.1 The yellow cluster contains two genes that are known to be in the stem cell pluripotency pathway and have been described as being co-amplified in brain metastases4; these patients are likely to have particularly aggressive disease. Future research will test the replicability of the results in other datasets, the utility of the above analytical approach in other cancer types.

Implementing a Hash-based Privacy-Preserving Entity Resolution Tool in the OneFlorida Clinical Data Research Network

Jiang Bian, PhD1, Andrei Sura, BS1, Gloria Lipori, MT, MBA1, Yi Guo, PhD1, François Modave, PhD1, Zhe He, PhD2, Elizabeth Shenkman, PhD1, William Hogan, MD, MS1

1University of Florida, Gainesville, Florida, USA; 2Florida State University, Tallahassee, Florida, USA;

Introduction: The OneFlorida Clinical Research Consortium is one of the 13 PCORI-funded Clinical Research Data Networks as part of the National Patient-Centered Clinical Research Network (PCORnet) in support of large-scale pragmatic clinical trials and implementation science studies. A key component of OneFlorida is its Data Trust, a secure data repository currently containing 10.6 million patient records, currently including pediatric claims data from Florida Medicaid and electronic health record (EHR) data from 9 unique health systems across the network. However, data records of the same patient can come from different data sources in the OneFlorida network. For example, EHRs and claims have complimentary data records for the same patient. Thus, entity resolution (ER)—linking related data and resolving duplicates—at the individual level in a research network is a significant task in improving the data quality. Nevertheless, linking patient records is not a trivial task balancing between linking efficiency and privacy needs. Record linkage is nonetheless a well explored problem. In this study, we adapted a privacy-preserving record linkage method1 and implemented it as an open source tool (available at: https://github.com/ufbmi/onefl-deduper).

Methods: We used a deterministic (rule-based) ER method. Unlike existing methods, we did not use any direct identifiers, such as social security numbers (SSN). Instead, our linkage rules are combinations of quasi-identifiers such as name, date of birth (dob), race, and sex. We consider two records (A and B) to be about the same patient if one or more combinations of quasi-identifiers have the same corresponding values (e.g., A.name + A.dob + A.race = B.name + B.dob + B.race) and these combinations can uniquely identify the patient in the datasets. Thus, the problem of linking patient data is transformed into equivalence tests based on these linkage rules. We learned these linkage rules—combinations of quasi-identifiers that maximize linking precision (i.e., minimize false positives)—using publically-accessible Florida voter-registration data. We tested the rules using a sample (~1000) of University of Florida (UF) Health and Florida pediatric Medicaid patient data that were linked using Medicaid beneficiary identifiers and manual review.

Results: Using the Florida voter registration data (~13 million), we learned two rules: 1) first name + last name + dob + race; and 2) first name + last name + dob + gender, that can uniquely identify a person (0.03% and 0.04% duplication rates, respectively). On the manually-curated linked sample data, both rules achieved perfect precision (no false positives), and reasonable recall (0.463 and 0.715, respectively). Using both rules, we implemented a Python-based open-source ER tool for linking patient records in the OneFlorida network. We consider two records to be about the same patient if either of the two rules predict a match. The overall recall of the system is at least 0.715, with a perfect precision. To preserve patient privacy, we used a one-way, collision-resistant, cryptographic hash function (seeded SHA-256) to scramble the protected health information (PHI) used in these linkage rules. It is computationally impossible to reverse the hash function to find the original PHI based on only the hash values. Further, to account for common data entry issues, we also incorporated several data normalization procedures.

Conclusion: Using the developed ER tool, we linked the entire UF Health and Florida pediatric Medicaid patients, and found 204,919 matches. A privacy-preserving ER solution is highly desired for clinical research networks like OneFlorida to improve data quality while ensuring the privacy of all whose data are in the Data Trust.

Validation of Diabetes Identification within Electronic Health Records

Katie E Bickett, MS₁, Timothy D. Imler, MD, MS₁, ᴲ
¹Regenstrief Institute, Indianapolis, IN, USA; ²Indiana University School of Medicine, Indianapolis, IN, USA

Introduction: Diabetes mellitus (DM) affects 9.3% of the United States population and was estimated to cost $245 billion in 2012.¹ DM is commonly studied in large-scale populations or as a sub-population of clinical trials. However, this is often done utilizing the International Classification of Diseases (ICD) with the large potential for misidentifying patients and classifying them incorrectly due partly to unintentional and intentional coder errors. The identification methods developed over time by individual researchers has never fully been clinically and statistically validated.

Aim: Validate statistical measures of the current standard query for identification of DM patients with clinical review.

Methods: After IRB approval, available clinical data from the Indiana Network for Patient Care (INPC) a large regional health information exchange receiving eMR data in real time, was utilized from 1/2/2014 through 12/31/2014. Patients were identified as having DM if they met at least one of the following conditions: 1) a clinical encounter (e.g., clinic visit) representative of DM (ICD diagnosis codes), 2) pharmacy order/fills for particular medications (e.g., insulin, tobutamid, glipizide, acarbose, etc.), or at least two of one of the following conditions: 3) abnormal fasting and resting glucose values, or 4) hemoglobin A1c values. Patients were excluded if they were < 18 years or > 89 years of age during 2014 (Figure 1).

Patients from the assumed DM and non-DM populations were randomly sampled limiting to one institution to allow complete manual clinical review (83 from DM population, 67 from non-DM). Each patient’s clinical text was reviewed by a clinician (TI) in a blinded manner (random mixing of DM identified and non-DM identified patients). The review served as the gold standard for the study and placed the patients into DM Type I, DM Type II, DM other (e.g., pancreatic type), and no DM categories. Groups DM I, II, and other were considered diabetics and utilized for analysis.

Sensitivity, specificity, and positive predictive value (PPV), and negative predictive value (NPV) along with their exact binomial 95% confidence intervals (CI) calculated based on the results of the standard query and manual review. Statistical analysis was done utilizing SAS version 9.4.

Results: In total, there were 3,742,500 patients seen in 2014 within the INPC and specifically, 148,651 at the institution for manual review. There were 10.5% of patients identified as having diabetes with average age 54.5±13.7 (range) with 58% female (Table 1).

The identification of diabetes achieved a sensitivity of 98% (95% CI (0.91-0.99)), specificity of 94% (95% CI(0.86-0.98)), PPV of 95% (95% CI (0.88-0.98)) and NPV of 97% (95% CI (0.90-0.99)).

Conclusion: Standardization and validation of common clinical diseases for population tracking and clinical trials is a necessary part of the complex and siloed electronic health care system. We demonstrate the ability to clinically and statistically validate within a health information exchange one of the most common diseases utilized for both primary and secondary research analysis. Further discussion is needed to create a standardized repository of validated queries from real-world electronic health data.

RxNorm Concept History Service

Olivier Bodenreider, M.D., PhD and Lee Peters, M.S.
U.S. National Library of Medicine, National Institutes of Health, Bethesda, Maryland, USA
Contact information: RXNAVINFO@LIST.NIH.GOV

Motivation
RxNorm contains drug concepts which represent the currently marketed drugs in the U.S. With each monthly RxNorm release, new drug products are added and obsolete drug products are removed. While this curation supports e-prescribing and drug information exchange use cases, it is detrimental to analytics use cases. The issue in this case is that some of the RxNorm drug identifiers (RxCUIs) stored in clinical data warehouses have become obsolete and can no longer be interpreted in reference to the current RxNorm dataset. There are over 122,000 obsolete RxCUIs, compared to 114,000 current ones. To address this issue, we started developing an RxNorm concept history service as part of the NLM drug APIs (https://rxnav.nlm.nih.gov/). This service is similar to what we developed for managing obsolete identifiers from the National Drug Code (NDC) Directory. For each obsolete RxCUI, the service returns a canonical representation of the drug concept, making it possible to relate an obsolete drug product to a class through its ingredient or to find a similar active drug product based on ingredient, strength and dose form information.

Creating the Historical Concept Data
To create the historical concept information, the RxNorm monthly releases starting in 2007 were queried to reconstruct the history of every RxNorm concept. Relevant features extracted include:
- The ingredient name(s) and RxCUI(s) related to the concept
- The term type (TTY)
- Start and end dates when the concept was active
- Indication if the concept is currently active
- Indication if the concept represents a brand
- Indication if the concept contains multiple ingredients
- Strength (number and unit) of each ingredient
- Dose form name and RxCUI
- For Packs (TTY=GPCK and BPCK), pack alias name, product component RxCUIs and pack numbers

Table 1 shows an example of the history data returned for the RxCUI =853056

Does Semantic Tag Usage in SNOMED CT Match its Concept Hierarchy?
Jonathan P. Bona, PhD
1
1University of Arkansas for Medical Sciences, Little Rock, AR, USA

Introduction

Every SNOMED CT concept is described by a Fully Specified Name (FSN) ending in a semantic tag that disambiguates it from other concepts with similar names and indicates where it fits into the SNOMED concept hierarchy. For example, the concepts [35566002 | Hematoma (morphologic abnormality)] and [385494008 | Hematoma (disorder)] are tagged ‘morphologic abnormality’ and ‘disorder’. In the hierarchy these are subsumed by the highest-level concepts (i.e. closest to the top concept) for morphologic abnormalities and disorders, respectively.

Because semantic tags are substrings within names, and not represented as part of SNOMED’s formal model, it is non-trivial to know whether a concept’s tag should be taken to mean that the concept is necessarily part of the same sub-hierarchy as others with that tag. A concept’s tag would strictly identify its place within the hierarchy if each tag had a single, high-level corresponding concept that used it, and every concept using the tag was below that high-level concept in the hierarchy. For instance, in the clinical finding hierarchy, [404684003 | Clinical finding (finding)] subsumes all other finding concepts. This work examines the January 31, 2017 International Release of SNOMED CT to determine the extent to which semantic tag usage by concepts matches concept placement in the hierarchy.

Methods

We developed computational procedures to answer the question: given a semantic tag S, and a corresponding concept C, is it the case that every concept tagged with S is subsumed by C in SNOMED CT’s concept hierarchy?

For each semantic tag we identified a tag corresponding concept – the concept closest to SNOMED’s root that uses the tag. In the January 31, 2017 release there is one such concept for every tag. To make use of the subsumption reasoning built into semantic web tools, we constructed an RDF/OWL model of SNOMED CT’s concept hierarchy, with each of the 300,000+ SNOMED concepts represented as an OWL class with separate annotations for its FSN and semantic tag. Each SNOMED is-a relation between concepts has a corresponding rdf:subClassOf assertion.

This model was loaded into a triple store database that pre-computed subsumption information, making it accessible for very fast retrieval using simple SPARQL queries. For each semantic tag a query finds every concept with that tag but that is not subsumed by its corresponding concept. Where such concepts exist, they seem to be misplaced or mis-tagged. That is, they are concepts whose semantic tags do not accurately represent their positions in the hierarchy.

Results

While nearly all of SNOMED’s semantic tags (35 out of 42) do have clear corresponding concepts that subsume all other concepts that use the tag, we found exceptions. Two instructive examples are.

- The tag ‘substance’ has a corresponding high-level concept, [105590001 | Substance (substance)] that subsumes 26,000+ concepts also tagged ‘substance’. There is only one single concept tagged ‘substance’ that it does not subsume: [109186003 | Sickle cell test kit (substance)]. This is a direct sub-concept of [385387009 | Test kit (physical object)], as are many other types of test kits. That is, it is situated in the right area of the SNOMED hierarchy, but inconsistently tagged. This is likely an error.

- The ‘disorder’ tag’s corresponding high-level concept, [64572001 | Disease (disorder)] subsumes 72,000+ concepts tagged ‘disorder’. There are 84 ‘disorder’ concepts that it does not subsume, including: [250054005 | Frontal gait disorder (disorder)], [431193003 | Infection of bloodstream (disorder)], and [708484008 | Vesiculoerosive lesion (disorder)]. These require further investigation. No clear pattern is evident at this stage, nor is there an obvious reason that these should not be subsumed by [64572001 | Disease (disorder)].

Whether or not a strict correspondence between tags and concept hierarchy is intended, examining cases where it does not hold is instructive in detecting anomalies that may be errors. A more formal and consistent use of semantic tags would improve their usefulness, both for knowledge representation and reasoning in software systems that use SNOMED CT, and for users working with SNOMED and with data annotated using it.

Electronic Health Records and their Modules: Impacts on Clinical Practice and Patient Care

Elizabeth M. Borycki, RN PhD¹, Andre W. Kushniruk, MSc PhD FACMI¹, Yalini Senthirajah PhD²
¹University of Victoria, Victoria, British Columbia, Canada; ²Hofstra Medical School, New York, United States of America²

Abstract

Health information technology (HIT) safety has emerged as an important issue. To date much of the research has focused on researching electronic health record (EHR) usability and safety. Less work has been conducted on the impacts of integrated EHR modules on overall EHR usability and patient safety.

Introduction and Background

HIT can have a significant effect on patient safety. HIT can improve patient safety, but it can also introduce new types of medical errors (i.e. technology-induced errors)¹. Technology-induced errors arise from interactions between health professionals and HIT during patient care. Researchers have studied the usability, workflows and safety of EHRs. Much of this work has focused on a complete EHR as the unit of analysis or individual modules that can be found in an EHR (e.g. e-prescribing, medication administration systems) as the unit of analysis. Less research has focused on the usability and workflow of integrated modules within an EHR and the effects of different user interface designs and workflows between these modules and how this might affect patient safety. In this poster we describe some of our preliminary findings arising from a pilot study of the integration of modules within an EHR.

Methods

Physicians and nurses (n=8) were recruited from medical units, in a fully digitized medical center in the United States that employs a robust EHR that is used by health professionals across the organization. The study took place in a laboratory setting, where participants were asked to review a patients’ EHR as they would in their day to day work. Participants were interviewed using a semi-structured interview approach about the EHR modules and their integration, while reviewing it. The participants’ verbalizations were audio recorded and transcribed. The data were coded using a published, qualitative coding scheme that focuses on usability and safety by three coders and their emerged a high degree of agreement.¹

Results

Findings suggest the EHR and its modules had specific usability and workflow issues that could influence safety. In terms of the overall EHR, it was noted, that activities such as logging on and off the system throughout the day diverted clinicians away from patient care activities and decreased opportunities for face-to-face contact with patients. Participants identified that EHR modules (i.e. clinician order entry, clinical documentation, laboratory information systems and diagnostic imaging systems) had differing usability and workflow issues and their lack of seamless integration affected cognitive and physical work involving patients. These issues included a diminished ability of clinicians to: (1) identify and monitor for patterns of disease and response to treatment, (2) respond expeditiously to new orders, and (3) spend time in direct patient care or face-to-face interactions with the patient.

Conclusion

Our preliminary findings from this pilot study suggest there is a need to analyze the usability and safety of a full EHR, its individual modules and the integration of EHR modules. Such analyses are important to identifying issues that may influence situational awareness of clinicians and diminish clinician ability to spend more time providing patient care. Research is needed to identify ways in which such issues may be overcome (i.e. use of composable EHRs, user interface and workflow guidelines for EHRs and their modules).

Leveraging Large-Scale Computing for Population Information Integration, Analysis, and Modeling

Jessica A. Boten, MPH¹, Donna R. Rivera, PharmD, MS¹, Madhumita Myneni, MBA, MS¹, Georgia Tourassi, PhD², Tanmoy Bhattacharya, PhD³, Ana Paula de Oliveira Sales, PhD⁴, Thomas Brettin, MS⁵, Paul A. Fearn, PhD¹, Lynne T. Penberthy, MD, MPH¹

¹National Cancer Institute, Rockville, MD; ²Oak Ridge National Laboratory, Oak Ridge, TN; ³Los Alamos National Laboratory, Los Alamos, NM; ⁴Lawrence Livermore National Laboratory, Livermore, CA; ⁵Argonne National Laboratory, Chicago, IL

Introduction

The National Cancer Institute’s (NCI) Surveillance, Epidemiology, and End Results (SEER) Program provides cancer data and statistics to support population-based research in an effort to examine and reduce the cancer burden in the United States. As the complexity of cancer care, the dispersion of cancer diagnosis and treatment across multiple healthcare providers and settings, and data generation to characterize each type of cancer increases, the SEER Program seeks methods to address these challenges. NCI is collaborating with four national laboratories of the Department of Energy (DOE) on a pilot project that will leverage the capabilities of high performance computing to support a comprehensive population-level cancer surveillance program and develop an integrated modeling framework.

Goals

The overarching goal of this pilot research program is to deliver the advanced computational and informatics solutions needed to support a comprehensive, scalable, and cost-effective cancer surveillance program and lay the foundation for an integrative data-driven approach to modeling cancer outcomes at scale. This goal has been broken into three aims. Aim 1 will develop scalable machine-learned natural language processing (NLP) tools for deep comprehension of unstructured clinical text to enable automated and accurate capture of reportable cancer surveillance data elements with case-specific uncertainties quantified to guide manual abstraction. Aim 2 will build a working infrastructure that integrates large scale linkage of heterogeneous data sources for research and discovery with a focus on methodology and bias assessment. Scalable graph and visual analytics tools guide exploration of disease specific cancer surveillance algorithms and methods to accelerate understanding of cancer outcomes including progression, recurrence, metastases, and survival. Aim 3 will develop a cancer surveillance data-driven modeling and simulation environment for predicting health trajectories of cancer patients.

Progress

NCI developed an infrastructure for document selection, annotation, algorithm development, and data hosting. This infrastructure has been utilized for human annotation of data elements in electronic pathology reports to facilitate algorithm development. Using deep learning methods, DOE researchers have been developing robust NLP tools that will identify, with known uncertainty, site, histology, laterality and behavior in pathology reports that will be utilized by cancer registries. External heterogeneous data sources have been identified for linkage with SEER data to enable development of longitudinal patient trajectories that will support modeling efforts. Extensive work in variable selection, clinical treatment pathways, and algorithm development is ongoing. Furthermore, clinical experts have joined the collaboration to identify and develop modeling use cases for specific cancer sites.

Conclusions

The NCI-DOE collaboration will enhance the SEER program through automated data abstraction, linkage and visualization of data sources, and predictive modeling. This application of data driven modeling seeks to answer key clinical oncology questions to empower clinician decision making tools which can improve patient treatment selection and health outcomes.
Detection of Opioid-Dependence: Extracting Opioid Use Patterns from Patient Secure Messages

Lina Bouayad, PhD¹ ², Dezon Finch, PhD¹, Stephen L. Luther, PhD¹

¹James Haley Veterans Hospital, Tampa, FL; ²Florida International University, Miami, FL

Introduction

Data about opioid use patterns that may be used to detect and predict the risk of opioid-dependence are stored in the EHR in both coded fields and progress notes. However, research indicates the structured data in EHR are often incomplete and inconsistent. Prior literature has targeted mining of clinical documents written by providers to increase data available for analysis. Yet, data extracted from unstructured progress notes contains provider-reported information only. Recently, secure messaging has been developed as a tool that provides patients with convenient and fast access to healthcare providers regarding non-urgent health concerns. As of October 2015, an exponential growth in secure messaging (SM) adoption was reported among veterans with more than over 1 million secure messages (SMs) sent. SMs represent an important new resource that was previously inaccessible for clinical care or research. Patient-reported use patterns can be extracted from SMs. Data extracted from SMs could be integrated into the EHR (as structured fields) to (1) enhance predictive risk models for opioid-dependence, and (2) improve treatment of patients with pain. To our knowledge, this would be the first study to use analytics to explore the content of SMs. If successful, the method could be applied to other high-frequency, high-risk, and/or high-cost conditions.

Methods

This retrospective study looked at cohort of Veterans who 1) have been diagnosed with pain, 2) have been prescribed opioid therapy during FY12-FY13, and 3) have used SM to communicate with clinicians. Analyzing our sample data, we identified 1,840,747 unique Veterans who were prescribed common opioids (CN101 for opioid analgesics, CN102 for opioid antagonist analgesics) between FY12 and FY13. We then searched for keywords indicating opioid use patterns within the secure messages associated with that cohort of patients - 100,000 randomly selected messages from patient with opioid dependence (ICD 9=304.01), and 100,000 randomly selected messages from patient without opioid dependence. Future text mining work on SMs can therefore be adapted to extract opioid use patterns and aberrant drug-taking behavior¹ (such as early refills, lost prescriptions, use despite harm, undertreated pain, confused and drug-taking behavior, chemical-coping behaviors, and self-medication). Results can then be applied to build models to detect and predict opioid dependence. Additional results will be presented at the conference.

Results

Using SM data (through the VA Informatics and Computing Infrastructure (VINCI)), we were able to complete two preliminary investigations. Results indicating the prevalence of keywords indicating opioid-related use patterns are listed in Table 1. Results also indicate 1) the presence of documentation of use patterns in patient secure messages, and 2) difference in frequency of these terms used by patients with and without opioid dependence. Future text mining work on SMs can therefore be adapted to extract opioid use patterns and aberrant drug-taking behavior¹ (such as early refills, lost prescriptions, use despite harm, undertreated pain, confused and drug-taking behavior, chemical-coping behaviors, and self-medication). Results can then be applied to build models to detect and predict opioid dependence. Additional results will be presented at the conference.

Conclusion

In the present study we assessed the presence of documentation of opioid use patterns in patients’ secure messages. Our future work intends to use text mining and machine learning algorithms to extract these use patterns from SMs which will enable (1) comparison between patient- and provider- reported data and (2) integration of patient-reported symptoms into structured fields for further analysis.

Toward a reliable and interoperable public repository for natural product-drug interaction study data

Richard D. Boyce, PhD1, Isabelle Ragueneau-Majlessi, MD, MS2, Jingjing Yu, PhD2, Jessica Sontheimer, PhD2, Chris Kinsella2, Mathias Brochhausen, PhD3, John Judkins, MS3, Bruce Pinkleton, PhD4, Rebecca Cooney, MA4, Mary F. Paine, RPh, PhD5, Jeannine S. McCune, PharmD2

1 University of Pittsburgh, PA; 2 University of Washington, Seattle, WA; 3 University of Arkansas for Medical Sciences; Washington State University, 4 Pullman and Spokane, WA

Introduction

Concomitant use of prescription drugs and natural products, including vitamin, mineral, or herbal supplements, is a frequent occurrence. Approximately 50% of Americans in the Midlife in the United States Study were exposed to prescription drugs at the same time as a natural product1, raising concerns for adverse natural product-drug interactions (NPDIs). In a different study, approximately 34% of patients prescribed warfarin were exposed to natural products that conferred a significant risk for an adverse interaction2. Pharmacokinetic-based NPDIs (PK-NPDIs) are of particular concern because their potential impact on drug effectiveness or toxicity is often unknown. To provide evidence-based information regarding purported PK-NPDIs, a new Center of Excellence for PK-NPDI Research was established (U54 AT008909). The Center is creating a publicly accessible database where researchers can access scientific results, raw data, and recommended approaches to optimally assess the clinical significance of PK-NPDIs.

Methods

One critical component of the Center is the Informatics Core (IC). The IC is leveraging prior experience with an existing proprietary repository of preclinical and clinical drug-drug interaction data3 to build the new publicly accessible PK-NPDI database. The IC works with the Center’s Analytical and Pharmacology Cores to gather, organize, and archive the various types of data that the teams are generating prospectively (Figure 1). In parallel, the IC is extending the Potential Drug-drug Interaction and Potential Drug-drug Interaction Evidence Ontology (DIDEO) ontology4 to provide a common set of data elements for the database. Finally, the IC is engaging PK-NPDI researchers in a user-centered design process to create a public facing portal to the PK-NPDI database that meets their information needs.

Conclusion

The IC has been operating since Fall 2015 and has 1) implemented a beta cloud-based data repository with a web-based data entry application, 2) made significant progress on the use of standardized terms and operating procedures for data entry, and 3) initiated a user-focused information needs questionnaire that will result in user scenarios for PK-NPDI researchers that will be useful for designing a public portal to the repository.

Leveraging Electronic Medical Record Data for Research with Consistency and Efficiency: A Use Case in an Ongoing Obstetrics Clinical Study

Robert L Bradford, BSBC, CCIS¹, Karen Dorman, RN, MS¹, Alison Stuebe, MD, MSc¹, Wanda Nicholson, MD, MPH, MBA¹, Kiira Lyons, MA¹, Anna Maria Siega-Riz, PhD²
¹University of North Carolina at Chapel Hill, Chapel Hill, NC; ²University of Virginia, Charlottesville, VA

Introduction:
Many epidemiological and clinical studies have proposed using the electronic medical record (EMR) for abstracting pertinent patient information for their research questions of interests. Additionally, by utilizing EMRs to obtain patient data, researchers strive to improve efficiency, consistency and reduce costs of clinical studies. However, inherent complexities within clinical operational data in EMRs present unique challenges for researchers in completing these tasks for clinical studies¹. For an on-going pregnancy cohort study (n=458), our goal was to identify information in the EMR (Epic 2014) in a consistent manner relating to pregnancy observations including: previous medical history, health habits, prenatal vitals that exists in flow sheets, medication use, clinical laboratory results, problem lists and details related to labor, delivery and the postpartum visits.

Methods:
Multiple efforts were necessary to complete the initial report and develop a re-usable algorithm for this study. Efforts included meetings of the clinical team and analyst, as well as continued communication throughout. Screenshots were used to develop the overall data flow, and to locate critical workflow items to be traced within the EMR database. Data tools including data dictionaries, vendor reporting documentation, and others were necessary to locate the required data. Two rounds of data extraction for women participating in the cohort allowed us to examine reproducibility of our methods.

Results:
The clinical objectives of the study required reconciling various clinical views and pathways in the Epic EMR with the data available in the Epic Clarity reporting database. Achieving this goal required deciphering and translating data in the database to a clinically relevant format, rebuilding relationships (i.e. connecting mothers with their infants), and addressing obstacles with patient identity tracking through medical record number changes over the course of the study. Addressing each of these obstacles required significant collaboration between the technical and clinical teams. The upfront investment of the clinical team and analyst totaled approximately 80 FTE hours, which were spread across meetings, programming, and testing to develop the initial data pull for 100 patients. In contrast to a second data pull (n=174), time required dropped significantly to 5 FTE hours.

Conclusions:
In this pregnancy cohort study, we addressed multiple challenges in extracting data to prepare a reconstruction of clinical views in the Epic EMR. While exploring these pathways, collaboration between clinicians and analysts was paramount to reconciling data discrepancies, and in some cases, modifying clinical workflows to bring consistency to data collection. Additionally, we developed functionality to handle medical record number changes and merges that can occur within the medical record system. These procedures can be universally employed by other EPIC users and be adapted for other EHR systems for the purpose of extracting data. Future considerations include potential changes in data flow resulting from system updates to Epic EMR requiring re-validation of the data extraction methods for accuracy and efficiency.

Enabling Collaboration for Building High Quality, Sustainable and Scalable National Health Information Systems in Resource-Limited Settings

Pascal Brandt, MSc1, William B. Lober, M.D., M.S., Jan Flowers, M.S.1
1School of Nursing, University of Washington

In resource-limited settings, health information systems are often developed by donor funded organizations. These organizations frequently work in silos to ensure they meet their specific grant requirements. As a result, efforts in the country are duplicated and developed solutions lack oversight and are underutilized. With development expertise lacking, best practices and standards are often not followed. Furthermore, knowledge gained is siloed within a single organization. While resulting systems may meet the functional requirements at the time of release, scalability and maintainability is challenging due to ad hoc development processes. As organizations scale these systems, they often end up with multiple software versions and configurations across facilities that are difficult to support and manage. Systems built with little coordination between organizations and a lack of interoperability results in a fragmented national healthcare information system. Ministries of Health faced with this fragmented system may struggle to effectively manage and use all of these systems to manage and improve care and outcomes in their country.

In order to address these issues and enable collaboration, shared technical infrastructure and processes need to be in place to support health information system development. Processes need to be agreed upon by all partners and well documented to enable onboarding of new members and organizations. Functionality should be designed collectively to enable broad applicability, final products should be well documented and demonstrated to allow knowledge transfer between individuals and organizations. Mechanisms should be in place to ensure the delivery of high quality products, and reliable automated delivery pipelines should ensure predictable release timelines and enable easy upgrading. Finally, systems developed should work together to enable a health information exchange.

In partnership with local stakeholders supporting the Ministry of Health, we implemented a solution in Mozambique that addresses some of these quality issues. The initial step was the establishment of a cross-organizational software development community to collaborate on OpenMRS, called eSaude1. The community has adopted a number of open sources tools for project management, including Trello for task scheduling, a Google Groups mailing list, and Slack for real-time chat between community members. For source code collaboration and version control, eSaude uses GitHub. The Travis continuous integration platform, which is free for open source projects, automatically runs tests against all newly contributed code and publishes a packaged deployable end product. The tests programmatically validate all new code against community agreed functional and style guidelines, ensuring every new feature is high quality and error free. This gives junior contributors the confidence to add their contributions, and as a result gain experience as developers. The community uses container technology by the open source Docker project to generate predictable and sharable deployable packages that are easy to install and upgrade across sites and ensure consistent versioning. An implementation packet, and related process and technical documentation was published to support consistent implementation process in the MoH facilities.

As a result of establishing the eSaude community in Mozambique, the 5 HIV care & treatment implementing partners work together to build shared health information systems, using software development best processes collectively agreed upon. The structured setup of standard tools and processes enables the effective contribution of developers with a range of experience, while deduplicating efforts across organizations, and creating a scalable and manageable national platform of HIS products. This process is ongoing, and we’ve successfully released numerous versions of a growing set of facility-level clinical applications.

Modular Health Informatics Architecture for a Patient Centered mHealth Diabetes Intervention
Ian M. Brooks, Ph.D.,1 Justin Gatwood, Ph.D., MPH,2 Bonnie Binkley, MA,3 Emanuel Villa, MS,4 Jennifer Featherston, MS,4 James E. Bailey, MD, MPH,3
1-Dept. Biomedical Informatics, MedStar Health Research Institute, Hyattsville, MD; 2-Col. of Pharmacy, UTHSC, Nashville, TN; 3-Center for Health Systems Improvement, UTHSC, Memphis, TN; 4-Center for Biomedical Informatics, UTHSC, Memphis

Introduction and Background
Safety-net primary care practices throughout the country are seeking to develop capacity to inform and activate their most vulnerable patients. Poor self-care behaviors are common, but behavioral interventions are intensive and sustaining health benefits over time requires individualized approaches to address patient-specific health beliefs. Text messaging (TM) is an effective, low-cost approach for engaging patients with chronic disease in better self-care, and research suggests that health-related, tailored TM effectively influences specific behaviors. Our previous research showed that diabetes patients living in medically underserved areas (MUA) were very interested in receiving TM from their physician’s office; however best approaches for effective delivery to people with chronic disease is unknown. Our PCORI-funded Management Of Diabetes in Everyday Life (MODEL) study examines the comparative effectiveness of patient-driven text messaging (TM) and health coaching for African-American adults with uncontrolled diabetes and multiple chronic conditions in MUA in the MidSouth. Here we present the innovative, modular, biomedical informatics architecture we developed to manage the data of our vulnerable patients in a chronic disease registry, with links to the research data from patients in the clinical trial, while also serving as a platform to implement our tailored mHealth diabetes intervention.

Methods and Tools
Three main components form the informatics stack: (1) the Diabetes Wellness and Prevention Coalition registry (DWPC-R); (2) a REDCap clinical trial data center; and (3) Mosio/Twilio SMS application. The DWPC-R hosts all patient medical data from a hospital EMR, augmented by data of uncontrolled diabetics retrieved from nine minority-serving community medical practices in the Memphis, TN area. Data are collected under a HIPAA waiver using encrypted file transfer, harmonized via n-gram matching using Talend DI software, and transformed to the OHDSI common data model. The DWPC-R is used to recruit for our clinical trial. Patients randomized to the TM arm undergo a structured interview to tailor their TM program for content and frequency. All clinical trial data are hosted in a REDCap database synched with the DWPC-R. Demographic information is harvested to build patient profiles in the TM messaging application. Twilio is a cloud-communications platform for en masse text messaging. Interfacing with Twilio requires computer programming, thus we used the Twilio extension Mosio. In Mosio we create batch messaging lists from our REDCap clinical trial demographics forms. These allow us to add/remove patients from messaging groups based on their responses to the TM process. Messages exist as “stems” which Mosio concatenates (greeting + tailored-content), adding personal salutations to create coherent and tailored messages (samples to be displayed in our poster). The message libraries are stored as .csv files and hosted on a server behind our firewall. Custom Python scripts shuttle these files to the Mosio messaging API.

Discussion and Conclusion
MODEL launched in summer 2016. Given the complexity of the technologies underlying the process, it is no surprise that development of these tools has not been without difficulties. Human factors have often proven the most challenging. Working with so many clinical partners highlighted issues in synchronizing data transfer and ensuring repeatability of data feeds. This is essential if we are to automate Extract/Transform/Load (ETL) without throwing errors each time the scripts run. Our patients use TM to report their health status. To ensure the internal consistency and repeatability of our experiment we must ensure patients correctly use the response process (1/good to 5/poor on a Likert scale). Additionally, some patients use a voice-to-text messaging app and some of these responses register as text, not integers, in our database forcing us to manually curate data and increasing the risk of coding errors. We believe we can overcome this issue programmatically. The MODEL study demonstrates how a tailored mHealth intervention can be empowered by a modular informatics architecture. We hope to bundle this application stack to allow others to use our experience to better serve their own at-risk patients.
TNF-alpha Use as a Risk Factor for Lymphoma in Rheumatoid Arthritis Patients Using the Virtual Research Data Center

Gregory T. Brown, MD, PhD, Fabricio S. Kury, MD, Clement J. McDonald, MD

1National Library of Medicine, National Institutes of Health, Bethesda, MD

Introduction

Lymphomas arising in immunocompromised patients are well-documented. Patients with rheumatoid arthritis (RA) are often treated with immunomodulators such as methotrexate, and failing that, TNF-alpha inhibitors (TNFαIs) such as infliximab. Several studies have examined the association between lymphoma and TNFAI use, but with no consensus. We address this by utilizing the Virtual Research Data Center (VRDC) which, collects and de-identifies vast amounts of data generated by Medicare.

Methodology

We reviewed beneficiary data from the VRDC covering the years 2007-2014, comprising 52,876,553 patients. We used two ICD-9 codes to identify RA patients, in addition to patients with lymphoma. We also included “other” inflammatory disorders that are treated with TNFαIs, such as psoriasis, psoriatic arthritis, and ankylosing spondylitis. The VRDC contains Medicare Part D information, and from that we identified patients billed for TNFαIs as a surrogate for TNFαI use. We cross-tabulated the populations to infer associations.

Results

With unadjusted preliminary data we identified 1,610,699 patients with RA, 605,403 with lymphoma, and 983,822 with “other” inflammatory disorders. Patients with both RA and lymphoma represent 1.75% of the total RA population. Those taking TNFαIs comprised 1.4%.

Table 1. Cross tabulation of VRDC data with RA, lymphoma, and TNFαI.

Conclusion

With large numbers of patients we can explore associations that might otherwise be difficult with clinical trials. To our knowledge this is the first study using big data to examine the question of lymphoma and TNFαI use. This simple analysis does not show increased risk of lymphoma while taking TNFαIs, and our findings are bolstered by the lack of definitive evidence in the literature. However care must be taken, as always, not to mistake association with causality. Further analyses, such as Cox regression and propensity scoring is required, as well as comparison to other diseases and conditions.

Knowledge-Enriched Data: Realizing the Riches of Our Data

Matthew Burton, M.D. 1,2, Amy Knopp, M.S. 1, Terri Glaze1, Meghan Sandberg1, Davide Sottara, Ph.D. 1,2, Scott Finnesgard1, James Buntrock1, Daryl J. Kor, M.D. 1

Introduction

Data management is an end-to-end and often cyclical process, covering every step from the original capture of data at its operational source to the final presentation or delivery of that data for use by each data consumer (i.e. other operational units, research, predictive analytics, population health) and all the storage, movement, and any manipulation of the data between. Much of the data manipulations in the data management process are data enrichments that not only derive new information from raw source system data, but also includes other (recursive) processes such as the integration, correlation, normalization, standardization, and interpretation of the data 1. Moreover, many enrichments processes are driven by clinical knowledge as much as the processes that leverage the enriched data, e.g. for decision-making.

Mayo Clinic has made strategic investments in a Unified Data Platform (UDP) that brings together diverse clinical and administrative data from multiple historical and operational databases to provide data access for all non-EHR applications and capabilities (e.g. advanced analytics, research and discovery, informatics innovations). The requisite enrichments are variable across numerous different teams working with the same data, with variation impacting the ability to capitalize on vast data and knowledge assets. Therefore, an initiative was launched with the purpose to advance data enrichment processes, capabilities, and quality assurance to achieve trustworthy data with increased value and utility. The initial phase of this initiative was a qualitative analysis of current and future state through the engagement of numerous internal stakeholders and a team of acknowledged experts.

Methods

We used a mixed-methods approach including conducting semi-structured interviews designed specifically for key cohorts (front-line managers, staff, and practice and IT leadership) with thematic analysis, surveys based on key themes, focus group discussions that built on key issues identified in interviews and surveys, and a modified Delphi approach to present the collective findings to a group of relevant experts and elicit feedback and recommendations. Questions posed were designed around broad assessment of current and desired future state for data enrichment including personnel, capabilities, tooling and technology, methods and processes. Over seventy semi-structured interviews were conducted along with relevant surveys for key cohorts. Three focus groups were conducted with prior findings from inquiry presented using a modified Delphi approach. All descriptive findings were analyzed using iterative thematic analysis and multiple abstractors. Detailed findings were documented in an internal report.

Results

Results included substantial data and insights from diverse organizational perspectives that are being used to establish new organizational alignments, standardize best practices, converge, enhance, and develop new technologies, and support workforce development. Key areas highlighted by staff and leadership alike included: data quality, practice engagement, documentation and knowledge representation, knowledge elicitation and collaborative knowledge engineering. Our panel of experts proposed a roadmap and framework for knowledge-enriched data addressing best practices across technological, process, and informatics perspectives. These recommendations are being implemented as part of the UDP business plan including: a functional Clinical Concept Glossary (for indexing and resolving high value enriched data); detailed descriptions of data enrichment processes, capabilities, and data categories; a pilot for and documentation of best practices for knowledge engineering in the context of enriched data, principles and best practices for metadata and persistence of enriched data; and implementation and documentation of best practice processes and tooling perspectives for a high performing, value-enhancing 'data enrichment factory'.

Physicians Behavior with a Non – Overriding Alert Prescriptions CDS Dosing System Developed in Argentina

María S. Hernández Caffot, MD, PhD*1,2, Carolina Vogt, Pharm.1, Solana Muñoz Fernandez, Pharm.3, Francisco Bernabeu, MD1, Bayan V. Khorsandnia, MD*1,2
1Departamento de Informática en Salud Hospital Privado Universitario de Córdoba; 2Instituto Universitario para las Ciencias Biomédicas de Córdoba (IUCBC), – Argentina.

Introduction
Clinical decision support system (CDSS) is an important tool to reduce the medication errors and to improve the quality and safety patient care [1]. There is a wide variability in their use and in how physicians respond to provider recommendations. Investigators have reported wide variations in over-ride rates, ranging from 25% to 96% depending on the site, settings, and alert type [2]. The objectives of this work were (i) to analyze the physician behavior with a hard stop alert with non-overriding option; (ii) explore adherence versus workaround with the dose red alert.

Material and Methods
The study took place at the Hospital Privado Universitario de Córdoba, Hospital Raúl Angel Ferreyra and Clínica Privada Richieri, from Córdoba, central Argentina. The data set corresponds to a period of 5 month: August to December 2016. We develop a complex CDS dosing system of two category alert (orange and red) for the most frequently prescribed drugs (248 in total). These drugs have adjusted doses, and we take into account the age group (pediatrics and adults), and patient/drug renal function.

We analyzed all the electronic prescription during this period in the three institutions and we focus in maximum doses red alert CDS category (non - overriding option): doses higher than maximum effective dose. Then we observe the behavior of the doctor with the alert, if they accept the suggestion by modifying the dose or canceling the prescription, in this case re-indicating it by an alternative mode (free text or oral request). In addition, we divided the dose in excess of the maximum allowable dose into three categories: a- up to 100%; b- between 100 and 500%; and c- over 500%.

Results
We registered 5157 CDS alerts (3.79%) on 135,873 medication orders during the study period. Among the pediatric patients the drugs that generate the highest numbers of hard stop alerts were the antifebrile, opioids and glucocorticoid; and among adults patients the highest number of hard stop alerts were generated by antibiotics, glucocorticoid and benzodiazepines. The 19.19% (990 alerts) corresponds to red alerts. The 87% (861) of the red alerts was accepted, from which the 83% (821) of physicians decided to modify the dose and the 17% (168) decided to canceled the prescription and do not prescribe it again. The remaining 13% (129) did not accept the alert; deciding to cancel the alerts and to realize the same prescriptions in free text or oral prescription. Physicians who accepted the alert were exceeded as follows: the 47.7% (473) in up to 100%, the 23.1% (228) exceeds between 100–500% and the 29.2% (289) of them more than 500%. Finally, from those who did not accept the hard stop alert, a 60.8% (78) of physicians exceeded the maximum allowable dose up to 100%, the 19.3% (25) between 100–500%, and the 19.9% (26) was in more than the 500%. Only 0.8% had false positive results.

Conclusions
There were 990 alerts for maximum dose, and we prevented 859 medication errors. Our CDSS prevent an 87% of serious to moderate adverse effects (respiratory and Central Nervous System depressions, myelotoxicity, renal failure, and cardiovascular disorders). Nevertheless, there were a 13% of the hard stop that physician managed to avoid in which we believed they correspond to serious or moderate adverse effects. Taking into account this system failure, we are currently working to prevent physicians to realize prescriptions by an alternative way. However, our CDS dosing system show to have high acceptance within physicians from the three institutions, and low level of workaround.

Introduction

Electronic medical records (EMR) have expanded opportunities for precision medicine research. A major barrier to fully realize the translational potential of EMR is the lack of tools for efficiently and accurately defining phenotypes. Developing phenotyping algorithms often requires labor intensive manual chart review, which is particularly challenging for healthcare systems such as the Veteran Affairs (VA) with large volumes of notes per patient. We introduce a novel unsupervised algorithm to rank the relevance of the notes to reduce the chart review burden.

Methods

Algorithm: We identified a set of concept unique identifiers (CUIs) related to the phenotype by extracting clinical terms from 5 relevant online knowledge sources including Wikipedia via the algorithm in Yu et al1. We mapped each CUI to a 300-length semantic vector (SV) obtained by performing a word-to-vec analysis of all PubMed Central articles via the “skip-gram” algorithm2. Using these CUIs as a dictionary, we performed NLP with NILE3 on each clinical note and counted the number of mentions for each CUI. We summarize the phenotype-specific semantic content of a note as a weighted average of the CUI-specific SVs with weights the standard TF-IDF weight multiplied by a prior weight \( w_{\text{prior}} \), calculated as the log-frequency of each CUI appearing in the Wikipedia article. We also obtained a reference SV as a TF-IDF weighted SV calculated for the Wikipedia article. The relevance of a note to the phenotype, denoted by \( R \), is calculated as the cosine-similarity between the reference SV and the summary SV for the note. Notes without any mention of any candidate CUI are assigned as uninformative. For remaining notes, we performed clustering on their \( R \) measures and classify them into uninformative (U), somewhat informative (S) and informative (I). Informative notes are prioritized for chart review.

Data and Metrics for Evaluation: We use the algorithm to rank 60128 notes from 130 VA patients sampled to annotate their ischemic stroke (IS) status. Chart review was performed on a random subset of 200 notes to annotate the relevance of each note to IS as informative, somewhat informative and on 20 patients to determine whether reviewing the top ranked notes was sufficient to determine the patient level IS status. We compared our method to the Latent Dirichlet Allocation (LDA) model and the Correlated Topics Model (CTM)4.

Results

The algorithm, classifying 27% notes as I and 26% as U, has a rank correlation of 64% with the gold standard annotation, while LDA and CTM yielded correlations between 18% and 32%. At the patient level, the chart review determined that the decision on the IS status can be achieved by only reviewing the top ranked notes in \( I \), which yielded about 50% reduction in review time needed per patient. Incorporating prior weights \( w_{\text{prior}} \) from Wikipedia results in better performance with higher sensitivity (95% w/ \( w_{\text{prior}} \) versus 90% w/o \( w_{\text{prior}} \)) while at the same time selecting fewer notes as informative (27% w/ \( w_{\text{prior}} \) versus 31% w/o \( w_{\text{prior}} \)).

Conclusion

Note ranking can greatly improve both the efficiency and accuracy of chart review. Incorporating prior knowledge on the disease based on semantic analysis can improve the selection performance.

Exploring Novel Graphical Representations of Clinical Data in a Learning EMR

Luca Calzoni, MD1, Gilles Clermont, MD MSc2, Gregory F. Cooper, MD PhD1,3, Shyam Visweswaran, MD PhD1,3, Harry Hochheiser, PhD1,3
1Department of Biomedical Informatics, University of Pittsburgh, Pittsburgh, PA, USA; 2Department of Critical Care Medicine, University of Pittsburgh, Pittsburgh, PA, USA; 3Intelligent Systems Program, University of Pittsburgh, Pittsburgh, PA, USA

To reduce the risks of cognitive overload associated with large amounts of data in Electronic Medical Records (EMRs), we are designing a Learning EMR that is able to draw a physician’s attention to the right patient data at the right time (1). The system, developed for use in Intensive Care Units (ICUs), uses a data-driven approach to analyze patterns of past EMR usage by clinicians and highlight the most relevant data for each patient.

In order to facilitate the development of an EMR user interface that prioritizes the presentation of high-value data, it is necessary to acquire a thorough understanding of the information practices of ICU providers. Most prior work in the literature focuses on investigating ICU clinicians’ data needs, reasoning strategies and use of information sources. A literature review provided us with useful insights on design aspects that we found applicable to the design of a Learning EMR. We identified four main themes:

1. EMRs should convey and summarize clinical information effectively, by encoding health parameters to visual attributes, and by utilizing information views that prioritize the display of high-value data, organize information into clinically relevant concepts, and provide quick overviews of the patient’s conditions.
2. EMRs should highlight changes in clinical outcomes across different data points or from an expected course: physicians prioritize cases based on level of concern. They are reassured by patients who are progressing as expected, while patients showing unexpected changes escalate on their prioritization list.
3. EMRs should offer features that facilitate comparisons across patients for clinical prioritization purposes, by helping physicians to quickly identify appropriate groupings for their patients, and by showing how a patient’s affinity towards different groupings changes over time.
4. EMRs should provide support for analytical reasoning, by visually arranging related data together, and by providing highly configurable user interfaces, smart search tools, and workspaces that make it easy to manipulate information at the level of entities and their relationships.

To inform the design of our Learning EMR user interface, we intend to combine the design principles identified above with observations and design activities. To gain a deeper understanding of information practices in ICUs, we will shadow ICU physicians and collect observational data on their information seeking activities and interactions with the EMR. Interviews conducted outside of care settings will be used to help characterize such activities and organize them into general process models, representing how ICU physicians interact with the EMR to perform care activities. We will use these models to inform the creation of a series of wireframes, identifying possible ways to highlight high-value data in our Learning EMR.

In a subsequent focus group session, we plan to actively involve ICU physicians in the user interface design process, using techniques inspired by Participatory Design. After learning about our goal to develop an EMR designed to reduce information overload in the ICU, clinicians will be asked to provide feedback about the concept. Physicians will then generate and discuss design ideas for the Learning EMR user interface, using craft materials and low-fidelity sketches. Participants will then be asked to provide their feedback on the user interface strategies for highlighting data of interest explored in our wireframes.

Study findings will help us gain a deeper understanding of ICU clinicians’ information practices and desiderata regarding EMR user interface design. Feedback on the Learning EMR concept and suggested design ideas will lead to the creation of a new series of wireframes reflecting participants’ work and preferences. These revised wireframes will inform future design choices for our Learning EMR, and eventually the implementation of a fully functional EMR user interface.

A Natural Language Processing System for Biomedical Dataset Retrieval
Xiaoling Chen, PhD1, Jun Xu, PhD1, Jinqqi Wang, MS1, Anupama Gururaj, PhD1, Lucila Ohno-Machado, MD, PhD2, Hua Xu, PhD1

1University of Texas Health Science Center at Houston, Houston, TX; 2University of California, San Diego, CA

Introduction
DataMed (https://datamed.org), a data discovery index prototype, is developed by bioCADDIE for users to find datasets efficiently in the biomedical domain. To improve the search performance in DataMed via query interpretation and resource retrieval, we developed a high-performance NLP system, which can recognize several important biomedical concepts (gene, disease, drug, biological process, cell line, MeSH terms) and integrated it into the DataMed prototype. We are currently working on performing direct comparison of search results with and without the NLP module. We will report our findings on the same at the symposium in our poster.

System Development
We adopted training datasets from different resources, using the bioCreative challenge1,2 corpora, with annotations for diseases, drugs and genes. We used our challenge-proved conditional random field (CRF) algorithm3 for recognizing gene, disease, drug and cell line. We developed a dictionary-based model for recognizing the biological process with a list from the QuickGo database2 (with 109550 entities) while the corpus provided by University of Turku1 was adopted for cell lines. For evaluation, we generated a corpus of randomly selected 700 test documents from 21 repositories included in DataMed. For each selected dataset, only the dataset title and description from the metadata were extracted. Two annotators with biomedical background worked separately to annotate these 700 documents based on the annotation guideline provided to them. The inter-rater reliability was 0.4475. The observed proportions of agreement were calculated for each entity and the final number is the average of all the entities. The adjudicator reviewed annotation disagreements and a final decision was made on the discrepancy after discussion.

To remediate the discrepancy between our training and test documents issue, post-processing rules were added to the algorithms to improve the performance of the system. The entities were also encoded to the UMLS Concept Unique Identifiers (CUIs) for normalization. The encoder is built based on Vector Space Model (VSM). Of the 131 search queries from DataMed, 104 (79.39%) of them mapped to UMLS CUIs. We also integrated MetaMapLite4 into our system to recognize MeSH terms.

Table 1 shows the performance of our NLP system. Due to low number of cell line entities, we have excluded it from the results. The NLP system is implemented in two ways, as a Java program for batch processing and a web service for real-time query processing. We have integrated the system into DataMed search process, in both metadata enrichment and query expansion. The challenges and possible solutions to address the low recall will be discussed in the poster.

Conclusion
We have developed a NLP system that recognizes the biomedical entities: diseases, drugs, genes, biological processes, cell lines and MeSH terms with high precision from the metadata of biomedical datasets. The system is integrated into the DataMed search process to improve dataset retrieval.

The Access of Bone Marrow Transplant Patients to Online Support

Ming-Yuan Chih, PhD, Jennifer Christian, BS, Kang Namkoong, PhD, Miranda Hatfield, MSW, Meghan Johnson, MPH, Rancie Hannah, BS, Jamie Studts, PhD, Robin Vanderpool, PhD, Gerhard Hildebrandt, MD, University of Kentucky, Lexington, KY, US

Abstract

An online support usage survey was completed by 30 adult blood and marrow transplant (BMT) patients at the University of Kentucky Markey Cancer Center (MCC). Results show that most patients, even with low socio-economic status, use advanced communication technologies regularly. Furthermore, these patients do not access cancer-related online support, and do want to seek health information and communicate with providers/peers online. Cancer center-sponsored online support may overcome patients’ barriers to accessing necessary support.

Introduction

BMT patients are often physically and mentally secluded during the transplant process. This isolation is an obstacle to seeking social support and clinical advice. One way to assist the patients through this process is to allow them to connect with other patients and professionals by way of an online or smartphone-based application. Existing literature in this area is mostly in pediatric BMT programs, not for adult patients. Smartphone and online support seeking among MCC patients, in particular those from rural Kentucky, is also unclear. To fill this gap, a pilot patient survey was designed to assess the adult BMT patient’s access to the Internet and online support resources.

Methods

Between 1 Sep 2016 and 6 Mar 2017, 30 pre-BMT patients at the MCC completed an online support usage survey. Survey questions include demographics and online support usage. These questions were developed based on Health Information National Trends Survey. Descriptive statistics were reported.

Results

Most survey patients are male (20/30), white (28/30) and without a college degree (19/30). Ages ranged from 23 to 71 (median: 59). Among the 30 patients, 17 were unemployed, 16 married, and 15 from rural Kentucky. The median annual household income was lower than $35,000. All but one reported having Internet access at home or elsewhere and 27 (90%) had faster Internet (cable and/or 3G/4G broadband). Twenty-seven (90%) patients had mobile devices, such as smartphones or tablets. All patients used text messaging and 80–90% of them used emails or mobile apps over the past 12 months. Twenty-three (70%) patients used social media, such as Facebook in the last 12 months while only 7 (23.3%) participated in cancer specific online support groups, such as American Cancer Society online forum. The main reasons that patients did not access cancer-related online support were because: 1) they did not know how to find an online support group (20%); 2) they did not know how to participate in an online support group (24%); or 3) they did not want to share personal information (20%). All but one expressed the desire to access health-related information and to communicate with their providers and peer patients online.

Conclusion

Patients referred for BMT at MCC have adequate personal access to information technology and are familiar with emails, text messages, and social networking sites. Their access to cancer related online support could be limited due to their unfamiliarity and discomfort of using these resources. A cancer center-sponsored, provider-facilitated application may be able to ease the discomfort and to improve the motivation to access available cancer information and social support online. Future efforts to connect patients with their healthcare providers and peer patients may enhance ongoing care and support to these patients.

Acknowledgment: The authors appreciate the support from NCI Cancer Center Support Grant (P30 CA177558).

Usability Evaluation of a Prototype mHealth App for Symptom Self-Management in Underserved Persons Living with HIV

Hwayoung Cho, PhDc, MSN, RN, Hestia Rojas, MPH, Casey Fulmer, MPH, Rebecca Schnall, PhD, MPH, RN-BC
School of Nursing, Columbia University, New York, NY, USA

Abstract Symptom management is essential for PLWH. mHealth apps are a potentially useful delivery mode of symptom self-management strategies. We developed a prototype mHealth app for symptom self-management for PLWH and tested its usability in a laboratory setting via end-user testing and a heuristic evaluation with HCI experts. The prototype was iteratively refined; further evaluation will be conducted in a 3-month feasibility trial.

Introduction
Persons living with HIV (PLWH) are confronted with persistent symptoms related to the disease, medication side effects and comorbidities making symptom management essential for improving quality of life. A team at UCSF developed a paper-based symptom management manual with self-care strategies for 21 common HIV symptoms. As mHealth apps can reduce challenges associated with racial/ethnic disparities by increasing access to health information, apps have the potential to be an effective delivery mode of symptom self-management strategies in underserved PLWH, yet no apps for symptom management currently exist. We developed a prototype app (mVIP) for symptom self-management in PLWH by incorporating these strategies into a mHealth tool. The purpose of this work was to evaluate the usability of the prototype app from both expert and end-user perspectives in a laboratory setting.

Methods
We conducted a usability evaluation of the prototype mVIP through end-user testing with 20 PLWH (10 using Android and 10 using iPhone) and a heuristic evaluation with 5 experts in human-computer interaction (using Morare software). The usability evaluation incorporated a think-aloud protocol of use case scenarios and the process was audio-recorded. The app’s usability was rated by end-users via a post-study system usability questionnaire (PSSUQ) and by experts via a heuristic evaluation checklist.

Results
The app’s content, functionality and interface were refined. Based on end-users’ recommendations, an error message ‘Check your credentials’ was changed to ‘Username or password you entered is not valid. Try again’ since the term of credentials was unfamiliar to several participants. We added instructions for ‘How our app works’ on the home page to help participants more easily use the app. The username was simplified from the user’s email address to a short code for easier text entry. The overall PSSUQ scores ranged from 1.00 to 2.88 (from 1-best to 7-worst), reflecting strong user acceptance of the app. Based on experts’ recommendations, the term ‘Dashboard’ was changed to ‘VIP Home,’ which was a more familiar term to end-users. To make the app’s functionality more generalizable, we added a response option of ‘Didn’t try’ in addition to ‘Yes/No’ options for the helpfulness assessment question for each of strategies suggested: if users select ‘Didn’t try’ of the strategy previously suggested, one more chance to try would be provided. The mean scores and sample comments resulting from the heuristic evaluation are listed in Table 1.

Conclusion
Based on the findings from this usability evaluation in a laboratory setting, a prototype mVIP was iteratively refined. Further evaluation will be conducted in a real world setting during a 3-month feasibility trial (n=80). Findings from this work have the potential to reduce health disparities and improve outcomes.

Evaluation of OMOP Vocabulary on Transplant Registry Data

Sylvia Cho, MHS\(^1\), Margaret Sin, BS\(^1\), Karthik Natarajan, PhD\(^1\)
\(^1\)Department of Biomedical Informatics, Columbia University, New York, NY

Introduction

Organ transplant is increasingly becoming a treatment option to improve the quality of life and survival rate for patients with organ failure. Thus, continuous efforts to improve the outcomes of transplant recipients within and across transplant centers is significantly important. The Center for Medicare and Medicaid Services (CMS) currently uses data from the United Network for Organ Sharing (UNOS) to track and monitor transplant outcomes. While UNOS registry data captures a wide range of baseline data, it lacks longitudinal patient-level data and important determinants of patient outcome\(^1\). Thus, augmenting the UNOS data with electronic health record (EHR) data can substantiate the outcomes analysis. However, barriers to interoperability exist due to disparate data models and concept representations among different transplant centers. While the Observational Medical Outcomes Partnership (OMOP) Common Data Model (CDM) is considered as an optimal infrastructure to integrate disparate observational databases, limitations such as potential data loss may exist.\(^2,3\) To our knowledge, there has been no assessment on whether the concepts in the UNOS registry database can be mapped to the OMOP standard concepts. Thus, in this preliminary study, we aim to evaluate the coverage of the OMOP vocabulary on UNOS data elements in order to build a gold standard mapping.

Methods

The UNOS data entry system collects transplant-related data through forms submitted by transplant centers. In this study, we used the Transplant Candidate Registration (TCR), Transplant Recipient Registration (TRR), and the Transplant Recipient Follow-up (TRF) forms which include the major transplant-related data for all organs. We extracted unique concepts from these forms and its corresponding look-up table concepts. We mapped the UNOS source concepts to OMOP standard concepts using the USAGI tool, an open-source application developed by the Observational Health Data Sciences and Informatics (OHDSI) community.\(^4\) Two researchers with biomedical informatics domain knowledge respectively mapped all concepts. We measured the content coverage of OMOP standard concepts on the UNOS source concepts by examining the percentage of UNOS source concepts which could not be mapped to the OMOP standard vocabulary coding system. The reliability of concept mapping was measured through the Cohen’s Kappa score which shows the degree of agreement between investigators.

Results

A total of 1,203 unique source concepts from UNOS were reviewed. The first and second annotator successfully mapped 554 (46\%) and 508 (42\%) source concepts to OMOP standard codes, respectively. A Kappa of 0.79 was calculated based on whether a UNOS element was mapped to an OMOP concept or not. Details of our results are presented in Table 1.

<table>
<thead>
<tr>

<td>40</td>
<td>3.33%</td>
</tr>
</tbody>
</table>

Table 1. Results on mapping UNOS registry source concepts to OMOP standard concept codes

Conclusion

The results of this study show that approximately half of the UNOS source concepts could not be mapped to OMOP standard concepts. Most of the unmapped concepts are related to transplant-specific clinical data and patient-reported outcomes which shows the need to extend OMOP vocabularies in these areas. We plan to involve clinicians to validate our results in order to develop a gold standard mapping between OMOP and UNOS data. This mapping will enable cross-institutional, transplant-specific outcomes analyses.

Use of Storyboarding in the Development of a Pain Management Mobile App: A Case Study

Jeeyae Choi, PhD, RN

1University of North Carolina Wilmington, Wilmington, NC, USA

Abstract
New mobile technologies are enabling care providers to deliver more effective and convenient care to patients. In order to develop a science-based mobile app, it is essential to use a guideline and communicate knowledge from that guideline accurately to a developer. During the development of a pain assessment mobile app, storyboarding was used to communicate knowledge from the guideline among research team members and its usefulness and benefits were explored.

Introduction
Mobile-health-based technology has grown exponentially due to its ubiquitous computing capability. Patients and care providers are increasingly using health-related apps to educate patients, to prevent and/or treat illness\(^1\). Pain management apps are no exception; however, studies have found a gap between the science of pain and commercially developed apps. In order to develop a science-based mobile app, it is necessary to translate and then communicate pain management guidelines accurately to the developer. Storyboarding is a popular technique used in filmmaking production\(^2\). Pictorial representations of story components are prepared and organized sequentially; each picture shows graphic representation as well as explanatory texts. However, the storyboarding technique hasn’t been used in health informatics research. In this project, the storyboarding technique was used to communicate translated knowledge from pain management guidelines. The purpose of this study was to explore the usefulness and benefits of storyboarding as a communication tool when developing a pain management mobile app.

Steps of knowledge translation and communication

**Step I:** Concepts related to pain management tasks were extracted from the National Cancer Institute recommendations for health professionals (Cancer Pain PDQ\(^5\)-health professional version). These concepts were then converted into activity diagrams in the Unified Modeling Language, representing the logics of the app. An expert oncology nurse was recruited to validate and modify the process of assessing pain management in the activity diagrams.

**Step II:** Using the National Cancer Institute recommendations for patients (Cancer Pain PDQ\(^5\)-Patient version), pain assessments and associated sub-assessments were categorized into general pain information, pain level, and past and current pain treatments, and patient’s goals and choices. The expert oncology nurse validated a table that categorized these pain assessments.

**Step III:** Two artifacts, activity diagrams and categorized pain assessments, were shared with the developer. The developmental team produced storyboards and the PI accepted or requested modification of storyboards. These iterative process was done three times and 17 storyboards were subsequently produced. Figure 1 is an example of a storyboard.

**Discussion**
Seventeen storyboards successfully visualized knowledge translated from pain management guidelines. Each storyboard is a pictorial representation of knowledge with explanatory text. With this visual representation, the researcher and the app developer were able to organize pain assessment knowledge from the guidelines without ambiguity into a pain management mobile app. The storyboarding process proved beneficial before production began because the 17 storyboards provided the structure and flow of the design of the mobile app. This is the first step in an ongoing study. After production and usability testing is complete, the true usefulness and benefits of storyboarding will be seen.

Validating a Single-Item Stress Scale for mHealth Interventions

Wonchan Choi, PhD\textsuperscript{1}, Sherry L. Pagoto, PhD\textsuperscript{2}, Edwin D. Boudreaux, PhD\textsuperscript{2}, Bengisu Tulu, PhD\textsuperscript{1}

\textsuperscript{1}Worcester Polytechnic Institute, Worcester, MA; \textsuperscript{2}University of Massachusetts Medical School, Worcester, MA

Introduction

This poster presents the results of an online survey that aims to validate a single-item stress scale that can be used in health care interventions targeting stress management, especially in the mHealth context. Our scale has six anchors with numerical values and visual indicators—faces corresponding to each of the six levels of stress in the scale. We adopted the definition of stress and question wording used in a validated single-item measure of stress symptoms: “Stress means a situation in which a person feels tense, restless, nervous or anxious or is unable to sleep at night because his/her mind is troubled all the time. Are you experiencing this kind of stress currently?”

Methods

Based on a pilot study we conducted in 2016\textsuperscript{2}, we made minor modifications to some of the visual indicators that seemed relatively less intuitive for users to distinguish the indented levels of stress—we adjusted the angles of eyebrows in the faces for “A Little Stress” and “A Whole Lot of Stress” (Table 1). We used an online crowdsourcing site, Amazon Mechanical Turk, to recruit large samples of participants. Of the 315 participants, 56.8% were males. In terms of racial background, a majority of them (76.8%) were White Caucasians. Each participant answered an online survey where they matched six different visual indicators (faces) we created with six anchors of stress. Participants were then asked to rank seven stressful events, which were selected from a validated stressor scale\textsuperscript{3}, in the order of intensity of stress and rate each of them using our stress scale.

Results

Overall, 80.3% (253 out of 315) of the participants matched all the six faces to the corresponding levels of stress as intended. In particular, as presented in Table 1, nearly the 90% or greater proportion of the participants successfully matched each of the faces to the intended levels of stress. A Spearman’s rank order correlation between the rank orders of and the ratings on the seven stressful events ($r_s = - .773, n = 2205, p < .001$) indicated a good concurrent validity of our single-item stress scale—the higher the stressful events were ranked, the more likely they received higher ratings on the stress scale.

<table>
<thead>
<tr>
<th></th>
<th>Visual Indicators (Faces)</th>
<th>Corresponding Labels for Stress Anchors</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>No Stress</td>
<td>295 (93.7%)</td>
</tr>
<tr>
<td>1</td>
<td>A Little Stress</td>
<td>288 (91.4%)</td>
</tr>
<tr>
<td>2</td>
<td>A Little More Stress</td>
<td>296 (94.0%)</td>
</tr>
<tr>
<td>3</td>
<td>Even More Stress</td>
<td>280 (88.9%)</td>
</tr>
<tr>
<td>4</td>
<td>A Whole Lot of Stress</td>
<td>283 (89.8%)</td>
</tr>
<tr>
<td>5</td>
<td>Worst Stress</td>
<td>301 (95.6%)</td>
</tr>
</tbody>
</table>

Conclusion

We will further validate our stress scale, especially in the mobile context. In a following study, we will examine the visual indicators whether they can capture users’ stress levels consistently and accurately without the numerical values or text labels (or both), which will be particularly useful for space-efficient mobile platforms.

Creating a Framework to Standardize Data Extraction from Electronic Health Record Systems for Researchers and to Support Distributed Queries

Mera Choi, JD, MPP, MPM1, Nagesh (Dragon) Bashyam2, Daniella Meeker, Ph.D3, Eliel Oliveira MS, MBA4

1Office of the National Coordinator for Health Information Technology, Washington, DC; 2Drajer LLC, Boyds, MD; 3pSCANNER, San Diego, CA; 4REACHnet, New Orleans, LA

Problem
Researchers and research networks face time-consuming challenges extracting and transforming patient data from multiple data sources, including electronic health records and data warehouses.

Objective
The Office of the National Coordinator for Health Information Technology (ONC) developed a Data Access Framework (DAF), a three phase effort to identify, test, and validate standards necessary to access and extract data from within an organization’s health IT systems, external organization’s health IT systems, and health IT systems across multiple organizations. The third phase, DAF for Research (DAF-R), is designed to increase access to patient data using standards for data queries, application programming interfaces (APIs), or services. Three organizations, REACHnet, Lincoln Peak, and pSCANNER, piloted DAF-R to enable researchers to create value out of complex data from multiple sources, without having to rely on existing access paths.

Methods
(1) Clinical Data Research Networks (CDRNs) use standardized data extraction mechanisms from multiple clinical data sources to populate data marts; (2) CDRNs publish standardized data mart metadata about source data, useful for researchers to determine the available data; (3) researchers use standardized query distribution mechanisms to query multiple data marts; (4) CDRNs use standardized aggregate query results to return data from data marts back to researchers in response to a query. The DAF-R pilots successfully: (1) implemented an API on an example FHIR® framework and demonstrated conformance; (2) mapped data elements from a data model; (3) aligned metadata management standards to be consistent with national and international standards; (4) automated queries at regular intervals.

Results
By standardizing access to patients’ data, DAF-R: helps researchers reduce the burden of customary data mapping for each data source; helps researchers standardize the metadata collected from the data source; enables the use of common security and privacy controls across networks; and allows researchers the ability to consume meaningful results from various research sites. DAF-R advances research efforts to develop an interoperable data network infrastructure to maximize efficiency, advances research opportunities, and improves future health policies. This project was funded by Patient-Centered Outcomes Research (PCOR) Trust Fund, managed by the Office of Assistant Secretary for Planning and Evaluation (ASPE) in the U.S. Department of Health and Human Services.

OMOP on FHIR as an Enabler for Analytics-As-A-Service

Myung Choi, PhD, Richard Starr, and Jon Duke, MD
Georgia Institute of Technology, Atlanta, GA, USA

Introduction

While advances in machine learning have greatly improved the performance of predictive models in healthcare, less progress has been made in facilitating the delivery of analytics at the point of care. As part of Georgia Tech’s Health Data Analytics Platform, we developed an interoperable framework to connect OMOP-based predictive models to clinical decision support systems via FHIR. This builds on our previous OMOP on FHIR project, which defined mappings between the Observational Medical Outcomes Partnership Common Data Model (OMOP CDM) and FHIR resources. In this poster, we will describe the new OMOP on FHIR (www.omoponfhir.org) architecture and provide example use cases for deployment.

OMOP on FHIR Architecture

The OMOP on FHIR architecture (Figure 1) provides mappings and workflow for reading and writing between FHIR and OMOP CDM. We decoupled reading and writing transaction flows to improve the data integrity and quality. For writing, we introduce staging tables for FHIR contents to be natively mapped before the ETL processes are triggered for transforming these staging tables to OMOP CDM. Several sub-operations can take place during these processes based on application needs. The ETL processes provide the auditing and quality control steps to ensure data are persisted into the proper locations and mapped appropriately. Once data are persisted into the OMOP CDM, we gain access to the Observational Health Data Sciences and Informatics (OHDSI) resources that can perform data aggregations and packages for cohort creation and various population level data analytics. As we are mapping the FHIR contents to OMOP CDM, any EHRs that can understand this data model can take advantage of our platform.

As some of data elements in FHIR cannot be one-to-one mapped from OMOP CDM, SQL views are used to map the OMOP CDM tables to the appropriate FHIR resources for read requests. By constructing FHIR-friendly views, the FHIR API layer can be implemented relatively easily and is more robust to changes in the OMOP model.

Analytics-As-A-Service

The OHDSI software provides various analytic tools that minimize the overhead for data scientists. These tools provide robust analytics capabilities but are limited in their real-world impact on clinical care. With OMOP on FHIR, any data analytics process can be turned into service (‘analytics-as-a-service’) for delivery at the point-of-care. Figure 2 depicts this process.

As a test case, we deployed a predictive model for assessing risk of C. Difficile colitis infection based on individual patient characteristics. We set up an API gateway that received test patient data via FHIR, transformed to OMOP, called the C. Diff predictive model, and returned the personalized risk prediction. Total transit time for ingestion, mapping, and result generation averages 5-6 seconds with mid-end virtual machines.

Conclusion

OMOP on FHIR is an open-source platform that provides bidirectional mapping processes between OMOP and FHIR as well as a framework for API-based analytics as a service using OMOP-based predictive models. Our future work includes expanding mappings and evaluating several OMOP-based predictive models for impact on clinical decision-making. We hope that tools such as OMOP on FHIR, which connect research analytics to the point-of-care, will advance the goals of precision medicine while allowing innovation in analytics.

Reproducibility in Biomedical Natural Language Processing

K Bretonnel Cohen, PhD1,2, Aurélie Névél, PhD2, Jingbo Xia, PhD3, Negacy Hailu, MSc1, Cyril Grouin, PhD2, Lawrence Hunter, PhD1, Pierre Zweigenbaum, PhD2

1 CNRS, LIMSI, Université Paris-Saclay, F-91405 Orsay; 2University of Colorado School of Medicine, Denver, USA; 3Huazhong Agricultural University, Wuhan, China

Introduction

There is a growing concern that the reproducibility of much work in science in general and in the biomedical field in particular is questionable. In order to improve the robustness of methods in biomedical Natural Language Processing (NLP), we need to assess the current situation in the field, after recent experiments on a shared task suggest reproducibility cannot be taken for granted even under favorable conditions where data, code and evaluation toolkits are available1. Nonetheless, data and code availability is the first requirement to enable reproducibility.

Methods

Herein, we apply a protocol previously put forth to assess reproducibility in computer science2: all 29 articles in the proceedings of the 2016 BioNLP workshop are reviewed by two analysts (one expert in the field of biomedical NLP and one computer scientist) to extract information on code and data availability. The article passages supporting the evidence of availability are marked. However, the retrieval of the material and actual reproduction of experiments are not attempted at this stage, but would be impossible without data and code. The annotation guidelines are available at https://github.com/KevinBretonnelCohen/InterRaterAgreementReproducibility. They were created by writing an initial draft, doing a pilot annotation project, modifying the guidelines based on findings of the pilot project, and then doing the full annotation as described above. Inter analyst agreement is computed in terms of Cohen’s kappa3 in order to assess the reliability of the annotation process as well as the understanding of the task by the analysts.

Results and Conclusion

Although 48% of papers provided pointers to data and 61% provided pointers to code, only 21% reported both. Inter-analyst agreement was 0.57 (moderate) for identifying data and 0.63 (substantial) for identifying code. This suggests that reports of data availability might require more domain knowledge to be identified, e.g. a link to github might be easier to follow as evidence of code availability than the name of a dataset possibly unknown to the reader. In addition, some disagreement on data availability occurred for subsets of MEDLINE where the expert considered data as not available if the specific subset and annotations were not explicitly linked. Although the kappa scores that we are reporting for the inter-analyst agreement are not high, those numbers badly underestimate the reliability of the analysis, as the calculation sets the value for expected agreement too high, resulting in an inappropriately low kappa value. The situation with respect to reproducibility in clinical natural language processing is arguably better than the situation in computer science, as Collberg et al. found that only 13% of papers in their study reported both code and data availability. However, we believe reproducibility in biomedical NLP should receive increased attention, with the introduction of guidelines for reporting work in a reproducible way. While the availability of code and data do not necessarily guarantee that work can be reproduced, it is a necessary condition and as a community we should strive to facilitate access to code, data and experimental set-up as a way to address reproducibility issues.

The Impact of Health IT Adoption: Are We Measuring the Right Outcomes?

Tiago K Colicchio¹, MBA, MS, Guilherme Del Fiol¹, MD, PhD, Watson A Bowes III¹,², MD, MS, Julio C Facelli¹, PhD, Debra L Scammon³, PhD, Scott P Narus¹,², PhD

¹Biomedical Informatics, University of Utah, Salt Lake City, UT; ²Medical Informatics, Intermountain Healthcare, Salt Lake City, UT; ³David Eccles School of Business, University of Utah, Salt Lake City, UT

Introduction

Electronic Health Record (EHR) systems adoption has rapidly increased in the U.S. partially due to financial incentives provided by the Meaningful Use program, and, as a result, the number of studies on the impact of EHR implementations on health care quality, productivity and safety, has also increased. Yet, previous studies have produced mixed-results, failing to increase our understanding of the full impact of health IT adoption. A contributing factor to this gap is the use of simple, non-standardized measurements in evaluations of the impact on health care from health IT adoption. In this study, we compare the most common measures in previous studies assessing the impact of health IT with measures suggested by experienced health care leaders and informaticists. Our goal was to determine if measures in prior studies provide a comprehensive coverage of processes likely impacted by EHR implementations.

Methods

We used a multi-method approach to identify relevant measures for monitoring health IT interventions, including implementations of new EHRs or new versions of current EHRs. We conducted semi-structured interviews with clinical and administrative leaders from Intermountain Healthcare. The leaders were identified via referrals from a convenience sample of medical informaticists. We combined their suggestions with the most commonly used measures from the literature¹, and classified them into the categories quality, productivity and safety using our previously published taxonomy⁷. The measures were included in two online surveys that were sent to informaticists nationwide. One survey included measures of ambulatory outcomes, and the other of hospital outcomes. Respondents were asked to provide suggestions of additional measures not included in our original lists. Survey invitations were sent to members of the AMIA Implementation Forum and HIMSS Nursing Informatics Alliance. We also invited research faculty with interest in EHRs or health IT adoption from several U.S. informatics academic programs.

Results

Thirty Intermountain Healthcare leaders suggested 63 measures. One-hundred twelve informaticists participated in the surveys and suggested 11 additional measures. We combined measures identified in previous studies with experts’ suggestions, producing an inventory of 102 measures. The experts suggested several measures not reported in the literature, including 13 of quality, 32 of productivity, and 16 of safety care processes (Figure 1).

Discussion

Experts suggested additional measures that have not been reported in the literature, especially for productivity and safety. These care processes deserve more attention from the informatics community. To increase our understanding of the impact of health IT adoption, we recommend future studies covering a wider range of quality, productivity and safety outcomes. Two separate studies are in development to (1) assess informatics experts’ perceptions of the relevance of these measures, and (2) develop a methodology to detect the impact of EHR implementations over time.

ProjectFlow: Configurable Clinical Trial Management with Enterprise Data Integration and Point-of-Care Study Support

Ryan C. Cornia, BS¹², Nilla Majahalme, BSE³, Danne C. Elbers, MS³, Svitlana Dipietro, BS³, Brian Ivie, BS¹², Brad Adams, MS¹², Ramana Seerapu, BS¹², Valmeek Kudesia, MD, MS¹³, Scott L. DuVall, PhD¹²

Abstract
Clinical trials offer tremendous value to medical research, but traditionally require extensive manual tracking or expensive and rigid IT investment for integrated electronic record tracking. We present the architecture that supports complete clinical trial tracking according to trial-defined requirements while allowing for easy integration with clinical data and services. The core of the system is ProjectFlow, a web application that allows users to define trial workflows, incorporate clinically relevant data, and integrate enterprise services.

Introduction
Tracking and managing clinical trial data has typically been an expensive and time-consuming task. While both open- and closed-source systems exist, they focus on electronic data capture (EDC) and clinical trial management (CTM), functionality is limited, and integration points are difficult. This forces study designers to fit their study to the features of the system by reducing integration with other enterprise systems and forcing study workflows to meet only those supported by third party EDC/CTM solutions.

Flexible data collection and workflow configuration can efficiently support a broad range of trials, including novel trial designs like point-of-care clinical trials.[1] Users should see only the patient data pertinent to the task they are completing, and workflows should be flexible enough to accommodate different paths through the clinical trial based on enterprise service input along the way. Clinical trial design needs to be flexible and user-adaptable to match varying requirements of clinical trials. ProjectFlow builds upon best-of-breed open source projects with a novel approach to accessing clinical data that streamlines clinical trial development and implementation in the Department of Veterans Affairs (VA).

System Description
ProjectFlow solves the complexity of clinical trials differently than existing EDC/CTM systems by:

• Allowing graphical workflow definition by clinical trial staff using the standards-based Business Process Model and Notation. No IT support is required to design, modify, or launch a trial and workflows are decoupled from data.
• Data is pulled directly from the existing enterprise relational database with no ETL or modification needed.
• Clinical trial designers create views of the data pertinent to each specific task in the workflow. Staff see a view of the data for a task that efficiently communicates the information they need to complete the task.
• Workflows can easily integrate with enterprise services to make decisions about how to route the workflow or to show specific selectable data customized to the participant.
• Patient paths can support a high level of complexity if needed, including decision points based on enterprise services or upstream data.

Conclusion
By allowing for flexible clinical trial design, investigators and trial staff have been able to implement complex clinical trial workflows that integrate with enterprise services at many key points along the way. Because of the flexibility of the system, trial staff are able to create and deploy trials, and modify existing trials as needed, all without developer support. The self-service nature has allowed VA to meet the changing requirements of existing trials and add new clinical trials in an efficient manner not previously possible.

Introduction

Drug-drug interactions (DDIs) have the potential to cause serious harm. Electronic health record (EHR) systems with integrated decision support can alert physicians to potentially dangerous DDIs during the prescribing process. However, these alert warnings are often overridden by prescribers, with override rates in excess of 80%. Previous studies have identified 15 high-priority DDIs which should always generate warnings in all EHRs\(^6\). 33 low-priority DDIs have also been identified that do not merit interruptive alerting\(^6\). The objective of this study was to investigate whether alert warnings for the high-priority and low-priority DDIs existed in five different international EHRs, compare the severity level assigned to them, and establish the rate at which they were overridden.

Methods

This was a comparative, retrospective, multinational study of five EHRs from the U.S., U.K., Republic of Korea and Belgium.

Results

Of those previously defined 15 high-priority DDIs, alert warnings were found to exist for 11 in the Korean and UK systems, 9 in the Belgian system, and all 15 in the US systems. Of 742 individual drug-drug combinations included in those 15 class-interactions, 619 (83.4%) were included in the Belgian system, 462 (62.3%) in the US inpatient and 441 (59.4%) in the US outpatient system, 212 (28.6%) in the UK system, and 53 (7.1%) in the Korean system. Alert warnings were active for all DDI combinations contained in the US and Korean EHRs, but only 8.4% and 52.4% in the Belgian and UK EHRs, respectively. The override rates for high-priority alerts requiring provider action ranged from 56.6% to 85.6%. Of those 33 previously defined low-priority DDIs, alerts existed only in the US systems for three class-based DDIs and the majority were non-interruptive (no provider action required). The inpatient and outpatient US systems generated 38 and 237 interruptive alerts, with override rates of 57.9% and 66.7%, respectively. The UK and Korean systems alerted on none of the 33 low-priority DDIs, the Belgian system included 24 inactive low-priority DDI alerts.

Conclusions: Alert warnings existed for the majority of high-priority DDIs in the different EHRs although it was easy to override some of the most severe interactions in most systems. Alerts were delivered for only a few low-priority DDIs. This study highlights a lack of consistency in how DDIs are configured in different knowledge bases. Future efforts should concentrate on enforcing an international standard for high risk DDIs and implementing strategies to minimize overriding of severe drug interaction alerts while balancing over- and under-alerting.

Automated Image Quality Assessment for Fundus Images in Retinopathy of Prematurity

Aaron S Coyner1,2, Ryan Swan1,2, Jayashree Kalpathy-Cramer1,3, Sang Jin Kim1,4, J. Peter Campbell1, Karyn E. Jonas5, Susan Ostmo6, R.V. Paul Chan6, Michael F. Chiang1

6. Ophthalmology, Illinois Eye and Ear Infirmary, Chicago, IL, United States.

Accurate image-based ophthalmic diagnosis relies on clarity of fundus images. This has important implications for the quality of ophthalmic diagnosis, and for emerging methods such as telemedicine and computer-based image analysis. The purpose of this study is to implement an algorithm for automatically assessing the quality of fundus images, and to evaluate its performance on a set of Retinopathy of Prematurity (ROP) images compared to expert assessment.

A data set of 30 wide-angle ROP images (RetCam; Natus, Pleasanton, CA) was collected from infants undergoing routine screening examinations. A previously published method by Bartling et. al for automated assessment of digital fundus images was implemented. Briefly, 30 images were resized and converted to grayscale. Each image was broken into 16x16 pixel blocks, and blocks were assessed using metrics for brightness and sharpness. Scores for each block were used to compute an overall image quality score for each image. Images were ranked by quality score from 1 (lowest quality score) to 30 (highest quality score). Six independent experts were provided the same set of 30 images and, using a web-based interface, were prompted to "select the higher quality image for diagnosis of plus disease." Elo rating values for each image were determined for each rater and for the consensus of all raters. Spearman rank correlation was used to assess the similarity of the algorithm’s performance to human raters when determining image quality.

Individual expert ranks correlated highly with one another (correlation coefficient [CC] 0.89-0.94) and with the consensus rank (CC 0.94-0.98). The algorithm rank correlated with individual expert ranks (CC 0.81-0.87) and the consensus rank (CC 0.86), but not as highly as individual experts (Table 1).

Experts in this study had high correlation to one another in assessing quality of ROP images. The computer-based algorithm assessed image quality with strong correlation to the expert consensus rank, although not as high as individual expert correlation with the consensus rank. Future studies will investigate discrepancies between the algorithm and the consensus, using the established consensus rank as a reliable training set.

Where’s the Data and Where Do I Start? Assessing Stakeholder Needs for Effective Use of Institutional Data

Chandrea Culbreath, MPH, BSN1; Maria Souden, PhD1; Melissa Nemon, PhD1,2; Holli Kreinbring12; Margaret Gonsoulin, PhD1; Denise M. Hynes, MPH, PhD, RN 1,3,4

1 US Department of Veterans Affairs (VA) Information Resource Center (VIReC), Edward Hines, Jr. VA Hospital, Hines, IL; 2 A-Team Solutions, LLC, Fulton, MD; 3 Center for Innovation in Complex Chronic Healthcare (CINCCH), Edward Hines, Jr. VA Hospital, Hines, IL; 4 College of Medicine and School of Public Health, University of Illinois, Chicago, IL

Introduction
The Veterans Health Administration (VHA) is the largest integrated healthcare system in the United States, providing care to almost nine million Veterans a year at over 1700 sites of care nationwide. Administrative and clinical data generated in the course of care are made available to VA clinical, operations, and research employees in order to inform healthcare decisions, improve the health system, and contribute to generalizable knowledge. The VA Information Resource Center (VIReC) is funded by VA Health Services Research & Development (HSR&D) to advance VA capacity to use data effectively for research and quality improvement (QI) projects. VIReC develops knowledge about data contents, structures, and methods for use and disseminates this knowledge through its communications and education programs. Recently the Center undertook a large-scale needs assessment to examine the challenges faced by some 5,000 users and potential users of VA data, identifying unmet needs for effective use of VA data and generating stakeholder recommendations for addressing those needs.

Methods & Sample
VIReC’s Needs Assessment is a multi-level study that includes three distinct phases of data collection in an iterative, mixed methods design. Participants for the first two phases were recruited from 4,675 VA staff using VIReC products and services or otherwise affiliated with the VA research and analytic enterprise, including health service and QI researchers, program office analysts, and clinical staff. In Phase 1 six focus groups were conducted with VA data users (n=44) in order to understand their data use concerns and challenges within the context of daily work activities. Phase 2 consisted of a survey of 829 data users, aimed at quantifying themes identified in Phase 1 and anticipating topical needs for knowledge resources and support. Phase 3 funneled data from the first two phases to six panels of leadership-level organizational stakeholders (n=50), including research centers, QI and evaluation programs, data offices, and advisory authorities. Stakeholder focus groups generated ideas for meeting data user needs and participants completed a follow-up survey (n=41) in order to develop consensus on the priority and feasibility of possible activities.

Results
Data collected from the first two phases of the assessment identified four major areas of concern or unmet needs for data users: 1) navigating the VA data landscape; 2) complicated data access processes and access delays; 3) data quality concerns; and 4) working effectively with VA data. In the final phase of the assessment, leadership-level panels considered these results and identified four high-priority and high-feasibility focal areas for VIReC: 1) Increase education about VIReC products and services, especially for new researchers; 2) Work towards affecting system change for improved data access and data access processes; 3) Facilitate community contributions around data quality, effective use of data, and code sharing; and 4) Facilitate acquisition of non-VA data.

Conclusions
Findings from the VIReC Needs Assessment provide insight into the challenges faced in supporting the use of institutional data resources for a broad range of users and use purposes. Effectively supporting the use of rich data resources within the context of a learning healthcare system requires supporting data knowledge and access throughout all phases of project activity and being attentive to the range of experience and perspectives brought to the data. Stakeholders envisioned solutions to user challenges that capitalized on the Center’s core strengths of data expertise, communication, collaboration, and facilitation. The needs assessment process presents a valuable framework for addressing user perspectives while accounting for the realities of leadership priorities and organizational constraints.
The Capture of Social and Behavioral Determinants of Health in Electronic Health Records
Theresa Cullen, MD, MS\(^2\), Katie Allen, BS\(^3\), Sara Armson MS\(^3\), Anna Roberts, MS, MS, Daniel J. Vreeman, PT, DPT, MS\(^2\)

- Regenstrief Institute, Indianapolis, IN; - Indiana University School of Medicine, Indianapolis, IN

Introduction

Increasingly, the clinical community is becoming cognizant that health status is dependent upon numerous external influences often referred to as social determinants of health (SDH). Precision health and personal health initiatives ask physicians to look at the whole person, including SDH, in addition to clinical factors. There have traditionally been limited ways to enter and retrieve SDH data within the EHR. In 2014, the Institute of Medicine released *Capturing Social and Behavioral Domains and Measures in Electronic Health Records: Phase 2*. The IOM identified core domains in Phase 1 of this work that were recommended for inclusion in patients health histories; Phase 2 endorsed specific measures for each of these core domains. In December 2015, the Regenstrief Institute, Inc, working with ONC, published a SDH panel in LOINC that contained SDH variables representing a minimum set of measures to be included in electronic health records. These LOINC terms were referenced as an optional component of the Meaningful Use incentive program’s 2015 Certification Criteria. This panel (80216-5), included social, psychological, and behavioral observations consistent with the IOM recommendations. We sought to understand how the availability of a standard, coded collection of SDH variables (endorsed by ONC within the MU program) would permeate into electronic record systems where these data were previously captured as free text elements (if at all). Specifically, we wanted to examine the impact of this new standard in supporting the capture of SDH elements in a large, regional, health information exchange (HIE) before and after the release of the Meaningful Use certification panel.

Methods

We sought to characterize the representation of SDH elements in the Indiana Network for Patient Care, one of the most comprehensive and longest tenured HIEs in the U.S. In this retrospective study, we leveraged existing clinical data from regional health systems. First, we created a cohort of patients aged 18 and older with at least two clinical visits (outpatient or emergency department) during the study period, to use as the denominator. Utilizing the clinical message flow within the HIE, the team examined Continuity of Care Documents (CCDs) for patients within the identified cohort. The study period was January 1, 2014 through December 31, 2016, corresponding with the IOM report and release of the LOINC panel. Presented data will include prevalence of the LOINC SDH panel codes in the periods pre/post the release of the Meaningful Use panel and a more detailed analysis for a subset of codes that were available prior to the IOM report. The subset includes content from three domains: exercise in days (68515-6); alcohol consumption (68518-0); and marital status (63503-7). Basic demographics and analysis will also be shared.

Evaluation Results

Our preliminary findings indicate minimal, if any, uptake of this LOINC panel as recorded in the HIE.

Conclusions

Identifying SDH elements from clinical notes requires providers to wade through a cacophony of unstructured data. Use of structured data elements, like the LOINC panel, should facilitate collection and longitudinal analysis of these important clinical factors. However, primary findings indicate minimal, if any, uptake of this LOINC panel as recorded in the INPC. Future work includes discussions with local CMIOs to identify how SDH data may be recorded and/or stored within the certified EMR and which data elements are selected for inclusion in CCDs. Future work may also include analysis in other health systems and a human factors usability evaluation.
Using Environmental Sensors to Estimate Users Activity

Dorothy W. Curtis, M.Sc., Mike Wang
Computer Science and Artificial Intelligence Laboratory, MIT, Cambridge, MA, USA

Overview
This project analyzes data from a prototype monitoring system designed for wheelchair users. This monitoring system has several sensors and a small computer mounted on the wheelchair. The computer collects the sensor data and transmits it to a central system for further analysis. The sensor data includes temperature and humidity data that can be used to generate alerts indicating excessive heat exposure. This project analyzes whether the temperature data can also be used to infer whether a user is indoors or outdoors, which could be helpful in determining the activity levels of wheelchair users. Our poster will show the results of our algorithm and evaluate its performance.

Methodology
Our program first extracts the raw temperature and humidity data from a Postgres database and writes the temperature and humidity values into a CSV file as a list of time-value pairs. Then it filters out any outliers and windows the data into 15 second windows. Based on estimated outdoors and indoors values for temperature, the program estimates whether a person is inside or outside at a particular time. However, in order to reduce the effect of noise when a person transitions from outside to inside or from outside to inside, the program requires that these transitions are at least 5 minutes apart. The program uses historical weather data to establish the baseline reference for the outdoor temperature. The initial inside temperature estimate is based on the initial readings from the temperature sensor because the wheelchair starts inside the facility every morning. Even though the facility is air conditioned, its ambient temperature increases during the day, and so the program updates its reference value for the indoor temperature to the median value of the most recent block of time when the person was inferred to be inside.

Evaluation

Figures 1 and 2 show some preliminary results from the algorithm. The y-axis is temperature in Fahrenheit and the x-axis is time of day in hours. The thin red line represents the reference indoor temperature. The green line represents the reference outdoor temperature. The strong red points in the graph are the raw temperature measurements. The thin blue line indicates whether the algorithm infers the person is outside or inside: when the blue line takes on the max value, the person is inferred to be outside and when the blue lines take the min value, the person is inferred to be inside. These plots illustrate some issues with the algorithm: for example, in the first graph, the algorithm indicates that the person went outside at 12.5 hours, though this is likely not the case and we expect that the algorithm became confused because the outdoor (green) and indoor (red) temperature reference lines crossed, i.e., it became cooler outside than inside, which is possible but unlikely in the summer in the daytime in Boston, MA, USA. In the second graph, the person is likely to have gone outside at around 16.5 hours even though the algorithms thinks the person stayed inside. This may be due to the algorithm requiring any transition to last at least five minutes.

Conclusion
We have developed an algorithm to infer whether a wheelchair user is inside or outside based on ambient temperature data. This experiment has shown that when we deploy this system we should also deploy stationary indoor and outdoor temperature sensors and improve our algorithm to handle more situations.
Mixed Methods Approach for Understanding Clinical Workflow
Ioana Danciu, MS\textsuperscript{a,b}, Stuart T. Weinberg, MD, FAAP\textsuperscript{b}, Daniel Fabbri, PhD\textsuperscript{a,b}, Kim M. Unertl, PhD\textsuperscript{b}

\textsuperscript{a}Vanderbilt University School of Engineering, 2301 Vanderbilt Pl., Nashville, TN 37235
\textsuperscript{b}Vanderbilt University School of Medicine, 1161 21st Ave S., Nashville, TN 37232

Introduction
Although the wealth of electronic patient record data is extremely promising for large-scale computational approaches, making causal inferences through purely computational methods can lead to potentially incomplete or misleading false conclusions. Qualitative methods can assist with understanding clinical processes through the perspectives of the participants, and generate a wealth of information about human behavior, work practices of healthcare teams, and technologies that are available to them. Qualitative methods however face challenges of scale across space, time and human participants. We propose a mixed methods approach (Figure 1) that links qualitative methods with data analytics to model clinical workflow and make causal inferences.

Methods
The Vanderbilt Ingram Cancer Center (VICC), one of 41 National Cancer Institute (NCI)-designated Comprehensive Cancer Centers, was the setting for our study. The data in our analyses were produced by a workflow and communication tool called the Outpatient Whiteboard which aggregates appointments, laboratory results, pharmacy medication dispenses, and other information, into a user-friendly web interface. In the last year on average 1900 Whiteboard transactions have been recorded on 225 patients every clinic day at VICC. We analyzed 25487 appointments for 6344 patients.

The metrics we selected were the total number of patients in a location at a given time aggregated over the two months study period and the average duration in minutes of each transition through the different areas. Over the course of two months during the summer of 2014, one researcher (ID) observed healthcare team members for 31 hours at the infusion center, the infusion center front desk, the VICC registration desk, the laboratory front desk, the laboratory, the pharmacy, and cancer clinic exam rooms. We used information collected during the observations about the workflows in the different areas, the performers and the technologies available to them to explain trends in the room movement quantitative data from the outpatient whiteboard.

Results
A trend in our observation data revolved around events being sequential and in a predefined order. When interacting with the VICC areas patients usually visit the registration area, the lab, the doctor’s office and the infusion area in this particular order. In addition, there are only two entry points into the system: the VICC front desk, and the infusion center front desk. The Pearson correlation between the number of patients and the time spent receiving care or waiting calculated over our 2 months study period (Table 1) shows some interesting trends. The time spent in the lab wait room is directly proportional to the number of patients. The time spent in the Lab correlates moderately with the number of patients because as we observed during the qualitative phase, the limiting factor is the staffing. The clinic wait room shows no correlation between our two metrics. The Infusion clinic time spent in the wait room time does not correlate with the number of patients in the area. Again, this could be due to patients arriving earlier for their scheduled appointments. The time spent in the infusion area is the longest for all areas, because as we observed during the qualitative phase, chemotherapy administration takes three hours on average. The infusion nurses we observed were extremely busy during the infusion start and the infusion end. Staggering patients when initially put in infusion rooms could lead to less busy discharges.

Discussion and Conclusion
In this work, we presented a mixed methods approach to understand and represent clinical workflow. Using data analytics, we were able to quantify workflow patterns in clinics. Qualitative observation assisted us with understanding trends in the data. Next steps include targeting the wait areas and understanding the factors that impact the time dependence of the delays. Also, incorporating other data sources such as the Laboratory Information System or the Outpatient Scheduler can provide vital insight into the trends observed in the Whiteboard data.
Structured Data Capture (SDC)

Farrah Darbouze¹, William E. Hammond, PhD², Richard Moldwin, MD, PhD³, Sue Dubman, PhD, MA⁴, Matthew Chudy⁵

¹Office of the National Coordinator for Health Information Technology, Washington, DC; ²Duke University, Durham, NC; ³College of American Pathologists, Northfield, IL; ⁴University of California, San Francisco, CA; ⁵Data Consulting Group, Detroit, MI

Problem

The use of electronic health record (EHR) data for secondary purposes is limited due to a lack of uniformity in data structure, transport, and definitions across EHR systems. Streamlining EHR data in a structured way can accelerate determination of coverage, quality and safety improvements, improve population health, and foster scientific research.

Project Objective

The Structured Data Capture (SDC) Initiative provides a standards-based infrastructure for the capture and use of patient-level data in EHR systems for adverse event reporting, public health reporting, and scientific research. The initiative adopted and enhanced four national standards specific to common data elements (CDEs) used in filling, structuring, or designing electronic forms/templates; standardizing EHR interaction functions; auto-populating forms/templates; and transporting structured data between systems.

Project Description

The SDC Workflow steps include: (1) a Form Filler requests a form/template from a Form Manager; (2) a Form Manager sends the requested form/template to the Form Filler; (3) the Form Filler converts, populates, and displays the form; (4) the Form Filler stores/transmits the structured data to an external data repository; (5) upon request, the external data repository extracts, transforms, and sends the completed structured data to the end user. Three pilot teams successfully completed end-to-end testing of multiple forms using the SDC architecture. The three forms are as follows: FormDesign, RequestForm and SubmitForm.

Conclusion

SDC forms are an efficient mechanism to achieve interoperability with standardized structured clinical content. This project was funded by the Patient-Centered Outcomes Research (PCOR) Trust Fund, managed by the Office of the Assistant Secretary for Planning and Evaluation (ASPE) in the U.S. Department of Health and Human Services.

Evaluating Health Kiosk Technology as an Enabler of Shared Decision Making

Selena Davis a, Karen L. Courtney a, and Judith T. Matthews b
a University of Victoria, Victoria, BC Canada; b University of Pittsburgh, Pittsburgh, PA US

Introduction

Today there is increased interest in health information technologies (HIT) that engage patients in decision making as part of self-management. Shared decision making (SDM) is a collaborative process that allows patients and their providers to make decisions together by considering the best available evidence as well as patient values and preferences, to identify the best strategy at a specific point in time. SDM involves choice, option, decision, and action to shift the patient’s initial preferences to informed preferences and culminates in a shared decision expressed in a care plan with explicit follow-up that respects and tracks outcomes related to those preferences. Effective SDM requires patients to have access to their health information, health management and decision support tools, and the means to communicate with their providers. Multi-user health kiosks provide an ideal platform for optimizing SDM.

Health Kiosk Application

Initially designed to assist older, community-dwelling adults in monitoring selected health parameters and communicating with their care team, our multi-user health kiosk has expanded to include screening and interactive intervention aimed at improving self-management of sleep, mobility, lifestyle, bladder control, and emotional health. Data are collected via several integrated devices as well as self-report. Recommendations are tailored to the patient.

Methods

By adapting a conceptual framework, which maps characteristics and elements of the SDM process to enabling personal health record system functions by patient activity, this descriptive qualitative study evaluates the enablement of SDM in context of our health kiosk. Using the adapted framework (SDM-HIT) and a 3-point scale, the researcher performed an onsite system walkthrough to simulate the user experience followed by individual semi-structured interviews with members of the development team to evaluate the availability of system functions for the user. Directed content analysis was used to reveal optimization of our Kiosk for SDM – e.g. SDM element “Receive decision support – Elicit personal preference in context of decision” was assessed as: (i) currently implemented; (ii) available but not implemented to enable SDM; and (iii) not currently implemented but recommended for future development.

Results

An assessment summary of our health kiosk functions that could be leveraged in support of SDM identified many areas for optimization, including diverse functionalities which enable patients to access health information, record health information, receive decision support and communicate with others – e.g. our Kiosk clinical profile comprises data from mostly self-report and a few integrated devices, a simple preference profile is created, unsophisticated decision support is used, and communications with others are limited including care providers.

Discussion

To engage patients in health self-management and decision making, systems must be designed for that purpose. The opportunities and identified gaps from this study may be translated into implementation and operational requirements for our health kiosk and other community-based, multi-user, self-management technologies. Using the SDM-HIT framework as an evaluation tool offers a novel approach to assessing HIT systems for the enablement of SDM.

Testing an Explainer Animation for Public Health Education

Jeffrey Day, MD, MA1, Anne Altemus, MA1
1Lister Hill National Center for Biomedical Communications, NLM, Bethesda, Maryland, USA

Abstract

We are experimenting with online explainer animations to improve the outreach mission of the National Library of Medicine. A short animation on histamine will accompany a food allergy article in NIH MedlinePlus magazine and we will see if it can help enrich the magazine articles, attract new audiences, and expand awareness of the NIH. If successful, this project can inspire more multimedia communication strategies to convey public health messages.

Overview

The National Library of Medicine (NLM) serves as a national health information source for the public, patients, and families.1 As part of this mission, NLM produces NIH MedlinePlus magazine to deliver popular, consumer-friendly content. To improve the magazine’s online presence, we will test the use of explainer animations to: 1. enrich the magazine’s written stories, 2. attract new audiences to magazine content, and 3. expand awareness of NIH.

Online video is a promising strategy to serve each of the above goals. Eighty-six percent of Americans now use the internet,2 over 70% of those users share content via social media,3 and social actions for video are growing faster than for any other shared content.4 Explainer animations in particular have been shown to quickly convey complex ideas to target groups in a short amount of time,5 making them ideal for delivering health information.

We will create a four-minute explainer animation on histamine to be released in conjunction with a food allergy article in the Summer 2017 issue of NIH MedlinePlus the Magazine. The animation will follow Section 508 standards of accessibility including audio described narration, closed captioning, and WCAG 2.0 AA contrast standards.

To gauge enrichment and user interest, a crossover study will compare the food allergy article and animation. Subjects will view the article and animation in two separate sessions, with half the subjects reading the article first, and the other half watching the animation first. Attitudes about the NIH and the magazine’s content will be surveyed before the sessions, after the first session, and after the second session, concluding with a debriefing interview. The crossover study will allow for A/B comparison, as well as user insights after subjects see both the article and video.

Measurements of a video’s ability to draw new audiences will be based on analytics from the magazine website, social actions, and YouTube views. Social actions will also be compared between a Spanish and English version of the explainer animation, which can provide insights into how the two different language demographics interact with the NLM’s online content.

This will be the first of several explainer animations created in conjunction with the magazine website, and can inform multimedia communication strategies to share public health messages at the NLM.

CTB: A Custom Taxonomy Builder for Named Entity Extraction
Dina Demner-Fushman, M.D., Ph.D. and Willie Rogers
US National Library of Medicine, Bethesda, MD

Abstract
Clinical researchers are often interested in finding specific disease phenotypes in clinical text. When using dictionary-based named entity recognition tools, they might need to add an important local terminology or limit the scope of named entities provided in the publicly available resources. In this poster, we present an online, as well as downloadable, open-source tool that allows constructing custom-built subsets of the UMLS Metathesaurus.

Introduction
Processing of biomedical or clinical text for a specific task often does not require the full contents of the Unified Medical Language System® (UMLS®) Metathesaurus®. Several tools for customizing the Metathesaurus are available: MetamorphoSys - the UMLS installation and customization program – allows excluding vocabularies, suppressible terms, languages, and semantic types, among other filters. The MetaMap Data File builder allows creating UMLS-like data models from a provided source. These tools, however, require download, installation, and potentially some knowledge of command line procedures. For users interested in creating their vocabulary in an online Graphical User Interface (GUI), we developed an open-source Custom Taxonomy Builder (CTB) that allows submitting a set of seed terms for a given task or phenotype, edit the automatically-generated taxonomy, and download the custom-built UMLS-like files for use with MetaMap Lite or MetaMap.

Methods
CTB is implemented in Clojure and Java and uses the UMLS MRCONSO.RRF files restricted to level 0 for public use, as well as the lexical tools (LVG) to generate variants and synonyms for the user-submitted seed terms. For each seed term, the system extracts the sub-terms using a MetaMap-like tokenizer and searches its local UMLS index files for synonyms of each sub-term. Candidate terms are then constructed from recombination of the synonyms using one synonym from each sub-term and ordering sub-terms in the original seed-term order. Any UMLS strings matching the candidate terms are added to the candidate synonym set with associated synonyms grouped by concept. If no UMLS strings are found, the LVG’s fruitful variants are applied to each of the sub-terms and the intersection of the UMLS and LVG synonyms are then added to the candidate synonym set using a synthetic concept id.

Results
The online CTB version can be used to generate vocabularies in real time. The downloadable version can be installed on any operating system that supports Java. The GUI allows selecting or de-selecting whole or partial synonymy sets for a given term. The resulting files can be downloaded and used with MetaMap Lite or processed using the MetaMap Data File builder.

Conclusions
We present a publicly available tool that allows to easily build a UMLS-based custom vocabulary for downstream use with MetaMap Lite, MetaMap or similar tools. In the future, we plan to add an option for including WordNet synonymy in the custom-built vocabulary. CTB can be accessed at https://ii-public1.nlm.nih.gov/ctb

Improving the Quality of Clinical Data Extracted from Text

Daniel Denhalter, BS\textsuperscript{1,2}, Olga V Patterson, PhD\textsuperscript{1,2}, Brian Robison, MPH\textsuperscript{1}, Scott L DuVall, PhD\textsuperscript{1,2}

\textsuperscript{1}VA Salt Lake City Health Care System; \textsuperscript{2}University of Utah, Salt Lake City, UT

Abstract

Data quality has an impact on all potential uses of the data. Natural language processing (NLP) can be used to complement structured data and increase both completeness and correctness by adding data extracted from clinical notes and reports. However, data quality errors can be amplified when data entry errors are combined with data extraction errors. This poster reports on data quality improvement steps implemented to detect and filter out incorrect entries resulting from NLP extraction of variables from large note data sets.

Introduction

The Department of Veterans Affairs (VA) Informatics and Computing Infrastructure (VINCI) aims to improve access to VA data and to facilitate the analysis of that data. One of the most requested variables for research in heart disease is left ventricular ejection fraction (LVEF). LVEF is a measure of heart function and is expressed as the percentage of total blood volume pumped out of the heart with each beat. Only a small fraction of LVEF values are available as structured data in the VA electronic medical record system; the majority are recorded within notes and reports. To improve availability of LVEF data, VINCI has developed an NLP system to extract LVEF values from these clinical documents. The system was validated with average precision of over 98% across different document types.[1] While it is a respectable performance for an NLP tool, additional data cleaning was required.

Methods

LVEF values extracted from a comprehensive set of VA clinical documents were combined with available structured data to create a combined set of 49 million records for 3.4 million patients. The NLP output included LVEF values (which could include single measures or two measures defining a range) and the corresponding phrase from the source document. The initial step in the analysis was plotting the values as a normalized histogram binned into intervals based on the American College of Cardiology recommendations for heart failure diagnosis.[2] Values outside the range were flagged as potential data entry or data extraction errors.

A disproportionally large number of records (209 thousand) were found to be between 0 and 1, which is not a viable value for LVEF. Manual review of the source phrases for 1000 random instances indicated that in most cases, the LVEF value was represented as a decimal number rather than percent. In a small number of instances, the source phrases revealed extraction errors. These errors could be identified by mismatching units of measure mentioned in the source phrase, such as “cm” or “ms”, as well as the use of double zeroes, which often appear in eye exam results. For example, the term “EF” in a phase “EF -0.50-1.00” stands for “Eye Field”. Similar issues were found for values that were above 1, therefore, all values with mismatching unit of measure keywords or double zeroes in the source phrase were marked as erroneous. The rest of the values between 0 and 1 were accepted as true LVEF values and were multiplied by 100 to be consistent with percent values.

To inform the planned improvements of the NLP system, a review of 800 randomly selected instances greater than 100 was conducted. The most frequently occurring error was mistaking date for the upper boundary of a range. For example, “EF 55%-2000” should be interpreted as the value measured in 2000.

After all marked values were removed from the dataset and duplicate instances of the same values on the same day for the same patients were filtered out, the resulting dataset is made available to any VA affiliated researchers with appropriate access authorizations. While the erroneous values comprised less than 0.2% of all instances, they accounted for a large number of records (~78 thousand). The final set contains 35 million LVEF values for 3.4 million patients with the date when the value was recorded.

Conclusion

Ensuring data quality is a vital step in any study. By providing NLP extracted values and performing data cleaning on a common data set, VINCI has made a major step from facilitating access to data to providing previously inaccessible high quality variables to research groups.

Blockchain for Privacy and Security: The Case of Health Informatics

Gurpreet Dhillon, PhD1, Kane J. Smith, MSIS1, Monica C. Tremblay, PhD2

1Virginia Commonwealth University, Richmond, VA; 2Florida International University, Miami, FL

Abstract

Blockchain implementation in Health Informatics is a significant challenge in a rapidly changing era of privacy and security concerns. When dealing with such concerns, healthcare institutions are presented with a serious problem in how to manage it and where to allocate resources to maximize value. It is important to understand how organizations address these concerns by exploring blockchain implementation so it can be managed in the context of cybersecurity. To do this the problem question is twofold: First, what objectives are important based on the strategic values of an organization with regard to the implementation of blockchain technology. Second, how can these objectives be used to evaluate proposed solutions for blockchain implementation in electronic medical record systems in healthcare organizations. In this research we utilize Keeney’s value focused thinking to demonstrate how the process can occur to maximize value-add within healthcare organizations implementing blockchain technology to address security and privacy concerns with respect to patient data.

Introduction and Background

To handle patient concerns healthcare institutions are presented with a serious problem; how to manage security and privacy and how to maximize value in the application of technological solutions. Hence, it is important to understand how organizations address these concerns by exploring blockchain implementation so it can be managed in the context of cybersecurity. Numerous academic contributions exist regarding the application of blockchain in health informatics for solving privacy and security concerns in healthcare organizations. However, there is currently no research with respect to the actual decision making process such that an organization might best select an implementation strategy for blockchain to maximize its benefits. Hence, our research proposes such a model using Keeney’s Value Focused Thinking (VFT) to create a decision framework model that organizations can adapt for these own use-case and we demonstrate its application on the decision context.

Methodology

To ensure greater measures of protection from digital crime using blockchain technology, it is necessary to identify the fundamental objectives for implementing the technology in Health Informatics. This is where Keeney’s VFT for decision analysis can help create an objective-based framework for healthcare and related organizations to model the necessary objectives for preventing digital crime using blockchain technology. This model can then be used to assess alternatives for implementation and demonstrate gaps in all proposed solution’s performance relative to the objective’s goals which acts as quantitative metrics for comparison. This process occurs in five basic steps adapted from Keeney and Merrick et al. and derives its objectives either directly from literature and expert users of blockchain technology and health informatics, which are interviewed to elicit the objectives as well as the necessary importance and swing weights to fully build out the proposed model.

Conclusion

The investigation mixes qualitative and quantitative methods, value-focused thinking and multi-attribute utility modeling to reveal that an objective-based framework can be utilized to create the necessary model by which an organization can evaluate how to secure patient records using blockchain technology. This will provide a significant contribution as previous research in this area is under-developed and as such falls short of evaluating alternative solutions in the context of maximizing application value within an organization. Preliminary results clearly indicate that a feasible model can be built using decision analytic techniques like VFT to create useful models for healthcare organizations faced with the difficult task of integrating solutions to manage privacy and security concerns.

1991
The Development of the Research Precision Oncology Program Data Repository (PODR) in the Veterans Affairs Healthcare System

MAVERIC, VA Boston Healthcare System, Boston, MA

Abstract

The objective of the VA’s Precision Oncology Program Data Repository is to collect genomic, proteomic, and phenotypic data from multiple sources such as the EHR, Corporate Data Warehouse, patient reported outcomes, and medical imaging archives from consented participants. PODR is an essential part of the VA’s effort towards a Rapid Learning Health-care System. PODR’s data will be accessible to researchers external to the VA through the National Cancer Institute’s (NCI) Genomic Data Commons.

Introduction

Through the Precision Oncology Program, the VA started offering genomic analysis to patients with advanced stage solid tumors in 2015 as part of routine clinical care. Recognizing that the promise of genomic-driven cancer medicine remains limited given the many challenges such as unexplained drug resistance and diversity of tumor mutations; the Massachusetts Veterans Epidemiology Research and Information Center (MAVERIC) started the Research for the Precision Oncology Program (RePOP) in 2016 to acquire the knowledge necessary to improve the care for Veterans with cancer. Since genes with driver mutations tend to be rare and more likely to be discovered through large numbers of patients, MAVERIC established PODR with an additional goal of data sharing with the larger research community outside of the VA.

Overview of System

Eligible patients for RePOP are identified once tissue biopsy and genomic analysis have been performed successfully. Patients are screened further for eligibility with their physicians and then contacted by mail with information and an opt-out option. A research coordinator then contacts the patient by phone to provide additional scripted information about the research program and the different options of informed consent. Once consented for enrollment in RePOP, the participant’s longitudinal data are collected from various data sources and stored in PODR. A combination of natural language processing (NLP) and chart review are used to extract and validate unstructured data. For data sharing, data is assembled, deidentified, and mapped to the NCI’s Genomic Data Commons (GDC) data model and Common Data Elements. If a VA clinical data element is not currently defined in the GDC’s data dictionary, then it will be made available to external researchers as part of the GDC’s clinical supplemental file submission.

Results

There are currently 34 Veterans enrolled in RePOP with a 71% successful recruitment rate. 100% of recruited Veterans consented to sharing their data for research within the VA, 91% consented to sharing de-identified data outside of the VA, 97% consented to future contact, and 88% consented to all three options. There are 28 patients with lung cancer and 6 with other cancers. Of those enrolled, 94% had mutations annotated as “Genetic Alterations of Medical Importance”. Initial analysis of the GDC data dictionary against the clinical data of four enrolled patients estimates that 38% (14/37) of GDC clinical data elements are available in the VA as structured data (e.g. diagnosis), and 46% (17/37) of GDC data can be found in the VA as unstructured clinical text (e.g. tumor staging) which necessitate the development of NLP tools to improve the efficiency of the curation process.

Conclusion

The development of the VA’s PODR is an essential part of the VA’s long-term strategies toward a Rapid Learning Health-care System. PODR is being built to collect all longitudinal data relevant to the patient’s cancer, and various approaches are being explored to accommodate the growing clinical, genomic, proteomic, medical images, and patient generated data streams. A partnership has been established between NCI and VA to use the NCI’s Genomic Data Commons to break through the barriers of data sharing and accelerate the pace of new discoveries.
Reasons for Rework in Clinical Data Provisioning: A Root-Cause Analysis

Amanda L. Do, MPH\textsuperscript{1,2}, Ruby Y. Wan, MS\textsuperscript{1,2}, Robert W. Follett\textsuperscript{1,2}, Marianne Zachariah\textsuperscript{1,2}, and Douglas S. Bell MD, PhD\textsuperscript{1,2}

\textsuperscript{1}Department of Medicine, UCLA David Geffen School of Medicine, Los Angeles, CA, and \textsuperscript{2}UCLA Clinical & Translational Science Institute, Los Angeles, CA

Introduction

Secondary use of electronic health record (EHR) data in clinical research has become more prevalent with the deployment of large-scale EHR systems. Challenges frequently arise in repurposing clinical data for research, and many investigators are unable to relate their needs to the existing clinical data. The UCLA Clinical & Translational Science Institute’s (CTSI) Informatics Program (IP) has implemented, and continues to refine, a data provisioning service model, which includes consulting and programming services, to assist investigators in defining EHR data requests that address their research questions. However, investigators sometimes find that a dataset does not meet their needs only after it has been provided, which costs the IP additional time and resources to remedy. The IP seeks to understand the reasons for this kind of rework within the context of the honest broker program at the UCLA CTSI.

Methods

IP data consultants analyzed requests for data from UCLA’s Integrated Clinical and Research Data Repository (xDR), a clinical data warehouse of UCLA’s CareConnect (Epic) EHR data, linked with data from older legacy systems and other sources. Data requests were specified via a standardized template, with two components: 1) definition of patient selection criteria and 2) selection of demographics and output variables e.g. diagnoses, lab results, etc. Data requests were considered complete once all template variables were queried, exported, and delivered to investigators. Rework was defined as any instance in which the original query code was revisited and modified. To identify and evaluate rework, we reviewed all records from our project tracking system, which included consulting and programming notes, email correspondence, or additional files sent by the investigator. Based on our consulting experience, we generated 6 classifications for rework: data variables needed, selection criteria adjustment, data processing errors, newly available data, formatting (data analysis optimization), or miscommunication. We assigned any one or combination of the 6 reasons to each rework request.

Results

From March 2014 to February 2017, 33 requests (16.4%) for rework have occurred out of a total 201 completed data requests. 19 out of the 33 requests (57.6%) had only 1 cause for rework. The remaining 14 requests (42.4%) had more than 1 rework reason. Among the 14 requests were: 11 requests with two reasons, 2 with three reasons, and 1 with four reasons. Adjustment of patient selection criteria was the most common reason given by investigators for rework, accounting for 21 out of 51 reasons. Requests for additional data variables comprised 14 reasons.

Conclusion

Overall, most investigators were able to use the data provisioned through the UCLA CTSI IP service model without needing to request revisions. Most instances of rework were related to inadequate specification of the original data request and few reworks were due to external factors such as data processing errors. The root cause of most rework may be insufficient understanding of the nature of EHRs by the investigator. EHR data is not collected for research purposes and may be incomplete or inaccurate. In order to conserve IP resources, further efforts are needed to address these limitations and to aid in the planning of well-specified data requests that would not require subsequent adjustments in selection criteria or output variables.

\begin{table}[h]
\centering
\begin{tabular}{|l|l|l|}
\hline
Rework Reason & Example & Frequency* (%) \\
\hline
Adjustment to patient selection criteria & Implement less restrictive criteria to identify more patients for recruitment & 21 (41.18) \\
\hline
Additional data variables & Request for additional laboratory results or medication data & 14 (24.45) \\
\hline
Data processing errors & Omissions due to technical issues in extract, transfer, load (ETL) process & 6 (11.76) \\
\hline
Formatting & Request for procedure ID to be added to every file for easier merging across files & 6 (11.76) \\
\hline
Newly Available Data & Transplant Registry data became available in xDR & 3 (5.88) \\
\hline
Miscommunication & Variables were discussed but were never captured on template & 1 (1.96) \\
\hline
\end{tabular}
\caption{Rework Reason Examples and Frequencies}
\end{table}

*Frequency: counts are not distinct. Rework requests could be assigned more than 1 reason.
Physician Conception of Patient Frailty in Cardiac Care Decisions

Kristina Doing-Harris, PhD1; Rashmee U Shah, MD2; Yijun Shao, PhD4; Bruce E Bray, MD2,3; Qing Zeng-Treitler, PhD4; Jennifer H. Garvin, PhD, MBA3; Charlene Weir, PhD3,5

1 University Buffalo, Department of Biomedical Informatics; 2Division of Cardiovascular Medicine, 3Department of Biomedical Informatics University of Utah; 4Medical Informatics Center at George Washington University; 5VA Healthcare System, Salt Lake City, UT

Introduction: Patient frailty is an important indicator of patient outcomes.[1] Frailty commonly represents a complex clinical syndrome of increased vulnerability to stressors, which results from multiple impairments across different systems.[2] However, there are large variations in relevant impairments and idiosyncratic applications between physicians. Despite these differences, frailty judgments are especially important in making decisions about cardiac interventions such as coronary revascularization or aortic valve replacement by surgical vs transcatheter methods.[1] We have found in prior work that clinicians document functional status and frailty extensively in regular progress notes and clinical documents. Our project’s overall purpose is to transform the descriptive narrative found in clinical notes into a structured, scaled, inclusive variable. Generating this variable requires an operational definition of frailty related to cardiac care decisions. Once we have narrowed the definition, we will score the relevant indications, find them in patient records, and calculate patient frailty.

In this study, we use physician interviews to generate a conception of frailty as it relates to cardiac care decisions. We investigate physician perception and application of frailty measures in their decision-making.

Method: The physicians on the research team developed vignettes describing 7 complex cardiac cases. Each case included a mix of indications of patient frailty, e.g., difficulties performing their Activities of Daily Living (ADLs), older age, and a variety of chronic co-morbid conditions (cancer, diabetes, renal failure). Treatment options were coronary artery bypass surgery (CABG), coronary stenting (PCI), or medical management. We interviewed 5 physicians (4 cardiologists, 1 CT surgeon). In order to elicit the interviewee’s conception and use of frailty indicators in decision-making, we generated open-ended questions and encouraged as much elaboration as possible.

We asked: How frail is the patient? What indicates patient frailty? What is a successful outcome? What role frailty plays in that outcome? What decisions need to be made? What is your treatment decision? Is frailty a factor? Two investigators extracted indications about physician conceptualizations of frailty and its impact on treatment decision.

Results: Common frailty indicators included age, social support, lower body strength, hospitalization-related deconditioning, and mental status. A key decision point was whether, or not, a frailty indication could be relieved by revascularization or medical management; taking into account time since symptom onset, patient’s baseline functionality, and symptom’s relationship to cardiac impairment. A key decision point, unrelated to frailty, was tenability of CABG/PCI indicated by coronary anatomy and blockage location and chronic co-morbid conditions (cancer, diabetes, renal failure). Participants varied in their final decision (there was no right or wrong answer).

Table 1. Key quotes from 5 physician interviews.

<table>
<thead>
<tr>
<th>Quote</th>
</tr>
</thead>
<tbody>
<tr>
<td>“He could get through surgery. So I would offer it… would only mean 3-5 extra days in nursing home.”</td>
</tr>
<tr>
<td>“I would want… her co-morbidities, possible malignancy causing night sweats, before I made a decision”</td>
</tr>
<tr>
<td>“…would live longer with by-pass (traditionally)… multiple reasons [to] consider staged PCI”</td>
</tr>
<tr>
<td>“CABG produces the best result. So surgery would decide. Him recovering well is for them to figure out.”</td>
</tr>
</tbody>
</table>

Discussion: We found some agreement about relevant impairments overall. Our results indicate that the frailty indicators used in decision-making fell into 2 groups symptoms that can be fixed by surgery or cardiac procedures and indicators of patient’s ability to thrive post-surgery. Most seemed to take the opinion that surgery provided the best symptom resolution. Thus, they applied frailty assessment as it indicated surgical survival.

Heuristics for Evaluation of Dashboard Visualizations

Dawn W. Dowding, PhD, RN, FAAN\textsuperscript{1,2}, Jacqueline A. Merrill, PhD, MPH, RN, FAAN, FACMI\textsuperscript{1}

\textsuperscript{1}Columbia University School of Nursing, New York, NY; \textsuperscript{2}Visiting Nurse Service of New York, New York

Introduction

Heuristic evaluation is a common method used in human computer interaction (HCI) to assess the usability of a system.\textsuperscript{1} The heuristics commonly used in HCI design are based on usability principles originally identified by Nielsen\textsuperscript{2}, and expanded by Pierotti.\textsuperscript{3} Whilst these cover general design principles their utility for evaluating systems that provide visualized data is not well established. In order to conduct a heuristic evaluation of a point of care dashboard for home care nurses, which uses data visualization to summarize information alongside more traditional design principles, we developed and refined a tailored set of heuristics for visualized data.

Methods

Nominal group technique using online survey methods. We constructed a list of heuristic principles with associated usability factors combining general principles\textsuperscript{3} with principles and usability factors pertinent to information visualization systems.\textsuperscript{1} Specifically, the heuristics and associated criteria identified by Forsell and Johnson\textsuperscript{1} were extracted from the original papers. An online survey was used to distribute the list of principles and factors to 12 experts selected because they have published in the field of nursing or biomedical informatics and information visualization. They were asked to rate each factor on its importance as an evaluation heuristic for visualization systems on a scale from 1 (definitely don’t include) to 10 (definitely include). After reviewing the distribution of scores the researchers established a median score \( \geq 8 \) to represent consensus for an item to be included in the final checklist.

Results

10 individuals responded to the online survey. The initial checklist had 7 general usability principles with 36 usability factors (visibility of system status, match between system and the real world, user control and freedom, consistency and standards, recognition rather than recall, flexibility and efficiency of use, aesthetic and minimalist design) and 7 information visualization specific principles with 21 usability factors (spatial organization, information coding, orientation and help, data set reduction, flexibility, consistency, remove the extraneous (ink)). After analysis of consensus responses, a total of 49 usability factors had a median score of \( \geq 8 \). These were organized into the final version of the checklist consisting of 10 principles and 49 usability factors. Individual factors from the visualization specific principles concerned with flexibility (n=4) and removing the extraneous (n=2) were combined with general usability principles (40 factors). In addition 3 visualization specific principles, with 9 factors remained (spatial organization, information coding and orientation).

Conclusion

To heuristically evaluate the usability of information systems that use visualization strategies to summarize data, it is necessary to incorporate general heuristic principles and information visualization design principles. We have developed a checklist that can be used by experts to conduct heuristic evaluation of visualization systems. The checklist subsequently has been used to evaluate a dashboard for home care nurses to use at the point of care.

Curbside Consultation in the Virtual Healthcare Environment: Mixed Methods Analysis Occupational Medicine Teleconsultation in the Veterans Health Administration

Jennifer Lipkowitz Eaton, MD MPH FACOEM, Amir Mohammad, MD MPH FACOEM

1Occupational Health Services, Office of Patient Care Services, Veterans Health Administration, Washington DC; 2Department of Internal Medicine, VA Connecticut Healthcare System/Yale Occupational & Environmental Medicine, New Haven CT

Background:
In an increasingly virtual healthcare environment, the role of informal provider-to-provider consultation remains unclear. Electronic curbside consultation is an evolving mechanism to answer clinical questions and build provider relationships.

Objective/Purpose:
This quality improvement study describes and compares the characteristics of complex cases referred for two types of electronic curbside consultation in Occupational and Environmental Medicine (OEM). We explore variation in cases evaluated through (1) direct, informal email consults versus (2) a formal specialty tele-consultation program.

Methods:
This analysis uses mixed methods techniques to describe and analyze cases submitted for two types of virtual curbside consultation. The VHA OEMedicine tele-consult initiative is a National provider-to-provider specialty practice group. Web-based intake and tracking processes generate data for clinical quality improvement efforts. Fifteen months of consult requests submitted to a formal, curbside tele-consult program were screened, coded and analyzed (n = 114). The comparison sample was comprised direct email or telephone consults to individual specialty physicians who participate in an online OEM community of practice (N=43). These informal email consults were forwarded directly to the QI team. Two OEM specialty physicians coded significant co-morbid conditions based on free text comments. Coder inter-rater reliability was 83.6%.

Results:
Professional comparisons revealed that all independent provider types were more likely to consult the formal tele-medicine group than choose an informal electronic curbside. Physicians were most likely to contact physician colleagues for informal curbsides (35.2% of cases) compared to Nurse Practitioners (26.2%) and Physician Assistants (7.4%). In chi-square tests, the distribution of consults did not vary significantly by specific medical condition (e.g. Endocrine, Cardiovascular, Infectious). Multi-morbidity did appear to be associated with greater frequency of formal tele-consultation (p<0.005). Average consult duration was significantly longer for direct consults to individual providers (31.51 vs 43.75 minutes, p<0.05). This did not vary significantly by profession.

Conclusion:
Findings suggest that electronic curbside consultation preferences and behaviors likely vary by case complexity. Compared to informal contacts, formal tele-consultation may create more opportunities for case collaboration between physicians and non-physicians. The results of this study can be used to integrate opportunities for curbside consultation into clinical process and informatics supports.

Implementation of an Informatics Solution to Improve Management of Pathology Specimens for the VA Precision Oncology Program

Danne C. Elbers MS, Robert B. Hall MS, Beth J. Katcher BS, Svitlana diPietro BS, Sung Feng-Chi MS, Sergey D. Goryachev MS, Karen E. Pierce-Murray RN BA, Corri L. DeDomenico BS, Lauren MacMullen BS, Helene Garcon MD, Nhan V Do MD, Louis D. Fiore MD

MAVERIC, VA Boston Healthcare System, Boston, MA

Introduction
The Veteran Affairs (VA) Precision Oncology Program (POP) is a clinical care effort intended to bring personalized health care and cutting edge cancer treatment to Veterans by sequencing tumor samples. The program includes a research component (RePOP), which consents patients to share their clinical, genetic and imaging data. Program staff initially relied on MS Excel and InfoPath to handle the activities to identify patients diagnosed with cancer, track pathology samples with vendors, and enroll Veterans into the RePOP cohort. As the program expanded across the VA a more scalable informatics approach was required to better manage current and future functions of the POP program. To meet these requirements we developed a workflow software application in-house called ProjectFlow with the VA Informatics and Computing Infrastructure (VINCI) group to manage this and other research activities. For the implementation we created an integrated system consisting of a database model, web services, stored procedures, ETL’s and workflows adhering to the BPMN20 standard.

Business Requirements and Technical Development
A key requirement was to provide a solution for POP/RePOP activities that could manage the high volume of specimens and patients. Captured data needed to be available for reporting and analysis purposes. The program needed the ability to grow and evolve with new workflows, auditing and reporting needs that would develop as operations expanded. BPMN20 workflows were designed for the ProjectFlow application to capture the attributes associated with the clinical and research operations. To assist these workflows in their execution a relational database model was developed as well as stored procedures and a web service to validate ProjectFlow’s input before storing data through stored procedures in the database schema. We created a scheduled ETL that queries pathology electronic health records for VA Region 4 based on SNOMED and ICD codes and incorporated them into the POP database as a starting point for specimen identification.

System Deployment
The POP application was deployed in August of 2016. To date 1085 pathology specimens have been managed through the application among 55 sites. The approach incorporated structured data items and a SQL relational database schema to capture business processes which improved efficiency by reducing input errors and improving data management efforts. A wider array of reports and graphs has been generated from the POP data repository utilizing reporting services rather than relying on InfoPath features. These reports have been informative in directing operational improvements such as enhancements to specimen selection. Future plans involve the deployment of a RePOP workflow version (in development) and expansion of the ETL to query specimens beyond VA Region 4.

Conclusion
The development of the ProjectFlow application demonstrates how a structured Informatics solution can facilitate and improve business operations in the precision medicine arena. The application allowed our developers to streamline business operations for the POP program with less data errors and improved reporting and querying capabilities. Our workflow application provides a scalable approach that can handle a large number of pathology records and consents, and is extendible for modifications and additions. The team overcame challenges with incorporating VA pathology data and CDW patient records into the application. Our team continues to integrate with the POP operations staff to improve and develop novel ways to implement new workflows, integrate more VA healthcare data, and enhance system usability.

Title: Distributed Health Data Networks: A Rapid, Systematic Approach to Verifying Machine-Generated Queries Within Different Systems

Background: Distributed health data networks allow for participants to maintain ownership over their data and to run queries/programs in the privacy of their own data environments. Some networks, such as the PCORnet Distributed Research Network, utilize machine-generated queries powered by PopMedNet that may be difficult for a human to parse. PCORnet's queries are automatically translated and directed to various relational database management systems (RDBMSs) in order to accommodate a larger variety of participants in a more rapid fashion. This presents various challenges when testing queries to ensure they perform as expected within each unique data environment. We describe a rapid, systematic approach to verify the accuracy of queries within different environments.

Objective: Create and maintain a process that continuously verifies the accuracy of machine-generated SQL queries directed to different RDBMSs/IT environments within a distributed health data network.

Methods: The approach consists of five steps: (1) understanding the intent/expected behavior of a query based on the human-supplied query input information and the researcher's intent, (2) creating a variety of fake patient records that fall within and outside the query parameters, (3) use an open-source Test Case Inserter tool (TCI) to enter patients into six test databases across three different RDBMS platforms (SQL Server, Oracle, and PostgreSQL), (4) run the given query against all six data sources, (5) review results to ensure the query runs and returns the expected fake patient records.

Using the TCI allows for (2) and (3) to be performed in a reliable fashion by any person as long as they are familiar with the data model used by a given network. Fake patient records are entered by hand within Microsoft Excel sheets, which are consumed by the TCI. The TCI also consumes a separate Excel sheet defining the structure of the target data model. When records are entered into databases, the TCI will roll back all changes if any single insert fails. This provides reliability of data without the need for a SQL expert's direct involvement.

To simulate the variety of RDBMSs, tests are performed in two different versions of SQL Server, Oracle, and PostgreSQL each. This testing can be started and concluded in as quickly as one day, allowing for minimal delay between query design and distribution.

Findings: This testing process has successfully identified unexpected query behavior in various conditions, most of which are fairly complex involving joins with patient-record information across several tables, or utilizing different encounter time windows with different associated patient information within a single query. Unexpected query input information (or unexpected amounts of query information) can be a major contributor to errors in resulting query behavior, although this is partially avoided in PopMedNet due to standardization of query input information.

Conclusion: Rapid, accurate query verification is vital to accommodate the diverse, fast-paced nature of distributed health data networks. This novel testing approach is designed specifically for this fast-paced and occasionally unexpected nature. It is extensible and flexible so that it can be applied to any data model and any type of health data network.

1998
Leveraging an Enterprise Data Warehouse to Support Clinical Workflow: Targeted Notification of Pathology Results

Michael Eubank¹, Janice Sung, MD¹, Krishna Juluru, MD¹
¹ Memorial Sloan Kettering Cancer Center, New York, NY

Introduction
Radiologists perform biopsies that guide patient care. The resulting pathology report (PR) may take several days to complete, requiring frequent checks of the electronic medical record (EMR), a time consuming process prone to lapses. Timely communication of results is necessary to minimize patient anxiety and guide treatment decisions. Institutional Enterprise Data Warehouses (EDW) are typically used for operational data analytics, but some recent applications have shown value in clinical and research support (1,2). We hypothesized that our EDW infrastructure and underlying data could be used to develop an application that would deliver automated notifications of PRs to a radiologist who generated the radiology procedure report (RPR).

Methods
The application was built using IBM DB2, Java, and open source Jquery JavaScript library. In this retrospective study, we assessed application activity from December 1, 2015 to January 31, 2017. Radiologists and pathologists generated and signed RPRs and PRs, respectively, per routine. The EDW received date of procedure (from Radiology systems), date of specimen (from Pathology systems, distinct from date of PR), text of all reports, and names of all radiologist signatories (residents, fellows, and faculty) in the RPR. When date of procedure in the RPR equaled date of biopsy specimen in the PR, a match was identified, and the application sent an email notification to the radiologist(s), with link to PR. Usage data was obtained from the application. Clinical impact was assessed through an anonymous, online survey distributed in March, 2017 to all participating radiologists.

Evaluation
During the study period, 52 radiologists participated in the service. The application tracked 6,487 patients and delivered notifications involving 12,047 pathology specimens. The average time from radiology procedure to PR was 5.5 days. 100% of notifications were sent within 1 day of PR creation. 30 radiologists completed the online survey (30/52 = 58%). Radiologist subspecialties were breast imaging (67%), interventional radiology (17%), body imaging (16%). Survey respondents included radiology faculty (85%) and fellows (17%). To the question, “Automated pathology results helped me deliver better patient care,” 97% of respondents answered ‘Strongly agree’ or ‘Agree’, with an average time savings of 3 hours per week. To the question, “I plan to continue using the automated pathology results system,” 97% of respondents answered ‘Strongly agree’.

Conclusion
We demonstrate in this study one application of EDWs in near-real time clinical support. The system saves the Radiologist time by eliminating the need to regularly check for pathology results, and also enables Radiologists to act on and communicate results more quickly, thereby staying integral to patient care.

Visual Query Combinators for BioMedical Query Mediation
Clark Evans, Charles Tirrell, Oleksiy Golovko, Andrey Popp, Jason Simeone,
Kyrylo Simonov PhD, Leon Rozenblit JD, PhD
Prometheus Research, LLC, New Haven, CT

Introduction. Even as informaticists continue to deliver better and larger central data stores to support research, three important goals have remained out of reach for biomedical research teams: (1) the ability for all team members, including ones who are not database specialists, to proficiently explore data stores for information relevant to their research questions; (2) frictionless sharing of resulting queries to serve as documentation for further refinement and discussion; (3) deep integration of meaningful statistical analysis with the queries. Lacking these capabilities, research teams must involve database specialists to mediate even the most basic database queries and to periodically refresh results. We evaluate whether all three goals can be achieved, and the need for mediation reduced, through an innovative query system.

Innovation. Prometheus Research has designed a combinator-based database query model (“Rabbit”) [1] and released an open source implementation [2]. Rabbit is a practical, declarative query language designed for domain experts. Unlike SQL and LINQ, Rabbit’s model lends itself to dynamic, incremental, visual query construction. Moreover, the Rabbit query model flexibly accommodates all sorts of statistical and domain specific operators. Queries in Rabbit notation can be understood and shared among all research team members, reducing the need for upstream query mediation. We include a visual query tool based on Rabbit in our open source RexDB system [3].

Methods. To validate our claims about the completeness and learnability of this visual query system, we conducted usability tests on a convenience sample of participants that included experienced data analysts and novice users. Each subject was given an unfamiliar data model and 3 minutes to explore the query interface. Subjects then answered a series of challenging timed questions about the data. For example, subjects were asked to select a table, add a column from a related table, perform a maximum value aggregation on the related table, and filter the primary table records based on this aggregate value.

Results. Novice query users with no SQL experience were able to generate complex queries using our interface, including multi-table joins with aggregation, advanced filtering, and distinct operations. Novice query users were able to complete an average of 71% of the 15 assigned tasks in under three minutes. We found that moderately technical query users with minimal SQL experience were able to complete 93.3% of the assigned tasks in under three minutes. Exceeding our expectations, we found that novice users were only 53.5% slower, on average, than more experienced data analysts.

Conclusion. The preliminary results suggest that a combinator-based visual query builder can empower a broader range of users to retrieve complex data from rich data stores. We expect to demonstrate in future research that this approach also facilitates sharing and refinement of queries, as well as the integration of statistical procedures into the queries themselves. Because our implementation uses a statistical processing language, Julia, deep integration of querying with with statistical analysis is technically straightforward.

Clinician, EHR Alerts, and Patient Outcome in Primary Care Setting
Mohammad A. Faysel, PhD¹, Tameca Miller, MS¹
¹SUNY Downstate Medical Center, Brooklyn, New York

Introduction

The use of Clinical Decision Support (CDS) tools in primary care settings has been increasing dramatically in the recent years, especially in managing patients with chronic conditions. However, their impact on patient outcome has not been widely studied. The purpose of this retrospective study is to evaluate whether clinician’s acknowledgement and adherence to alerts generated by CDS tools that are embedded within the electronic health record (EHR) system improve the outcome of patients with chronic diabetes.

Methods

De-identified one month clinical data of elderly (65 or older) diabetes patients with hemoglobin A₁C (HbA₁C) ≥ 6.5 were extracted from the clinical database of a multispecialty outpatient clinic that also provides primary care services. For each of these patients, a CDS alert indicating elevated HbA₁C was generated that required primary care clinician’s attention and further clinical intervention(s). To comply with the widely used National Institute of Diabetes and Digestive and Kidney Disease (NIDDK) guidelines, the organization’s protocol requires repeating HbA₁C test every 3 months for diabetes patients and every 6 months for patients whose blood sugar is well controlled. We used patient records whose alerts were acknowledged, and the records with ignored alerts to verify whether the clinician’s acknowledgement to CDS generated alerts improves chronic diabetes patient outcome.

For the group whose alerts were acknowledged, we claimed that due to clinician’s acknowledgement of the alerts, average HbA₁C value after alerts would be improved (lowered) compared to the average of the last HbA₁C values prior to the alerts. Our null hypothesis for this case was that the average HbA₁C would remain unchanged or worsened (elevated) after clinicians’ acknowledgement of the alerts. A paired t-test was performed to verify our claim. For the records whose alerts were ignored, we also claimed that the average HbA₁C value after the alerts would be worsened (elevated) compared to the average of their last HbA₁C values prior to the alerts due to clinicians’ ignoring of the alerts. Our null hypothesis for this case was that the average HbA₁C would remain unchanged or improved (lowered) before and after the alerts. We performed a paired t-test to test to verify our claim for this group. All the data analyses were performed, and statistical values and 95% Confidence Intervals (CI) were generated using SAS 9.4 software.

Results

Out of total 264 alerts, 191 (72.3%) were acknowledged by clinicians and 73 (27.7%) were ignored. For the group whose alerts were acknowledged, the paired t test produced a t value of 2.9 with a probability value of 0.004 (p-value < 0.05) which is sufficient to reject the null hypothesis and supported our claim. It also generated an HbA₁C mean difference of 0.24 (95% CI, 0.08-0.41) between before and after acknowledgement of the alerts. For the group whose alerts were ignored, the paired t test produced a t value of 1.87 with a probability value of 0.07 (p-value > 0.05) which supported the null hypothesis for this group and rejected our claim that the average HbA₁C value of this group after the alert would be worsen (elevated) compared to the average of their last HbA₁C values prior to the alerts. This test also showed that the average HbA₁C improved (lowered by 0.17) after alerts compared to the average of the last HbA₁C values prior to alert (95% CI, -0.01-0.36).

Conclusion

The study showed improved average HbA₁C values for patients whose CDS generated alerts were acknowledged by their clinicians and the group of patients whose CDS generated alerts were ignored by their clinicians thereby, suggesting that clinicians’ acknowledgement and adherence to embedded CDS generated alerts for chronic diabetes patient management do not have any effect on improvement in patient outcome. This could be due to the study dataset’s lack of detail information on clinicians’ adherence to organizational protocols. Future steps of the study will address this issue and verify the study claims using larger datasets from multiple sources.

Using EHR Clinical Decision Support to Improve Emergency Department Care for Children with High Risk Asthma

Daria F. Ferro, MD¹, Levon Utidjian, MD¹, Joseph J. Zorc, MD¹
¹Children’s Hospital of Philadelphia, Philadelphia, PA

Introduction
Asthma is the most common chronic childhood illness and a leading cause of pediatric hospitalization. Although evidence suggests that intervention strategies such as preventive controller medications, asthma action plans, and community-based programs can improve outcomes, delivery in busy clinical settings has been challenging, and frequent asthma emergency department (ED) visits and hospitalizations remain a challenge. We sought to bundle clinical decision support (CDS) tools within our electronic health record (EHR) to identify at risk patients and provide clinical decision support to the healthcare team to deliver a multidisciplinary intervention in the ED setting.

Methods
This project was developed as part of a multi-disciplinary Asthma Population Health Initiative that has focused its initial efforts on identifying high risk patients in a variety of settings across a large pediatric care network. It has also included the development of a pediatric asthma registry using EHR data.

We aimed to improve care for pediatric patients with asthma who were seen in the ED and subsequently discharged home. A multidisciplinary team developed a group of CDS tools driven by criteria from the pediatric asthma registry. High risk patients were defined as having at least 2 prior admissions for asthma in the past year and presenting to the ED with a chief complaint of respiratory distress. Primary outcomes include: (1) increasing healthcare team awareness and education in the ED; (2) providing an asthma care plan in all patients with persistent asthma; (3) initiating inhaled corticosteroids (ICS) in patients with persistent asthma symptoms without a prior ICS prescription; and (4) referral to case management for assessment of need for community asthma resources.

The CDS bundle consisted of vendor native EHR tools such as pop-up alerts and dynamic order sets that encouraged providers to alert other members of the healthcare team (respiratory therapy, nursing, case management) about the patient’s high risk status. The CDS tools went through an iterative design process with clinical domain experts in multiple roles (physicians, nurses, respiratory therapists) and the CDS design committee. We adopted low cost techniques to accelerate the iterative process including close monitoring of CDS behavior and user actions, as well as user directed retrospective aided recall. With the latter, we showed users screenshots of CDS as they would have seen at the time of their interaction and conducted semi-structured interviews. The CDS was modified accordingly in response to feedback.

Results
Preliminary data of the ED asthma CDS bundle shows increases in education ordering suggesting increased team awareness (2% baseline to 20%), increased asthma care plan filing (4% baseline to 11%), and increased case management referrals (3% baseline to 80%). Prescriptions of inhaled corticosteroid has remained high. Qualitatively we have identified several aspects of CDS development and implementation in need of improvement such as the need for high fidelity testing environments and the importance of user feedback after initial implementation.

Discussion
Through this work we have learned that close monitoring of CDS performance and low cost solicitation of user feedback can lead to rapid iteration and optimization of CDS tools. These tools can be combined in effective ways to address complex pediatric patients, such as those with asthma, with complex care challenges in an ED setting. Further data will be presented as data collection is ongoing.
Honest Broker Process Using System-Wide Permanent Research Identifiers

Robert W. Follett\textsuperscript{1,2}, Theona T. Tacorda\textsuperscript{1,2}, Javier Sanz\textsuperscript{1,2}, and Douglas S. Bell MD, PhD\textsuperscript{1,2}

\textsuperscript{1}Department of Medicine, UCLA David Geffen School of Medicine, Los Angeles, CA, and \textsuperscript{2}UCLA Clinical & Translational Science Institute, Los Angeles, CA

Introduction

Healthcare institutions are increasingly providing electronic health record (EHR) data for research purposes. Data is typically provided to researchers through an honest broker process, which is intended to protect patient privacy. The honest broker process often involves generation of a study id, which enables linkage of patient records without using protected health information (PHI).

In many cases, researchers need only de-identified information, but they often also need to associate data from the same patients across multiple files as well as from subsequent data extracts for the same project. In other cases, researchers may need identified information in order to perform chart review but PHI must be kept to a minimum during the provisioning process. Conversely, across separate projects, patient identities must be protected such that records cannot be linked without specific IRB approval. However, following approval, it may be necessary for investigators to collaborate across different projects with little effort.

We designed an honest broker process that is flexible enough to allow for all of these scenarios. Investigators do not have to create their own study id, and can easily separate PHI from non-PHI.

Methods

We assign a permanent global research identifier for every UCLA patient during the extract, transform, and load (ETL) process into our data warehouse. We also maintain a table used to track each research project or data requisition request. In addition to a project id, brief description of the project, and key project personnel, the table contains an encryption key used to generate a study-specific patient ID (study id) by encrypting the global research ID as well as the encryption method used.

Using our system of encryption, we can generate the same study ids for the same patients in subsequent or supplemental data pulls for a given project, without revealing the underlying global research ID. This system also enables us to unencrypt a study id if re-identification of patients becomes necessary and is IRB-approved. Separately tracking the encryption method for each research project gives us the flexibility to use different encryption functions and methods as the technology available in our ecosystem evolves.

When provisioning identified information, we supply one table or file which contains all PHI and the study id. Each additional file contains the study id with non-identifiable data. The study id is the key to linking the files together. This isolation of PHI makes it easy for an investigator to de-identify their data after PHI is no longer needed. When provisioning de-identified information, we simply use the study id in all files.

Results

We began using this system of encrypted global unique identifiers in January 2016. We have used the ID encryption process to provision more than 307 million records across 38 separate projects to date. For three projects, we have pulled daily or weekly incremental data an additional 23 times. We have pulled supplemental data for an additional two projects. No projects to date have needed to re-identify the encrypted global unique patient IDs or to link them across different studies.

Conclusion

We have implemented a system of creating permanent global research identifiers for the UCLA patient population and for providing studies with encrypted versions of this identifier. We are using this system successfully to link patient identities across sequential data sets within studies. It will also enable patient linkage across studies, if needed.
Crowdsourcing Evidence-Based Medicine (EBM)

Paul Fontelo, MD, MPH; Fang Liu, MS
National Library of Medicine, Bethesda, MD

Abstract

We developed a new crowdsourcing method to search, review, and rate recent evidence from PubMed citations. It provides an open environment for users to not only discover and rate the usefulness of a citation, but also read relevant citations previously rated by other clinicians. This tool harnesses the wisdom of the crowd and may help healthcare professionals find high quality evidence from PubMed, more efficiently.

Introduction

Searching high quality relevant citations in PubMed sometimes is a challenge for healthcare professionals because of the huge number of citations retrieved for a specific topic and lack of enough time to review them. Previously, we developed Web tools and Apps, like PICO and askMEDLINE, for helping users build the search query. A rating citation tool has been implemented in several of our existing utilities to evaluate the efficiency of the search tool and the usefulness of the retrieved citation. An open rating system through crowdsourcing may further help healthcare professionals to obtain the high-quality citations from PubMed, more quickly.

Methods

The crowdsourcing evidence project is designed as a Web tool\(^1\). The search and review interface (Figure 1) allows the user to search using PICO or simply posing a question and limited to publication type (randomized controlled trials, systematic review, meta-analysis, etc.) through PubMed’s E-Utilities API. After reviewing individual citations, the user can rate the usefulness and rationale for the score using a 7-point Likert scale. Previous crowdsourced evidence may be reviewed by the Archives with a topic filter or a score filter (Figure 2). The most recent reviewed citations are also available for browsing.

![Figure 1.](image)

![Figure 2.](image)

Result and Conclusion

We built a crowdsourcing evidence system and invited several clinicians to test the tool. Early feedback is positive. Users have the option of finding and rating as many as they find useful or only those they deem as useful clinically. The tool may provide some practical clinical information for decision-making powered by the crowd.

Introduction: Pediatrics are particularly vulnerable to medication errors and incidents are all too common.\(^1\) Computerized Provider Order Entry (CPOE) with Clinical Decision Support (CDS) has been associated with a reduction in medication errors.\(^2\) However, some new types of errors have also emerged with the use of these systems. We performed a systematic literature review to identify and understand the factors that contribute to medication errors associated with the use of CPOE in pediatrics and provide recommendations for improvement.

Methods: Our review was conducted according to the PRISMA guidelines and was registered with PROSPERO (CRD42016039984). We included primary research studies published in English that discussed the types and/or causes of errors generated when using CPOE systems. The timeframe was not restricted. Non-peer-reviewed publications, editorials and commentaries were excluded. We searched three large databases, the Cumulative Index Nursing and Allied Health Literature, Embase and Medline using broad search terms related to ‘CPOE’, ‘Errors’ and ‘Pediatrics’. Three authors independently reviewed the titles; abstracts and full texts were then reviewed independently by two authors, with one acting as a constant. Data were extracted onto a data extraction sheet. We then developed a narrative synthesis of all eligible studies.

Results: We identified 414 papers of which 47 (44 full texts and 3 conference abstracts) published between 2004 and 2015 met our inclusion criteria. Table 1 outlines five key factors that contributed to the occurrence of medication errors made when using CPOE systems and potential recommendations.

<table>
<thead>
<tr>
<th>Key Factor</th>
<th>Example</th>
<th>Recommendations</th>
</tr>
</thead>
</table>
| Lack of drug dosing alerts          | • Failure to warn clinicians about errors because dosing support was not active.  
• Absence of patient weight in the system prevented safety checks. | • Utilize dosing support         
• Up-to-date weight should be obtained before alerting. |
| Generation of inappropriate dosing alerts | • Presentation of the maximum dosing alert only if the highest possible dose on the system was exceeded, regardless of the drug indication | • Indication based dosing decision support or order sentences |
| Inappropriate drug duplication alerts | • False-positive warnings due a lack of consideration of the route, drug name, strength or time of administration | • More sophisticated context-specific CDS. |
| Drop-down menu selection            | • 1000X overdose as a result of mis-selection from a drop-down menu       | • Indication included next to specific drug dose |
| Inappropriate system design         | • Lack of available dosing options on the system                         | • Evaluation of workflow         
• ‘Select all’ function in order sets | • Limited use of select all functionality                                 |

Table 1: summary of results and recommendations

Conclusions: This review outlines five key factors which contributed to the occurrence of medication errors associated with use of CPOE in pediatrics. The use of CDS, and design safeguards, are critically important.

Improving Ambulatory Care Patient Safety for Community Acquired Pneumonia through a New Electronic Clinical Decision Support

Maysoun Freij, PhD, MPH,1 Prashila Dullabh, MD,1 Richard Shiffman, MD, MCIS,2 Nitu Kashyap, MD,3 Rajdeep Brar, MD,2 Katherine Donaldson, MHI,1 Sarah Islam, MSPH,1 Richard Ricciardi, PHD, NP, FAANP, FAAN4

1NORC at the University of Chicago, Bethesda, MD, 2 Yale University, New Haven, CT, 3Yale New Haven Health System, New Haven, CT,
4Agency for Healthcare Research and Quality, Rockville, MD

Overview of Methodology

Inspired by the Agency for Healthcare Research and Quality’s (AHRQ) technical brief “Patient Safety in Ambulatory Settings”, and funding from AHRQ (contract HHSP233201500023I), the project specifically addresses the safety concern area of diagnostic errors in ambulatory settings through the use of health information technology (HIT). HIT provides several tools to improve patient safety, yet challenges to adoption in ambulatory settings prevent more widespread use. Therefore, investigators developed an electronic clinical decision support (CDS) tool for providers in the process of diagnosing the highly prevalent and sometimes catastrophic condition of community acquired pneumonia (CAP), and evaluate its implementation in two ambulatory care settings.

Investigators adapted the CURB-65 instrument for determining the severity of CAP into an electronic CDS based upon an analysis of the workflow in two ambulatory care practices: an emergency department (ED) and a primary care practice (PCP). The validated CURB-65 provides guidance in making an accurate CAP diagnosis and determining an appropriate treatment in outpatient or inpatient settings using five indicators: confusion, uremia, respiratory rate, blood pressure, and age 65 years or older. The workflow analysis in each setting led to two CDS designs: an interruptive alert for the ED, and a passive alert in the PCP. Prior to its implementation in each practice, the usability of the CDS was tested in a laboratory setting with nine providers; refinements were made to the design to clarify the necessary actions required of the user.

The CDS was implemented in the two settings from March-July 2017, and an evaluation was designed to assess successes and challenges with its implementation in the two real-world settings. Site visits were conducted in June 2017 to conduct interviews with providers about the design and utility; and the frequency of usage of the CDS was monitored throughout the pilot period. Investigators explored the extent to which the CDS was integrated into the practice’s workflow, and how usage varied across the two sites.

Evaluation Results

Based upon the qualitative interviews conducted four months post-implementation and data on CDS usage, the ED setting had much higher usage of the CDS than the primary care practice, and providers in this setting were much more accustomed to engaging with alerts in their practice than the primary care setting. Interviews suggest that changes to the sensitivity and contextual relevance of when and why the CDS is activated would improve its usability and ultimate utility to the providers. In addition, providers recommended removing the hard-stop interruptive alert, and making the valuable tool simply available on-demand.

Conclusion

While there may be validated diagnostic tools to improve patient safety, integrating them into EHRs in different types of ambulatory settings must take into account contextual differences in order to be effective. This project informs how diagnostic decision support tools can be leveraged as part of EHRs to make decisions that impact the disposition of patients with CAP.

Using Systems Engineering Methods to Identify, Assess, and Mitigate Preventable Harm as Part of a Patient Safety Learning Laboratory

Theresa E. Fuller¹, Anuj K. Dalal, MD¹,², Dominic J. Breuer, MS³, Pamela M. Neri, MS⁴, David W. Bates MD, MSc¹,², James C. Benneyan, PhDb

¹Brigham and Women’s Hospital, Boston, MA; ²Harvard Medical School, Boston, MA; ³Northeastern University’s Healthcare Systems Engineering Institute, Boston, MA; ⁴Partners Healthcare Information Systems, Boston, MA

Introduction: Adverse events are a significant burden on patients, families, and health systems¹. As part of a Patient Safety Learning Laboratory (PSLL), we are implementing an integrated suite of electronic patient- and provider-facing tools for the inpatient setting designed to identify, assess, and mitigate preventable harms in the acute care setting. This large and dynamic system combines myriad users, technologies, and environments, spanning multiple clinical services, and units. In this study, we describe the systems engineering methods employed during implementation of our tools that have allowed us to prospectively identify potential failures, and retrospectively learn from actual safety events.

Methods: We assembled a team of systems engineers, human factors experts, clinicians, and data analysts, who recommended two risk management methods: 1) prospective Failure Modes Effects Analysis (FMEA), and 2) retrospective Root Cause Analysis (RCA) assessments. In FMEA, potential failures were brainstormed according to the Systems Engineering Initiative for Patient Safety (SEIPS) domains² (users, technology, organizational, and environmental) with input from researchers, hospital administrators, clinical leadership, and unit staff in structured sessions. Failure modes were graded with Risk Priority Numbers (RPN), and then reviewed with the main research team. Event-based “RCA huddles” were structured to align with the operational work of the hospital. The team analyzed actual adverse events (Falls, Central-line Associate Blood Stream Infections) and risky states (e.g. “Code Status presumed”) through the lens of the PSLL tools. The information gathered and lessons learned from these risk assessments were used to inform how the tools could be refined to prevent failures.

Results: The primary results of the failure analysis are shown in Table One. From the initial FMEA, education and communication failures were identified as the primary targets for high impact improvement. From an event-based RCA (CLABSI), we determined that we would need to adjust dashboard logic to trigger a high-risk state for central lines in place for 7 days or more. Most importantly, risk assessment system allowed us to further engage end-users.

Conclusion: Structured risk assessments are proving an effective way to engage clinical and administrative staff while implementing our tools. Discussion with staff has promoted awareness, helping to resolve a potential failure mode (education/communication). Our experience to date underscores the value of using system engineering methods pragmatically during the implementation of new technology to improve patient safety in a hospital setting.

The presence of highly similar notes within the MIMIC-III dataset
Rodney A Gabriel, MD, Sanjeev Shenoy, MS, Tsung-Ting Kuo, PhD, Julian McAuley, PhD, Chun-Nan Hsu, PhD
University of California, San Diego, La Jolla, CA, USA

Introduction
With the advent of the electronic medical record system, there became a widespread presence of copy-and-pasting when composing clinical notes. Highly similar or even identical notes are problematic when one is compiling statistics or training predictive algorithms that model the language or attributes in notes. For example, duplicates may cause an outlier detection algorithm to erroneously identify a rare condition as being common or a predictive model may erroneously identify correlations between symptoms.

Methods
We sought to explore the presence of highly similar notes within the Multiparameter Intelligent Monitoring in Intensive Care (MIMIC-III) dataset.1 We used an approximation algorithm that minimizes pairwise comparisons and consists of three phases: 1) Minhashing2 with Locality Sensitive Hashing3. Minhashing was first used in the Alta Vista search engine to detect duplicate web pages scalable to the entire World Wide Web1; 2) a clustering method using tree-structured disjoint sets; and 3) classification of these highly similar notes via pairwise comparisons of notes in each cluster. We use Jaccard similarity (JS) to calculate the similarity between notes — in which all notes within a cluster has a JS above a certain threshold with at least one other note in that cluster. Classification of notes were grouped into three defined categories: 1) “exact copies” – defined as notes that have a JS of 1.0 and are for the same patient with an identical date stamp; 2) “common output notes” – defined as notes that have a JS of 1.0 but are for different patients and/or different date stamps; and 3) “template” – defined as notes with JS greater than or equal to 0.7. We explored all clinical notes with greater than 10 words from MIMIC-III. To validate results, the JS of 10 million random pairs of notes from MIMIC III were calculated. All pairs generated with JS >0.3 were then checked to see if they were either correctly or incorrectly placed in the same cluster.

Results
First, we tested the algorithm on a sample set consisting of 500 notes, in which 54 were considered near-duplicates or duplicates with at least one other note. Our algorithm correctly clustered 94% of the notes and provided no false positives. We then explored 2,065,096 notes from MIMIC III and identified 110,029 clusters of notes with high similarity (JS greater than or equal to 0.7). Among these clusters, there were a total of 310,227 notes. Validation results demonstrated that there was only 1 note pair out of 291 random pairs that was incorrectly clustered while 99% of random pairs (110 out of 111) with JS >=0.7 were appropriately placed in a cluster. Of all the notes, 61,672 were exact copies, 26,403 were common output notes, and 222,152 were templates. Fifty random clusters were selected and upon review of those notes, there was 100% agreement between manual review and assignment from our algorithm.

Conclusion
We found that there were multiple instances of exact copies, common outputs, and template notes form the public domain MIMIC-III dataset. It is unclear for the reasons of highly similar notes, but this could be related to pervasive practice of copy-and-pasting, note template utilization, common outputted notes from automated machines, and technical errors in note processing. The identified clusters will be made available for public knowledge and research efforts.

Feasibility of State Public Health Agencies Linking National Program of Cancer Registries and Birth Certificate Data: Outcomes and Lessons Learned

Roland E. Gamache, PhD MBA1, Timothy Jay Carney, PhD MPH MBA2, Mary Ann Cooney, MPH MSN2, Emily Moore, MPH2

1 Gamache Consulting, Rockville, MD, USA; 2Association of State and Territorial Health Officials, Arlington, VA, USA

Introduction

This pilot project will assess the feasibility of linking data from cancer registries and vital records systems to answer questions about birth outcomes for cancer survivors, as there have been limited studies on this subject.1,2 State public health agencies support many information systems to collect, store, and manage critical information on the health of the communities and populations they serve. These information systems are often siloed in different registries, dedicated to meeting the specific needs of particular programs and diseases. This project is a collaboration between three states, the Association of State and Territorial Health Officials (ASTHO), and the Centers for Disease Control and Prevention (CDC).

Methodology

Three states participating in this pilot project will link previously collected National Program of Cancer Registry (NPCR) data of female residents diagnosed with a reportable cancer between the ages of 0 – 20 years with the birth certificate files of those women’s subsequent children born in the same state using a probabilistic approach. In each state, a comparison group of female non-cancer survivors with a live birth will also be selected. The linkage protocol will utilize the Link Plus, a probabilistic linkage program developed by CDC, to perform the linkages.3 Manual review and Lexus-Nexus Accurint software will help determine true matches.

Results

Results from this project will yield information on the utility of the protocol, threshold values for the linking algorithm, and a longitudinal assessment of the quality of the matching variables over a fifteen-year period. Additionally, the number of links and the frequency of missing values will be evaluated. Furthermore, we will assess the quality and representativeness of maternal and infant outcome data of the cancer survivors. Table 1 represents data for each of the three states and the number of potential comparisons.

Table 1. Number of Potential Comparisons

<td>113,489</td>
<td>114,375</td>
<td>114,465</td>
<td>1,945,899</td>
</tr>
</tbody>
</table>

Conclusion

Lessons learned about the feasibility of this type of linkages will inform future public health surveillance programs. Further, this pilot project enhances the field’s understanding of maternal cancer on birth outcomes. Moving toward interoperable data that can be exchanged and linked across systems has the potential to provide more complete views of population health while leveraging the strengths and infrastructure of existing systems.

An Exploratory Study of Older Adults’ Strengths, Needs, and Outcomes Using Electronic Health Record Data in a Senior Living Community

Grace Gao, DNP, RN-BC, Madeleine Kerr, PhD, RN, Ruth Lindquist, PhD, RN, FAAN, Chih-Lin Chi, PhD, MBA, Karen A. Monsen, PhD, RN, FAAN
School of Nursing, University of Minnesota, Minneapolis, MN, USA

Problem
Living well with chronic conditions is a goal for the growing aging population. The Institute of Medicine describes the concept of living well as an achievable healthy state characterized by optimum physical, mental, and social wellbeing. The predominant problem-oriented health care infrastructure, however, creates a data gap related to the documentation of individuals’ strengths and wellbeing in electronic health records (EHRs). Without adequate data to describe a comprehensive assessment of an individual’s health, there is a lack of necessary information to generate integrated knowledge and incorporate person-centered wisdom into practice. Studies are needed to describe whole-person knowledge representation that communicates not only older adults’ problems/needs, but also their strengths; and to explore associations with health care interventions and outcomes, toward bridging the data gap that persists in problem-oriented clinical practice and documentation.

Purpose/Aims
The purpose of this study is to describe and compare strengths and needs of older adults, interventions they receive, and related Knowledge, Behavior, and Status (KBS) outcomes documented by the standardized terminology, the Omaha System, using the EHR data in a senior living community to inform care practice and documentation. The aims of this study are to (1) describe the strengths and needs of residents, nursing interventions they receive, and their initial and final KBS outcome scores in the EHR dataset; (2) examine the relationships among residents’ strengths, needs, and the interventions they receive; and (3) explore the relationships among residents’ strengths and needs, and their KBS outcomes.

Methodology
This study employs a descriptive, comparative design using existing EHR data generated from multiple facilities of a senior living community in a Midwest metropolitan area. A convenience sample comprises de-identified data from documentation of strengths, needs, interventions, and outcomes for over 900 assisted living residents. Descriptive statistics will be used to summarize strength and need attributes, interventions, and KBS outcomes. The sample will be split between those with a higher vs. lower proportion of strengths to needs. Inferential statistics will be used to compare interventions and KBS outcomes between the higher strength group and the lower strength group.

Results
Preliminary results demonstrate that it is feasible to collect comprehensive holistic data using the Omaha System as a framework for strengths, needs, interventions, and outcomes. Final results about residents’ strengths and needs attributes, relationships among strengths, needs, and interventions, and relationships among strengths, needs, and KBS outcomes associated with the three research aims will be reported in the poster.

Conclusion
The study will discover new knowledge regarding relationships among strengths, needs, interventions and outcomes of older adults and create a platform for further research use of a whole-person, strength-based ontology to expand beyond a problem-oriented information structure in practice and documentation.

Leveraging Crowdsourcing to Help Classify Social Media Data for Medical and Patient Safety Insights

Alex Gartland¹, Arooj Akhtar, PharmD, MBS², Richard Le¹,2, Greg E. Powell, PharmD, MBA³
¹University of North Carolina at Chapel Hill, Chapel Hill, NC; ²ZeroChaos, Orlando, FL; ³GlaxoSmithKline, Research Triangle Park, NC

Abstract
Classifying social media data for insights is time consuming and costly. This research evaluates whether crowdsourcing, via Amazon Mechanical Turk (MTurk) can be used as a platform to accurately and efficiently classify basic content in social media posts. We concluded that crowdsourcing is a cost effective and efficient method for classifying basic social media content which allows trained drug safety experts to focus on assessing social media data for medical and patient safety insights.

Introduction
The classification/curation of social media data for use in drug safety is both time consuming and costly. This research aims to demonstrate how crowdsourcing can be used to accurately and efficiently classify social media data, potentially reducing associated cost, allowing trained drug safety experts to focus their time and expertise on assessing social media data.

Materials and Methods
A dataset consisting of 15,000 uniquely authored social media posts was previously curated by GlaxoSmithKline drug safety professionals and served as the gold standard for comparing crowdsourced classifications. Amazon Mechanical Turk (MTurk) was chosen to crowdsource basic classification of social media posts using the gold standard dataset. The intent was to measure cost, accuracy and time (Phase one) and quality and time (Phase two). Phase one, consisting of three identical batches of 500 randomly selected posts, was tested at three variable price points -- $0.03, $0.03 with a $1.00 bonus per 50 posts, and $0.05. Each post was worked upon by three unique MTurk workers (Turkers) and compared to the gold standard using a majority voting system. Phase two consisted of 5,000 randomly selected posts where each post was reviewed by one Turker and then compared to the gold standard. To help ensure quality we implemented measures to detect (e.g. use of bots) and then applied an accept/reject system to posts completed by Turkers.

Results
The results from Phase one yielded an overall percent accuracy with the gold standard as follows: 92.7% for the $0.03 batch, 92.7% for the $0.03 batch with a bonus, and 92.4% for the $0.05 batch. All three batches were completed, reviewed, and accepted/rejected within approximately 72 hours of posting. Phase two took less than 48 hours and had an overall percent accuracy of 91.6%.

Discussion
These results show that the average Turker can review and classify social media posts for poster type and other basic content of interest with over 90% accuracy as compared to a trained drug safety expert at a fraction of the cost. Additionally, it was found that there was no substantial difference in accuracy when considering the compensation rate for an assignment. Additional research is required to further assess the value of using crowdsourcing to evaluate various social media types (images, video, etc.) and to perform more advanced classification/curation for the purpose of obtaining drug development and safety insights.

Conclusion
Crowdsourcing is a cost effective and efficient method for classifying basic information contained in social media posts which allows trained drug safety experts to focus their time and expertise on assessing social media data for medical and patient safety insights.
Clinicians’ Perceptions of Usefulness of the PubMed4Hh App for Clinical Decision-Making at the Point of Care

Kyungsook Gartrell, RN, PhD1, 2, Caitlin W. Brennan, PhD, APRN2, Fang Liu1 MS, Gwyneth R. Wallen, RN, PhD2, Paul Fontelo, MD, MPH1
1National Library of Medicine, Bethesda, Maryland; 2National Institutes of Health/Clinical Center Nursing Department, Bethesda, Maryland

Introduction

Evidence-based practice in healthcare has been facilitated by ubiquitous wireless mobile devices. Access to online health information affects clinicians’ decision-making, through improvement in knowledge. Point of care decision support tools provide clinicians with useful information in a timely manner for informing patient care and improving patient-physician communication. However, research evidence is still lacking on the effectiveness of clinical decision support for clinicians at the point of care.

PubMed4Hh is a Web app as well as an app for iOS and Android devices from the National Library Medicine (NLM) for finding relevant health information from biomedical literature. The purpose of this study was to explore how evidence provided as abstracts and the bottom-line (TBL) summaries, accessed with mobile devices in wireless network, affects clinical decision-making at the point of care.

Methods

This pilot study was conducted at the National Institutes of Health Clinical Center (NIH CC) from February 2016 to January 2017 as a collaboration between the Lister Hill National Center for Biomedical Communications, NLM and the NIH CC Nursing Department. The original PubMed4Hh website was modified to include features which highlighted key terms, as well as an online survey questionnaire for clinicians to rate the usefulness of abstracts and TBLs. NIH clinicians’ group e-mail distribution lists were used to send invitations and reminders to participate in the study. Participants were instructed on how to search and were asked 1) to rate the usefulness of retrieved TBLs and abstracts, 2) the reason of scoring on a 7-point Likert scale for the usefulness rating, and 3) the location of use of the PubMed4Hh (e.g., point of care or office). The three questions were collected anonymously and archived on a server at the NLM. The study was approved by the Office of Human Subjects Research Protections of the NIH and exempted from full Institutional Review Board review.

Results

Study participants reviewed 34 abstracts and 40 TBLs. Ninety-nine percent (73/74) of scores were based on the review of only one citation. The overall usefulness Likert score (1=the least useful, 7=the most useful) was 6.00±1.15, and there was a statistically significant difference in mean scores for abstracts (6.38±0.74) and TBLs (5.68±1.33): t (62.76) = -2.88, p=0.005. The Likert scale mode for abstracts and TBLs were both ‘7’ (18/34=52.9% for abstracts and 13/40=32.5% for TBLs). Eighty-nine percent (66/74) of usefulness reviews provided rationales for the rating Likert score. The most frequent reason (27.3%) was that it confirmed current or tentative diagnostic or treatment plan, followed by ‘led to new diagnostic skill, additional test, new management’ (21.2%), then ‘modified clinical skill, test, or treatment plan’ (13.6%). There was no difference between abstract and TBLs for providing the rationale of usefulness. Also, there was no statistically significant difference in usefulness scores among three reasons (confirmed, led, and modified). More than half of abstracts or TBLs were used at the office (n=36, 58.9%) compared at the point of care (n=20, 35.7%). The TBLs were used more in the office (n=23, 79.3%), and abstracts were used more at point of care (n=14, 51.9%): p=0.031. There was a statistically significant difference in usefulness mean scores for point of care (6.55±0.76) versus the office (5.75±1.30): t (54) = 2.56, p=0.015.

Conclusion

Our results show that retrieving relevant health information from biomedical literature using PubMed4Hh may be useful for decision-making. In this study with clinicians’, information access at the office was higher (79.3%) than at the point of care. Abstracts were used more often but not significantly and no significant difference was found in the rationale for scoring the evidence (confirmed, led, and modified) although participants seemed to favor “confirm” more.
Clinical Information Displays in the Emergency Department:
Evaluation of Cognitive Support to Improve Patient Safety

Carolina Gatica, RN1, Carolina Diaz, RN1, Juan Pablo Salazar, MD2, Po-Yin Yen, RN, PhD3, Mario Barbé, MD4, Marcelo Lopetegui, MD, MS3,4
1Departamento de Enfermería, Clínica Alemana de Santiago, Chile; 2Departamento de Urgencia, Facultad de Medicina Clínica Alemana Universidad del Desarrollo, Chile; 3Department of Biomedical Informatics, The Ohio State University, OH, USA; 4Departamento de Informática Biomédica / Centro de Innovación e Investigación en Informática Biomédica, Facultad de Medicina Clínica Alemana Universidad del Desarrollo, Chile

Introduction. Electronic health records (EHR) have the potential to improve quality and patient safety by serving as a ubiquitous source of reliable information. Clinical dashboards are being incorporated within EHRs aiming at improving cognitive support (providing the right information, in the right format, when and where required)1. However, previous studies have reported that, despite the use of EHRs, information gaps still exist, mainly due to difficulty accessing the information1. Several efforts have been made to improve usability and workflow integration of these systems to achieve effective cognitive support. However, unlike the ability of immediately reviewing data from paper charts, clinicians must securely access the electronic health records, for a single patient at the time, and often share limited workstations.

We hypothesize that the continuous availability of timely relevant information to nurses in the emergency department could fill information gaps, resulting in a safer healthcare. This poster will present initial assessments of the pilot phase for a study that aims to test this hypothesis on a large academic hospital in Chile. We present the development of clinical information displays that integrate to our existing EHR, which provide relevant information, alerts and reminders.

Methods. Following a user-centered design process, we iteratively worked with clinical staff to identify opportunities to improve patient safety given the appropriate cognitive support were provided. Three themes emerged: frequency of vital signs measurements, assessment of patient’s risk of falling, and awareness of allergies. We defined the context of use for each intervention, designed the components for the application and evaluated accordingly. We developed a web-application optimized for tablet computers that integrated with our home-grown EHR to retrieve real-time clinical information. Only non-sensitive information was made available in the information display modules.

In this pilot, we evaluated the impact of the intervention on adherence to evidence-based nursing protocols in the emergency department (which regulate the minimum frequency of vital signs assessments) and awareness of allergies, thus aiming at improving patient safety. Due to the nature of the pilot phase, only four tablets were installed: each one outside a given room, right by the door; other rooms were not intervened. Clinical staff including nurses and nurse assistants were trained in group regarding relevant functionalities. A visual and audible alarm triggered on the app every time vital signs expired for a patient, which is variable depending on their pain levels: 60 min for 0-2/10, 30 min for 3-6/10, 15 min for 7-10/10. In order to consider repeated observations, we used mixed models with random effects, adjusting for triage.

Results. Three weeks of preliminary data were analyzed. Frequency of vital signs measurements were compared for patients in a room with tablet against patients in rooms without tablet (excluding patients who switched from a room with tablet to a room without tablet and vice-versa). Considering only measurements that did not meet the required minimum interval, those in rooms with a tablet had vital signs taken 7.2 minutes earlier than those without, adjusting for triage.

Discussion. We present an early prototype of the application with positive preliminary results. Ongoing assessment of new modules will be presented in a future report, including a perception of usefulness and acceptability, and analysis of six months of data to address potential Hawthorne effect and to evaluate alert fatigue.

A Flexible Computational Neuroinformatics Workflow for Computing Functional Networks in Epilepsy Neurological Disorder

Arthur L. Gershon, Ph.D.¹; Bilal Zonjy, M.D.²; Curtis Tatsuoka, Ph.D.²; Kaushik Ghosh, Ph.D.³; Samden D. Lhatoo, M.D.²; Satya S. Sahoo, Ph.D.¹

¹Department of Population & Quantitative Health Sciences, School of Medicine, Case Western Reserve University, Cleveland, OH; ²Department of Neurology, School of Medicine, Case Western Reserve University, Cleveland, OH; ³Department of Mathematical Sciences, College of Sciences, University of Nevada Las Vegas, Las Vegas, NV

Introduction & Motivation. The derivation of brain connectivity measures is essential to understand cranial function & neural circuit formation, and how these change via natural aging or traumatic disorders. Epilepsy is a neurological disorder affecting more than 50 million people with seizures. Epileptic seizure events form intracranial functional networks, and accurate spatial/temporal classification of these is critical for pre-surgical evaluation of patients not responsive to anti-epileptic medication. There are, however, challenges with studying functional connectivity in epilepsy, including handling large data volumes, & modeling/storing/analyzing complex data.

We describe the creation of a novel signal data format called Cloudwave Signal Format (CSF) featuring: (1) support for ontological annotation, (2) adaptability for use with distributed file systems such as the Hadoop Distributed File System (HDFS), and (3) ability to retrieve channel-specific signal data segments for time-series analysis. The effectiveness of this new format is shown by its use within a flexible & scalable neuroinformatics computational workflow for quantitatively measuring functional connections in epileptic events. The workflow and associated computational libraries are being developed as part of the National Science Foundation (NSF)-funded Advanced Computational Neuroscience Network (ACNN).

Computational Workflow & Cloudwave Signal Format. At present, electroencephalograph (EEG) recordings of epileptic activity are stored in the European Data Format (EDF) [1]. Although EDF supports the storage of large volume of signal data in a single file, it has drawbacks, such as limited support for parallel processing and methods of storing data in such a way as to obstruct time series analyses necessary for determining connectivity.

To address these and other limitations of the EDF format, we developed CSF, and showed its compatibility with the Hadoop parallel computing technology stack over a 31-node computing cluster [2]. The first step of our workflow converts given EDF files to a collection of CSF files per user options, and reorients data values as time series.

Using the resulting CSF files, the pipeline applies user-specified correlation measures to pairs of signals input by the user as active in an epileptic event. At present, we are implementing three correlation measures to derive functional connectivity: (1) Pearson’s linear regression coefficient [3], (2) a non-linear regression coefficient by Pijn [4], and (3) a (non-linear) frequency-based measure known as mean phase coherence [5]. We compute matrices from these measures that are, after applying normalization to identify statistically significant connections, used to create network graphs that can be analyzed for patterns.

Conclusion. We describe a scalable computational neuroinformatics workflow based on a novel CSF data format for electrophysiological signal data, which we are using to derive brain functional connectivity measures in epilepsy.

A Data-driven Method for the Early Identification of Diabetes and Prediabetes

Travis R. Goodwin, MS\textsuperscript{1}, Michael E. Bowen, MD, MPH, MSCS\textsuperscript{2}, Sanda M. Harabagiu, PhD\textsuperscript{1}

\textsuperscript{1}The University of Texas at Dallas, Richardson, TX; \textsuperscript{2}The University of Texas Southwestern Medical Center, Dallas, TX

Introduction

Type-II diabetes is projected to affect as many as one in three adults by 2050 in the United States\textsuperscript{1}. This is exacerbated by the fact that an estimated 8 million people with diabetes and 80 million people with prediabetes remain undiagnosed or unaware of their conditions\textsuperscript{1}, despite the prevalence of well-established diabetes screening criteria. To improve the early detection of individuals at risk for diabetes and prediabetes, we present a data-driven method that automatically infers a patient’s risk for diabetes/prediabetes at any arbitrary time in the patient’s future without relying on pre-specified criteria. Our method jointly learns how to (1) cluster patients into an optimal set of latent sub-populations based on patient’s diabetes trajectories and (2) infer a personalized predictive model of diabetes/prediabetes risk for each latent sub-population.

Methods

The data-driven model was trained using a cohort of 974 patients from the MIMIC-III clinical care database who were eventually coded with an ICD-9 code indicating type-II diabetes (i.e., 250.00). Every patient \(n \in [1, N]\) was associated with a contiguous sequence of \(T_n\) dates in which the patient had recorded laboratory tests. Each date \(t \in [1, T^n]\) was associated with (1) the set of all laboratory tests and values recorded on that date, \(L_n^t\), (2) the diabetes status of the patient, \(D_n^t\), and (3) the elapsed time \(e_n^t\) between date \(t\) and the previous date, \(t−1\). The patient’s diabetes and prediabetes status was determined using HbA\textsubscript{1C} as the criterion; as in Bowen et al. (2015)\textsuperscript{1}, diabetes was determined as an HbA\textsubscript{1C} $\geq 6.5\%$ and prediabetes as $5.7\% \leq$ HbA\textsubscript{1C} $< 6.5\%$. We implemented the predictive models associated with each latent sub-population using gradient boosting machines. The model, illustrated in Figure 1 and extended from Goodwin and Harabagiu (2015)\textsuperscript{2}, considers \(V\) as the total number of laboratory tests recorded in the database, and learns (1) the optimal assignment \(z^{*}\) of all \(N\) patients into a given number of latent sub-populations and (2) a (different) set of optimal weights for every laboratory test for the predictive models associated with each latent sub-population.

Results

We evaluated the performance of our model using 5-fold cross validation in two experimental settings: predicting (1) the patient’s HbA\textsubscript{1C} or (2) whether the patient is at risk for developing diabetes/prediabetes. In both cases, for every date \(t\) associated with every patient \(n\), we compared the predictions produced by the model given \(L_n^t\) and \(e_n^{t+1}\) against the laboratory values or diabetes status at date \((t+1)\). In all experiments, we found considering $> 8$ latent sub-populations provided no significant improvements. To assess the model’s ability to predict a patient’s HbA\textsubscript{1C}, we computed the Mean Absolute Error (MAE) between the percentage predicted by the model and the HbA\textsubscript{1C} recorded in the patient’s labs and found that, on average, the percentage predicted by the model differed from the HbA\textsubscript{1C} test by 0.73 of a percent. The model’s ability to predict diabetes/prediabetes risk was assessed as a multi-class classification problem, and measured using Precision, Sensitivity/Recall, and $F_1$-measure. Table 1 illustrates these results.

Conclusions

The ability to discover latent patient populations positively impacts the quality of the prediction results, both in terms of diabetes/prediabetes and HbA\textsubscript{1C}, leading to potentially improved screening and identification of patients with undiagnosed diabetes/prediabetes. Continued study is needed to identify the characteristics of the latent sub-populations inferred by the model to provide new perspectives on early identification of diabetes and prediabetes.

Vitals Risk Index: A Simplified Pediatric Early Warning Index that Relies Solely on Objective Measures

Tyler Gorham, PhD1, Steve Rust, PhD1, Jing Yang, MS1, James Lin1,2, Richard Hoyt1, Swan Bee Liu, MS1, Jeffrey Hoffman, MD1, Tensing Maa, MD1, Yungui Huang, PhD1, Simon Lin, MD, MBA1

1The Research Institute at Nationwide Children’s Hospital, Columbus, OH; 2Ohio State University College of Medicine, Columbus, OH

Introduction

Delayed intervention for deteriorating pediatric ward patients increases morbidity and mortality. Several pediatric early warning systems (PEWS) that reflect patient condition have been in existence for decades. At Nationwide Children’s Hospital (NCH), Monaghan’s PEWS is utilized to evaluate floor patients and determine the need for assessment and consultation by the ICU to reduce the likelihood of cardiopulmonary emergencies (Code Blue). The PEWS scoring system requires subjective assessment by caregivers at least once every four hours, a frequency that can be burdensome to hospital staff. Moreover, many likely preventable Code Blue events still occur despite use of the PEWS to initiate preventive measures. In this study, we sought to develop a completely objective, automated real-time risk stratification model based only on vital sign measures to preemptively identify pediatric inpatients with a high risk for Code Blue events.

Methods

EHR records for the time period between 1/1/2011 and 11/30/2016 were retrospectively reviewed. During this period, NCH had 260 pediatric encounters involving Code Blue events on the inpatient wards. The rest of 84,748 pediatric inpatient encounters were classified as controls. This data was split into two datasets, one for model development and one for model testing. All the encounters with admission dates before 2015 were employed to develop a weighted logistic regression model. The independent model variables (heart rate, O2 flow rate, O2 saturation, respiratory rate, systolic blood pressure, and temperature) were selected and the associated clinical values were converted into scores of 0, 1 or 2 based upon the deviation from the normal range suggested by the clinical experts. During model training, model stability was assessed by repeated 10-fold cross-validation. The risk score generated from the model was translated into a Vitals Risk Index (VRI) with the range from 0 to 100. Model performance was characterized on the held-out testing dataset.

Results

This testing set consisted of 63 code events, which happened outside of ICU unit, and 22,826 controls. For the test data, the VRI achieved 81.0% area under the receiver-operator characteristic (ROC) curve (AUC), and 54.0% true positive rate and 7.8% false positive rate for a VRI threshold of 42.3. Evaluated on the same test dataset, PEWS has a 73.3% AUC, and true positive rate of 33.3% and false positive rate of 7.8% for a PEWS threshold of 4. Beyond very small false positive rates, the VRI exhibits superior performance when compared to PEWS.

Conclusions

Our findings suggest that we have developed an automated ward risk stratification model, which performs better than the current warning system in identifying deteriorating pediatric inpatients in NCH. Such a tool may help perceive potential cardiopulmonary arrests while not generating too many alerts that would fatigue the caregivers. Relying solely on objective measurements would reduce nursing workload, whereas it may miss signs of patient deterioration that would be captured by subjective evaluation. Longer-term nursing workload reduction can be achieved by identifying which elements of subjective patient evaluation can be replaced by automated assessment.

State-Level Adoption of National Guidelines for Norovirus Outbreaks in Healthcare Settings: Implications for Decision Support

Carl J. Grafe, MS¹, Catherine J. Staes, BSN, MPH, PhD¹, Kensaku Kawamoto, MD, PhD¹, Matthew Samore, MD¹, R. Scott Evans, MS, PhD¹

¹Department of Biomedical Informatics, University of Utah, Salt Lake City, Utah

Introduction

Computerized decision support systems can help investigating officials to follow best practices when responding to infectious disease outbreaks,¹ but variation in local guidelines may make such systems more difficult to develop and implement. In 2011, the U.S. Centers for Disease Control and Prevention (CDC) published guidelines for the prevention and control of norovirus outbreaks in healthcare settings.² Many U.S. state and local jurisdictions have since published or updated their own norovirus or general acute gastroenteritis outbreak guidelines with recommendations tailored to the perceived needs of their individual jurisdictions. Failure to adopt national guidelines could result in the use of ineffective strategies for outbreak response and lead to disparities in outbreak data collection and reporting between jurisdictions. This study aimed to identify the extent to which state-level guidelines adhere to national guidelines for norovirus outbreak response in healthcare settings.

Methods

State guidelines were obtained from internet searches and direct email or webform contact with state public health officials in early 2016. Guidelines specific to healthcare settings were then reviewed and categorized based on alignment with elements of the CDC’s guidelines. General recommendations, such as increased hand hygiene and patient cohorting, were grouped broadly under one of the CDC’s guidelines’ twelve evidence-based recommendations for prevention and control. Specific recommendations, such as number of stool specimens or time ranges for patient isolation, were tabulated based on the specific guidance indicated. Recommendations on topics that were not covered in the CDC’s guidelines were included if they occurred in at least 10 states’ guidelines.

Results

Guidelines were obtained from 41 of 45 (91%) state health departments (the remaining five did not respond). The state guidelines generally covered the CDC’s twelve primary recommendations, but specific recommendations within those categories varied considerably. For example, there were five different recommended time ranges for isolation of ill patients, six different recommended time ranges for exclusion of ill employees, and 21 different recommended ranges for numbers of stool specimens to collect. High levels of variation were also found in recommendations that were not found in the CDC’s guidelines, including 11 unique recommendations for outbreak detection, 14 for outbreak resolution, six for determining mode of transmission, and six for conducting environmental health assessments. These varying recommendations were likely to impact key aspects of outbreak response, such as determining which outbreaks to investigate, which cases to include, and which data fields to collect. Ultimately, 31 states (76%) contradicted at least one recommendation from the CDC’s guidelines, but 22 of these 31 states (71%) had the CDC’s guidelines cited in their documents or hyperlinked on their websites.

Conclusion

This study identified substantial variation in state healthcare-associated norovirus outbreak response guidelines. Such variation could necessitate taking a state-by-state or jurisdiction-by-jurisdiction approach to decision support, with associated increases in complexity and cost. These findings are useful in determining the scope of decision support development projects and in the interpretation of national outbreak data and analyses. More research is needed to understand why this variation exists, how it might impact outbreak outcomes, and where further evidence-based recommendations or alternate methods for communicating national guidance might be beneficial.

Critical Appraisal of Models for Prediction of Readmission (CAMPR): A Quality Tool to Assess Models that Predict Hospital Readmissions

Lisa V. Grossman¹, Rollin R. Reeder²,3, Colin G. Walsh²,3,4, Devan Kansagara⁵, David K. Vawdrey⁶, Hojjat Salmasian¹,6

¹Department of Biomedical Informatics, Columbia University, New York, NY, ²Departments of Biomedical Informatics, ³Medicine, ⁴Psychiatry, Vanderbilt University, Nashville, TN, ⁵Oregon Health & Science University / Portland VA Medical Center, Portland, OR, ⁶The Value Institute at NewYork-Presbyterian Hospital, New York, NY

Objective

Despite the rapidly growing number of studies devoted to the development and validation of models predicting hospital readmission risk,¹,² few data exist on the quality of these models, their clinical relevance, and institutions' success in implementing them. We developed "Critical Appraisal of Models for Prediction of Readmission" (CAMPR), a quality tool that assesses the design and implementation potential of readmission risk prediction models, as well as the necessary environment to effectively implement one.

Methods

We conducted a national online survey of domain experts in the development, validation, and implementation of models for predicting readmission. We publicly distributed the survey to the American Medical Informatics Association (AMIA) mailing lists and also sent it directly to the primary authors of studies on readmission prediction from two recent systematic reviews.¹,² The survey assessed perceived barriers to model quality, use, and implementation. Two independent researchers (LVG, RRR) conducted thematic analysis of qualitative content in NVivo Version 11 (QSR International). The survey results have been previously reported.³ Based on the thematic analysis, the authors identified and classified measures to operationalize two quality dimensions of readmission risk models: (1) design, and (2) implementation.

Results

The preliminary CAMPR tool contains 51 questions, categorized into 15 key domains and further classified into two quality dimensions. Domains under design include overall quality, predictors, timeframe, heterogeneity and subgroups, data availability and quality, and clinical relevance. Domains under implementation include data availability, validation and generalizability, resources, vision and buy-in, workflow integration, clinical relevance, and continuous improvement.

Conclusion

CAMPR is a potential new tool to assess quality of current readmission risk prediction models and guide the development of future models. Our next steps include refinement and reduction of items through expert review, as well as establishing the reliability and validity of the tool by applying it to the previously published literature.

A Machine Learning-Based Approach for Identifying Atopic Dermatitis in Adults from Electronic Health Records

Erin N. Gustafson, PhD, Al’ona Furmanchuk, PhD, Jennifer A. Pacheco, Firas H. Wehbe, MD, PhD, Kathryn L. Jackson, Abel N. Kho, MD, MS, William K. Thompson, PhD, Jonathan I. Silverberg, MD, PhD, MPH
Feinberg School of Medicine, Northwestern University, Chicago, IL

Introduction
Atopic dermatitis (AD) is a chronic inflammatory disease associated with intense itch and skin hyper-reactivity to environmental triggers that are innocuous to non-atopic individuals. The complex etiology of AD drives a growing need to acquire large-scale cohorts with detailed granular data for clinical research. Here we present an electronic health record phenotype algorithm for this purpose, developed as part of the NIH-funded electronic Medical Records and Genomics network. Diagnostic criteria for AD rely on clinical observations of disease manifestations and laboratory measurements. AD is difficult to distinguish from other dermatoses due a complex, multi-dimensional clinical presentation (i.e., atypical signs and symptoms). As a result, estimation of AD prevalence, clear understanding of sub-phenotypes, and nationwide guidelines for AD prevention may be inconsistent or inaccurate. Our algorithm is designed to address these challenges.

Methods
This work was based on the analysis of an existing registry of 562 patients from Northwestern Medicine with at least one AD diagnosis code. Following chart review, a diagnostic criteria was applied to assign AD diagnosis (278 cases). Our approach expanded on previous phenotype algorithms using diagnosis codes by including information extracted from encounter notes using Natural Language Processing (NLP). We utilized AD diagnostic criteria to create a phenotype-specific dictionary of more than 400 AD concepts for our NLP pipeline. We opted to use lasso logistic regression (rather than a decision tree) due to its high interpretability. Counts of NLP-derived concepts and other numerical input from coded sources were log-transformed and served as features in the regression, which output a predicted class label (i.e., presence or absence of AD diagnosis). The regression was trained using 10-fold cross validation to choose the best value for the parameter lambda. This phenotype algorithm will be applied at Northwestern to identify additional AD cases in order to characterize sub-phenotypes of AD using hierarchical clustering. Within each cluster (i.e., sub-phenotype), we will examine the most influential features that determine cluster membership. For example, we predict that patients who have the same comorbid conditions (or risk factors) will fall within the same sub-phenotype, and that features representing these conditions will be highly influential for that cluster.

Results and Conclusion
The results of the lasso logistic regression improved upon previous algorithms, with a positive predictive value of 85.2%, a recall of 82.1%, and an F-measure of 83.6%. Improvements to model performance could be achieved by refining the NLP approach (e.g., capturing mentions disease change over time) or the machine learning approach (e.g., ensemble methods such as random forest classification). These initial results demonstrate that current diagnostics and understanding of AD could be significantly improved with machine learning and NLP. As patients within a sub-phenotype are likely to have similar disease severity and response to medications, identification of sub-phenotypes of AD and their unique clinical presentations has implications for developing guidelines for proactive measures in delivering adequate health services to the right risk groups.

Inpatient Perspectives and Information Needs for Error Prevention

Shefali Haldar¹, Sonali R. Mishra¹, Ari H. Pollack, MD¹², Wanda Pratt, PhD¹
¹University of Washington, Seattle, WA; ²Seattle Children’s Hospital, Seattle, WA

Abstract
Hospital safety has long been acknowledged as a problem in the United States. Although patients and caregivers have great potential to help prevent these errors, less is known about their perspectives and information needs regarding these quality and safety problems. To fill this knowledge gap, we surveyed 246 individuals at two hospital sites. Our analysis informs the design of inpatient tools to further involve patients and caregivers in error prevention.

Introduction: For almost twenty years, much attention has been given to the problem of preventable medical errors in United States hospitals (1). Despite this attention, a recent estimate suggests medical errors are the third leading cause of death (2). Because inpatients and caregivers are witnesses to all care they receive, they have great potential to play a key role in preventing a broad spectrum of quality and safety problems, and in avoiding harm. However, inpatients and caregivers currently do not have sufficient tools to help them identify these errors and manage their effects. To design powerful technologies for patients and caregivers to prevent error, we must first understand their experiences and know their information needs.

Methods: We created a web-based, anonymized survey asking patients and caregivers to describe their experiences with undesirable events, which we define in our survey as something that was (1) a small or big concern, (2) was unpleasant or caused harm, and (3) could have been avoided. Recruitment took place at two sites: a pediatric hospital and adult hospital. Patients and caregivers were approached in-person and were eligible if they were: well enough to provide informed consent, comfortable communicating in English, had experienced an undesirable event during a previous or the current hospital stay, and had spent at least one night in the hospital during their current visit. Participants were asked to identify as either a patient or caregiver, describe their undesirable event experience in their own words, and specify what information would have been important to know at the time of the event. Two research team members conducted an iterative and inductive qualitative analysis to examine the types of events that participants described. Descriptive statistics were used to analyze the information needs identified.

Results: Our research team approached a total of 606 patients and caregivers, of which 312 (51.5%) were eligible for participation. Out of 312, we received 246 survey responses (response rate 77.56%). Our qualitative analysis revealed 19 types of undesirable events, many of which fall outside of traditional clinical definitions of error. Additionally, a wide variety of information needs were identified, spanning all aspects of the hospital stay (e.g., introduction to care team, institution-specific resources, discharge details). The relationship between the type of undesirable event and types of information needs proved to be complicated, as each person’s experience and needs manifested in a unique way. Although every experience was different, we found patterns of information needs among patients and caregivers. For example, patients tended to favor information about their care team and daily schedules, while caregivers wanted information regarding treatment plans and who to contact for help or questions. The use of a qualitative, open-ended method revealed findings that suggest hospitalized individuals want information at a deeper level: not just the what, but also the why behind care decisions. Knowing these details can help facilitate more substantial and informed conversations with their care team as an undesirable event unfolds. However, this information is not easily accessible to patients and caregivers, and their needs go beyond what is offered by existing patient portals and Electronic Health Records. Therefore, more work is necessary for patient-facing systems to incorporate inpatient perspectives and information needs regarding safety issues in the hospital.

Conclusion: Understanding what types of problems patients and caregivers experience, and knowing the information these individuals need to prevent these problems, will help guide the design and implementation of inpatient systems that will successfully involve inpatients and caregivers in error identification, prevention, and reporting.

Development of a VA Clinical Trial Matching Application (POP CTMatch) to Enhance Clinical Ability to Bring Trials to Veterans

Robert B. Hall MS\textsuperscript{1}, Elly J. Cohen PhD\textsuperscript{2}, Thomas P. Bechtold MBA\textsuperscript{3}, Susan L. Colen\textsuperscript{2}, Karen E. Pierce-Murray RN BA\textsuperscript{1}, Nhan V Do MD\textsuperscript{1}, Louis D. Fiore MD\textsuperscript{1}

\textsuperscript{1}MAVERIC, VA Boston Healthcare System, Boston, MA; \textsuperscript{2}University of California San Francisco (UCSF) Department of Surgery, San Francisco, CA; \textsuperscript{3}QuantumLeap Healthcare Collaborative (QLHC), San Francisco, CA

Introduction

In 2015, the Veteran Affairs (VA) launched the Precision Oncology Program (POP) to offer genomic analysis as part of routine clinical care for patients with solid tumors. The POP program will include several applications as part of a knowledge-based suite of services including a molecular tumor board and web-based clinical trial matching application. There are multiple barriers to consider for adoption of matching programs such as difficulty of finding relevant trials and usability of available tools. We partnered with the CTMatch team at UCSF and QuantumLeap Healthcare Collaborative to develop a matching application for non-small cell lung cancer (NSCLC) on the CTMatch platform (POP CTMatch). Our goals were to identify and accurately match to trials at both VA and non-VA sites, and to create a usable interface for providers that would enhance adoption.

Overview of Application and Technical Features

POP CTMatch uses data from ClinicalTrials.gov (CT.gov) that have been tagged for NSCLC as well as basket trials in the National Cancer Institute (NCI) Physician Desk Query (PDQ) Cancer Trials Registry that have been tagged as “unspecified adult solid tumor, protocol specific”. Cancer subtype, stage, and biomarker status (EGFR, ALK, KRAS) were manually curated with agreed upon coding rules while eligibility criteria of gender, age, location, and recruiting status were automatically obtained from CT.gov data feed. The list of matching trials highlighted studies within the VA system that were actively recruiting patients with easy access to non-VA sites nationwide that could be filtered by patient’s location. Patient data, entered on a web-based form, consisted of date of birth, gender, cancer subtype, stage, and biomarker status. To provide greater currency, we focused on open and recruiting trials that were updated and verified within the past two years. Further design objectives included: displaying an easy-to-read format of relevant trial information, ordering trials by proximity to the patient location, easy access to eligibility criteria through pop-ups, links to CT.gov for additional trial information, and display of last updated and last verified dates. This prototype seeks to maximize sensitivity of the search, while future versions will include more patient relevant data and deeper trial curation to increase specificity.

Evaluation

We evaluated the pilot by assessing quality of matching and provider usability. Because of the POP CTMatch curation process, trial matches were more refined than with CT.gov based on the markers of cancer status (stage, biomarker, subtype). Comparisons of patient use cases between the applications found a larger number of relevant trial matches with POP CTMatch than search criteria entered through CT.gov. Usability was measured with the System Usability Scale (SUS) and compared to experience with CT.gov. System usability of POP CTMatch was rated higher than CT.gov. An evaluation from five VA Boston clinical providers found the average SUS score for POP CT Match was 94 ± 6.3 while the average SUS score for CT.gov was 34.5 ± 14.2 (p-value < 0.0001).

Conclusion

The POP CTMatch trial matching apparatus provides succinct results to assist clinicians in identifying novel therapeutics for cancer patients including trials targeted to genomic alterations. The approach focuses on matching via patient criteria, highlights trials available in the VA Healthcare System, and provides functionality to assist trial investigation activities. Application usability proved better than experience with ClinicalTrials.gov. Our team continues to identify means to improve the matching algorithm and system interface in order to enhance usability and greater adoption as part of the suite of Precision Oncology informatics applications.

2021
Understanding Use of Health IT to support Treatment of Youth with Substance Abuse Disorders using Evidence-Based Practices

Saira N. Haque, PhD, MHSA, Shellery Ebron, MS, Erin Mallonee, MS, Laura Dunlap, PhD
RTI International, Research Triangle Park, NC

Abstract

Analysis of experiences with technology to support implementation of evidence based practices to care for youth with substance abuse disorders for SAMHSA Youth Cooperative Agreement grantees. Uses of technology include Electronic Health Records, web-based training and technical assistance, health information exchange, mHealth and social media. Grantee-reported experiences with technology include time spent manually entering data in several systems and indicated that existing technology was not designed for their needs. Other findings included use of social media to connect to youth and associated privacy and security concerns. As the grant continues, we will continue to identify how grantees use technology and associated barriers and facilitators.

Introduction

Addressing substance abuse disorders in youth is a significant priority for the United States because youth make up a significant portion of the substance abuse treatment population. The Substance Abuse and Mental Health Services Administration (SAMHSA) has funded grant programs to support use of evidence based practices (EBPs) in caring for youth with substance abuse disorders. Caring for youth with substance abuse disorders requires that information be shared by multiple providers across organizations and systems. Health Information Technology (IT) is an important component of infrastructure that can support use of clinically appropriate EBPs. We sought to understand how grantees using EBPs to care for youth with substance abuse disorders use health information technology.

Methods

We analyzed information gathered during the course of a larger program evaluation including grantee-prepared progress reports, applications and notes from meetings, which were then coded and thematically analyzed in Atlas-ti, a qualitative analysis program. We then extracted themes related to HIT use, barriers and facilitators.

Results

Grantees noted that services were delivered across providers and settings. Thus HIT use varied within grantee organizations. Grantees used HIT as a communication device, document repository, and to promote client and family engagement. These uses were supported by Electronic Health Records (EHRs) and related systems, telehealth, mobile health, social media and web-based platforms for training. EHRs are used for documentation, reporting and decision support. Key challenges were cost, confidentiality, interoperability and functionality concerns. Meaningful use incentives do not apply to non-physician providers, so providers reported financial barriers to obtaining HIT. Confidentiality was a concern noted for care coordination in the absence of a robust health information exchange and when using social media to engage with youth and their families. Interoperability made coordination across disparate providers difficult due to a lack of uniform data standards. Finally, grantees noted that system requirements for caring for youth were not necessarily met by available systems and cited missing functionality they would prefer.

Conclusion

Behavioral health treatment programs for youth are not typically integrated, but occur in silos with substance abuse treatment often provided separately from mental health services and other systems-related services. Each of these silos has its own information systems and requirements, which were not necessarily connected through HIE. Future work could include requirements gathering for different types of HIT for those who care for this population and identification of best practices in system use for this population.

The Effect of Relational Coordination on Handoff Routines: A Case Study

Saira N. Haque, PhD, MHSA1, Carsten S Østerlund, PhD2, Lawrence M. Fagan, MD, PhD3
1RTI International, Research Triangle Park, NC; 2Syracuse University, Syracuse, NY; 3Stanford University, Palo Alto, CA

Abstract

We sought to understand the impact of relational coordination on the handoff routine. We identified handoff routines in the interventional cardiology unit of a community hospital and administered the relational coordination survey to their participants. We found significant differences in how those in different roles perceived relational coordination. When relational coordination between roles is low, systems and processes such as information systems must bridge the gap across handoff routines. This can be used to inform system design.

Introduction

Participants in a handoff routine must effectively communicate information about the patient and his or her expected trajectory for a successful handoff1. Handoff routines often differ from their ideal-types, but these differences do not always lead to exceptions. We posited that relational coordination is one reason why some handoff routines lead to exceptions and others do not. Relational coordination is a measure of the strength and quality of relationships between roles, including communication and shared goals2. Previous work has studied relational coordination with delivery of acute, emergency, trauma and older patients. However, the effect of relational coordination on handoffs is not as well studied. Thus, we sought to understand the impact of relational coordination on handoff routines.

Methods

We identified handoff routines and their participants in the interventional cardiology unit of a community hospital in the Midwest as part of a larger study examining coordination1. We observed handoff routines in practice and identified where handoff routines differed from their ideal-types and where there were exceptions.

We administered the relational coordination survey2 via paper to handoff routine participants. Participants in the handoff routines were in a number of occupational roles (cardiologists, nurses, technologists, administrative staff. There were 22 respondents to the survey which we analyzed using the Kruskal-Wallis method for non-parametric statistics.

Results

There was a significant difference in relational coordination across role groups (Kruskal-Wallis test, p<.05). That means the perceptions of each role about the frequency, accuracy and timeliness of communication, shared goals, mutual respect and knowledge of each other’s work vary. We found that physicians experienced the highest degree of relational coordination, followed by scrub techs and cath lab nurses. Nurses in other units experienced lower relational coordination. In all analyses, relational coordination between handoff participants was related to handoff exceptions. As relational coordination increased, the number of handoff exceptions decreased. Exceptions were closely aligned with differences for handoff routines external to the unit but not for handoff routines internal to the unit.

Conclusion

This study illuminates the importance of relational coordination between roles. Where relational coordination is low, handoff routine exceptions are more likely and systems and processes must bridge the communication gap. Where relational coordination between roles is high, then formalized mechanisms to facilitate communication are of less importance. In addition, the study highlights the importance of promoting relational coordination within and across hospital units.

From Scoping Review to Metadata: An Evidence-Based Approach to Identifying Informed Consent Metadata for Biorepositories

Marcelline Harris PhD RN1, Frank J. Manion PhD(c)1,2, Hsing-Yi Song MPH2, Muhammad Amith PhD(c)2, Yongqun He PhD DVM1, Cui Tao PhD2
University of Michigan, Ann Arbor MI; University of Texas Health Science Center, Houston TX

Introduction and Background The rapid growth in the number of biorepositories, attributed to technical and informatics capabilities, is characterized by increasing complexity in the management and use of the specimens, data, and information managed by repositories and the networks in which they may participate. Concurrently, there are increasing demands to introduce standard practices to assure the quality of specimens, associated data, and overall operations; nontechnical operations such as governance and oversight of informed consent processes are emphasized. On a routine basis, biorepositories deal with managing consent, collection access, specimen and data use and sharing limitations, etc. To date, research on informed consent had emphasized the perspective of those donating specimens, however, the management of informed consent information from the perspective of biorepository data and information management has received far less attention. The complex set of regulatory, legal, privacy, security requirements, and information flows involved in biorepository specimens and data, as well as paper-based workflows in legacy repositories, challenges our ability to effectively build information systems that support discovery and sharing of research data, specimens and other research artifacts at scale, and fidelity to the intent of the specimen donor.

Methodology Our overall goal is the development of an ontology of informed consent metadata in the context of biorepositories. In this project, we report on a scoping review to identify relevant metadata from the perspective of biorepository operations, and the application of NLP processes to enrich metadata content. We are conducting a scoping review, a type of systematic review that is particularly appropriate when the need is to systematically map the literature available on an evolving topic in order to identify key concepts, theories, sources of evidence, and gaps in the research. The research question driving the review is: What is the evidence base for metadata needed to manage informed consent information across biorepositories, and support best practices in the management of that informed consent information? Eligibility criteria include: a) best practice guidelines (e.g., ISBER, OECD, NCI) b) the biorepository classification literature; and c) literature that specifically addresses informed consent and biorepository operational perspectives. Literature: We conducted a broad search of MEDLINE for the timeframe Jan 2010 through current on Feb 25 2017, using combinations of MeSH terms and keywords including: (biobank OR biorepository OR biospecimen resource) AND informed consent; (biobank OR biorepository OR biospecimen resource) AND informed consent information? Eligibility criteria include: a) best practice guidelines (e.g., ISBER, OECD, NCI) b) the biorepository classification literature; and c) literature that specifically addresses informed consent and biorepository operational perspectives. Literature: We conducted a broad search of MEDLINE for the timeframe Jan 2010 through current on Feb 25 2017, using combinations of MeSH terms and keywords including: (biobank OR biorepository OR biospecimen resource) AND informed consent; (biobank OR biorepository OR biospecimen resource) AND informed consent AND classification; (biobank OR biorepository OR biospecimen resource) AND informed consent AND classification. Selection: Abstracts and articles were reviewed for suggestions of relevant metadata and data elements. Analysis: After identifying relevant content within each document, we first apply open information extraction, a natural language processing method that extracts knowledge triples irrespective of domain specificity, and then apply our custom interface for ClausIE to attain a high accurate extraction of subject, predicate, and object information. We did not pre-select the documents or modify the existing verbiage as previously done. The output produced subject-predicate-object triples. A spreadsheet that allows for online collaboration is being used to iteratively refine columns labeled ‘category’, ‘relationship’, and ‘value set’.

Results 283 abstracts were retrieved, 10 duplicates were removed, 106 abstracts were excluded for non-relevance, leaving 106 articles and documents retrieved for full text review. Our qualitative summary of the scoping review indicates that while the literature calls out the specific need for policies for managing information about informed consents relevant to biorepository specimens and data, we found few suggestions/indications of higher level metadata needs for consent management. Best practice guidelines clearly address governance of processes related to informed consent information management, but the focus is on general principles. While metadata needed to address principles are suggested/indicated, metadata needs at the detailed level of implementation are not evident. The literature on classification of biorepositories was highly focused on implementation and operational perspectives, including indications of metadata for managing informed consent information. Jointly, these three literature sources provide evidence of information and metadata needs that should be enabled by a metadata ontology. The NLP-enrichment processes are augmenting the identification of triples need for the ontology, with 2,131 entities and 614 predicates currently identified.

Conclusion Next steps involve normalization, developing the ontology and engaging domain expert stakeholders in validation.

Development & Implementation of a Clinical Decision Support Tool for Familial Hypercholesterolemia

Ali Hasnie M.D.1, Pedro Caraballo M.D.2, Robert R. Freimuth Ph.D3, Iftikhar Kullo M.D.1

1Department of Cardiovascular Diseases, Mayo Clinic 2Division of General Internal Medicine, Mayo Clinic, Rochester, MN, 3Department of Health Sciences Research, Mayo Clinic, Rochester, MN

Introduction:
The 2009 Health Information Technology for Economic and Clinical Health (HITECH) Act mandated hospitals and medical clinics to demonstrate meaningful use of electronic health records (EHR). Subsequently, there is increasing interest in leveraging the EHR to assist providers at the point of care, including reminders to screen for certain conditions [1], implement preventive measures [1], and even to assist providers in the diagnosis and management of certain conditions [1]. We sought to develop and implement a clinical decision support (CDS) tool to assist providers in caring for patients with Familial Hypercholesterolemia (FH), a relatively common genetic disorder associated with increased risk of coronary heart disease.

Methods:
We utilized a mixed methods approach to obtain physician input to inform development of a clinical decision support (CDS) tool for FH. A total of 1166 physicians were queried on their opinions on key elements of a CDS tool using an enterprise-wide survey. Specific feedback was elicited relating to: 1) the primary focus of the CDS Alert (diagnosis vs. management), 2) the utility of an order set, and 3) the ideal location within the EHR for an alert to appear. In addition, focus group discussions were held to guide the development of the tool as well as gather specific recommendations for the development and implementation of the CDS tool.

Results:
The response rate to the survey was 17.4% (n=203). The vast majority (97%) of respondents favored development of a CDS tool for FH and believed it would be helpful in the management of an FH patient. Subsequent focus group discussions revealed several key themes. Participants prioritized guidance on the initial management, diagnostic workup, and appropriate referrals of patients suspected with FH. Opinions regarding a passive alert and an active alert were divided with majority preferring a passive alert. Based on this feedback we developed a prototype CDS tool incorporating key elements listed in Table 1.

Table 1. Key elements of a CDS tool for FH

| Essential facts related to the diagnosis and treatment of FH |
| Reminder to rule out secondary causes of hypercholesterolemia |
| Reminder to screen family members |
| Guidance to initiate/optimize lipid lowering therapy |
| Alert presented upon reviewing the laboratory data (e.g. lipid profile) |
| An ORDER-SET that includes cardiovascular genomics consultation, lipid profile, and reminder to test family members |

Figure 1: Steps in developing a CDS tool for FH. The final phases will involve testing the tool and deploying it in the EHR.

Conclusion:
Based on feedback from a survey and focus discussions, we developed a prototype CDS tool for FH. We will use this tool in a sample of genetically confirmed FH patients. Usability and outcomes of the tool will be assessed and refinements made. Following this, the tool will be deployed in the Mayo Clinic EHR and implementation metrics and outcomes will be assessed. The impact of this tool could be significant given the low awareness, control and detection of FH [2].

Screening the Contribution of Medical Reports to Electronic Diagnostic Systems

Peter J. Haug, MD1,2, Jeffrey P. Ferraro, PhD1,2, Nathan Dean, MD1,2
1Intermountain Healthcare, Salt Lake City, Utah; 2University of Utah, Salt Lake City, Utah

Introduction
In recent years, we have sought more efficient ways to build diagnostic tools from accumulated EHR data. We previously described a tool designed to largely automate the initial development of diagnostic, clinical decision support systems1. This application used disease models embedded in an ontology to drive extraction of data stored in an Enterprise Data Warehouse (EDW), to select features relevant to diseases of interest, to develop diagnostic systems for these diseases, and to evaluate the accuracy of these automatically derived systems. These rapid-turnaround prototypes help determine whether to develop a fully realized diagnostic decision support system.

Experience with several diseases2,3 has convinced us that this approach leads to promising diagnostic applications. Relevant diagnostic data are often available in health information systems. However, much of the most informative clinical data for diagnostic applications are embedded in free-text documents. In order to use these data effectively, these medical reports must undergo Natural Language Processing (NLP) to produce the needed clinical information.

In a previous evaluation of pneumonia diagnosis1, the system automatically extracted all of the structured data necessary but relied on an existing NLP sub-system to parse radiology reports. Development of this text-processing tool added substantially to the overall effort necessary to produce the diagnostic system.

This observation led us to experiment with reduced-effort approaches to NLP that can be incorporated into a system designed to automatically screen existing, computerized data for diagnostic power. The approaches described here use off-the-shelf tools to process reports and generate features. They rely on either minimal human annotation or pre-existing annotation derived from diagnostic conclusions routinely captured in the EDW (for instance, ICD codes).

Methods
We tested these two approaches to extracting relevant report data. In the first, physicians perform minimal annotation: they mark each report as indicating either “positive”, “negative”, or “possible” pneumonia. For this analysis, “positive” and “possible” were collapsed into a single category. In the second approach, no annotation is required. The report is assigned “positive” or “negative” based on the discharge diagnosis recorded in the EDW. In either case, we then apply an algorithm that 1) breaks each report into N-grams, 2) assigns TF-IDF values to each n-gram for each report, 3) applies a feature selection algorithm to reduce the number of available features, and 4) constructs and evaluates several predictive, machine-learning models to determine the operating characteristics of the report classifier.

Results
We assessed AUROC and F-Score to determine the potential usefulness of these report classifiers in a diagnostic CDS system. Two separate collections of chest imaging reports were used in these two evaluation.

Minimal Annotation: We used unigrams, bigrams, and trigrams extracted from 2198 chest imaging reports and tested in 1132 independent reports; this approach produced an AUROC of 0.932, and an F-Score of 0.925.

No Annotation: Using unigrams, bigrams, and trigrams extracted from 4938 chest imaging reports, we tested 2544 independent reports; this approach produced an AUROC of 0.933, and an F-Score of 0.917.

Conclusion
The goal of this research has been to determine whether sufficient information can be extracted from medical reports to automate the production of prototypic diagnostic systems. Familiar tools from the realm of information retrieval are used to screen the free-text information in the EDW and estimate its potential contribution. The objective is an economical, scalable way to predict the suitability of information in the EDW to contribute to a meaningful diagnostic application. The promising results seen here warrant additional effort towards refining the system for clinical use.

Using Modular Reasoning to Improve Classification Performance of the SNOMED CT Ontology With Added Description Logic Features

Robert R. Hausam, MD
Hausam Consulting LLC, Midvale, Utah

Introduction

SNOMED CT is a large, comprehensive clinical ontology based on the OWL 2 EL profile (EL++) description logic. This allows for efficient and tractable reasoning, but lacks more advanced description logic features, including universal restriction and negation. The addition of logical negation to the ontology allows creating new fully defined concepts such as “Non-bacterial infectious pneumonia” \(^1\), as well as fully defining and properly classifying existing concepts (e.g., “127302008 |Traumatic brain injury with no loss of consciousness (disorder)|”).

Currently available description logic reasoners such as FaCT++ and HermiT support negation and other advanced capabilities, but this additional capability typically comes with a significant performance cost, often making it impossible or impractical to classify a large ontology such as SNOMED CT. On the other hand, faster OWL 2 EL reasoners, such as ELK and Snorocket, perform well in classifying SNOMED CT, but lack the advanced logic capabilities.

A novel approach to providing enhanced reasoning capability while maintaining an adequate level of performance utilizes modular combinations of OWL reasoners. \(^2\) This approach uses a module extraction technique to divide the reasoning workload between a more expressive OWL 2 reasoner (e.g., FaCT++ or HermiT) and an efficient reasoner (e.g., ELK) and assigns the bulk of the reasoning workload to the latter. The MORe reasoner from the University of Oxford utilizes this technique.

Methods

An updated version of the MORe reasoner was developed as a plugin for the Protégé ontology editor tool. An OWL 2 ontology version of the SNOMED CT Jan. 2017 International Edition was generated using the distributed Perl script. This ontology was enhanced to add the fully defined concept of “Non-bacterial infectious pneumonia” (the definition includes “not (‘Causative agent’ some ‘Bacteria’)”). In addition, to achieve the expected classification results with the logical negation, it is necessary to add disjoint axioms between the “Bacteria” and “Virus” (and other) organism concept subhierarchies. Only with the disjoint axiom does the reasoner infer that “Virus” and its subtypes are not also subtypes of “Bacteria”. It is also necessary to add a universal restriction closure axiom (e.g., ‘Causative agent' only 'Virus') to the definitions of the expected subtypes of “Non-bacterial infectious pneumonia”, including “Viral pneumonia”, as only with the closure axiom does the reasoner infer that “Viral pneumonia” does not have additional unknown causative agents which may be a type of bacteria or other “non-viral” organism.

Results

Classification of the entire SNOMED CT ontology with the additional negated concept and supporting logic was performed using the expressive OWL 2 reasoner Fact++ in approx. 11.9 minutes. Classifying the same ontology using the MORe reasoner combining the ELK and Fact++ reasoners was performed in 5.2 minutes, a 56% reduction in classification time.

Conclusion

The initial results of using the modular combination reasoner for reducing classification time are promising. This likely can be enhanced using different strategies for module segmentation and different combinations of reasoners, and this will be explored in continuing work.

Facilitators and Barriers to PHR Adoption Experienced by Pediatric Primary Care Providers

Kisha H. Hawthorne, MHA, MBA, Ph.D. Candidate1,2, Anthony Luberti, MD2, Patricia Lee, BS2, Erin Sladek2
1Drexel University, College of Informatics and Computing, Philadelphia, PA; 2Children’s Hospital of Philadelphia, Philadelphia, PA

Introduction

The overall adoption of Personal Health Records by both physicians and patients is growing; however the pace of PHR adoption in the pediatric community is not as high. Limited studies regarding PHR adoption have been completed specifically focusing on the pediatric provider community. Facilitators and barriers impacting tethered PHR adoption are explored in this study conducted at one of the nation’s leading pediatric institutions. The current patient PHR adoption ranges from 5% to 10% for all but one of the practice (68%) in the study. The organizational average adoption rate is 30%.

Two hundred providers practicing at eleven academic primary care practices were invited to participate in the research study. Provider roles included in the study were pediatricians, nurse practitioners and medical directors. The Ambulatory Care Network leaders assisted in recruiting participants. All primary care practices were based in a large urban city center, the encompassing county and contiguous counties.

Data collection was conducted using REDCap (Research Electronic Data Capture). The survey questions were constructed based on an extensive literature review of PHRs, patient portal and technology acceptance and adoption models. The 21 question survey tool focused on provider perceived patient PHR adoption, practice setting and location, factors impacting adoption, PHR utility and functionality, health literacy, enrollment and clinical workflow, marketing and health promotion, and individual participant technology and PHR use.

Results

Fifty five survey participants were asked to select their practice location(s), setting choices urban or suburban and rate the perceived adoption rate. All participants used a sliding scale 0 to 100, to indicate what they believed the overall perceived PHR patient adoption rate, % of patients using the PHR, in their practice. The adoption rating scale was determined to be low = <34, medium = 34-67, and high = >67 (Figure 1). In 100% of provider survey participant’s opinion, their practice cares for disadvantaged patient populations. Twenty-two participants (40%) indicated that their practice was suburban and the remaining 33 participants (60%) classifying as the practice as urban.

Factors and Barriers Impacting Adoption

Study participants were asked, “Do any of the following factors(8) impact PHR utilization?” Socioeconomic levels (78%), clinical issues, i.e. non-standard PHR activation or enrollment workflow or clinical staffing inconsistencies; (57%), family structure, i.e. parents, grandparents, and guardians are surrogates for patients, (44%); ethnicity (35%); and patient age (28%) represents the top five answered identified. While patients’ privacy and access differ in the pediatric community, only 22% or 12 participants identified this as a factor impacting adoption. Regarding barriers, providers were asked to choose from 6 barriers, rating patient PHR adoption as high, medium or low. Limited access to technology (60%), digital health literacy (58%) and lack of network or wireless service (53%) were the top three barriers.

Conclusion

Pediatric providers face unique opportunities with PHR adoption including significantly improved mobile device access to the Internet, growth of consumerism and heightened desire for patient engagement. However, challenges universally expressed still included limited access to technology devices, digital health literacy, PHR promotion and enrollment. The next phase of the research will consist of pediatric primary care focus groups and comparison of actual enrollment data to validate provider perceptions.
A Visual Analysis Tool of Qualitative Eligibility Criteria of Clinical Studies

Zhe He, PhD1, Zhiwei Chen, BS1, Sarah Mixon1, Jiang Bian, PhD2

1Florida State University, Tallahassee, FL; 2University of Florida, Gainesville, FL

Introduction

Clinical studies are conducted for testing the efficacy and safety of treatments or interventions such as a new drug. Clinical trials have been widely accepted as a gold standard in modern medical research. Nevertheless, they are often criticized of lacking generalizability. For example, qualitative eligibility criteria with moderate or strict restrictions were frequently observed in cancer clinical trials, which hampers their generalizability. In previous work, we developed a rule-based parsing tool called qUalitative eLigibility cRiteriA parser (ULTRA) that leverages lexical patterns to structure qualitative eligibility criteria automatically [1]. To allow trial designers to visualize the temporal constraints of eligibility criteria, we built a Web-based visual analysis tool called VATEC (Visual Analysis Tool of Qualitative Eligibility Criteria of Clinical Studies). Using this tool, a user can select trials with certain characteristics (e.g., medical condition, study phase, intervention type), view the frequently used qualitative eligibility criteria in these trials, and visualize the temporal constraints that are often applied on a certain criterion.

Method

Our recent publication [1] describes the detailed process of using Stanford CoreNLP and lexical patterns to structure free text eligibility criteria with temporal constraints. VATEC was built with the Python Flask framework and deployed through the Amazon Web Services Elastic Beanstalk. The backend of VATEC is a MySQL relational database with eligibility criteria structured by ULTRA. VATEC has four modules: a condition selection module, a query builder module, a criterion frequency analysis module, and a visualization module. VATEC allows its users to visualize the usage pattern of a qualitative eligibility criterion in clinical studies such as temporal constraints, anchor events of the temporal constraint (e.g., “History of myocardial infarction within 6 months prior to randomization”), and other criteria that co-occur with the selected one. We used the Google Charts API to visualize the distribution of the temporal constraints of a certain eligibility criterion in a set of similar cancer studies. A typical workflow for a user is as follows: (1) select a medical condition; (2) select one or more study descriptors (e.g., study phase, intervention type) and the number of frequent qualitative features to be retrieved; (3) choose a qualitative eligibility criterion; and (4) retrieve the visual analysis results. The data about these trials are collected from ClinicalTrials.gov.

Results

The VATEC tool is publically available at https://is.gd/VATEC. To demonstrate the functionality of VATEC, let us use the following example. A user wants to examine a criterion, “malignancy”, frequently used in Phase II interventional “lung cancer” studies, and to visualize the temporal constraints applied on this criterion in these trials. As shown in Figure 1, among the 791 trials that use the criterion, 170 (21.5%) trials applied temporal constraints. Among these 170 trials, 115 (67.6%) trials used 60 months as the temporal constraint (e.g., “no malignancy within the last five years”), and 36 (21.2%) trials used 36 months as the temporal constraint. To evaluate the accuracy of the extraction of criteria and temporal constraints, we randomly selected 200 eligibility criteria sentences from cancer studies on ClinicalTrials.gov. A biochemistry undergraduate student (SM) manually extracted the criteria and the temporal constraints to form the gold-standard testing data. We then compared the performance of ULTRA with MetaMap. The results show that our tool achieved a better recall than MetaMap (95.6% vs. 74.3%). The accuracy of extracting and unifying the temporal constraints is 100%.

Conclusion

In this work, we developed a web-based tool to visualize the temporal constraints of the eligibility criteria in cancer studies. Further usability assessment is needed to test the usability of the tool in the trial design.

Quality Improvement Dashboard to Monitor Oral Manifestations of Dysglycemic Patients

Harshad Hegde, M.S.1, Alok Sagar Panny, M.S.1, Rajesh Koralkar, MSHI2,
Amit Acharya, M.S., Ph.D1,2

1Institute for Oral and Systemic Health, Marshfield Clinic Research Institute, Marshfield, WI; 2Biomedical Informatics Research Center, Marshfield Clinic Research Institute, Marshfield, WI;

Abstract: Diabetes mellitus (DM), the most common chronic disease encountered in dental practice has a large impact both on systemic and oral health. The abstract provides a brief description of a dashboard which summarizes various oral manifestations in patients with dysglycemia being developed by a large health system providing medical and dental.

Introduction: The relationship between periodontal disease (PD) and DM is bi-directional. Diabetic patients are more susceptible to periodontal destruction and PD which in turn can lead to poor glycemic control. Understanding this relationship is important for dental and medical providers to aid in informing and counseling patients to seek additional medical or dental assessments as needed. To improve the oral health related quality of life among these patients there is a need to develop strong data visualization platforms to summarize various oral manifestations in patients with dysglycemia (pre-diabetes, gestational diabetes, Type I DM and Type II DM). The Dental Quality Analytics Dashboard (DQAD) graphically presents information of dysglycemic patients served by the dental and medical centers with in Marshfield Clinic Health System.

Methods: An extensive literature review was done to better understand various oral manifestations of DM, gestational diabetes, prediabetes and relationship between periodontitis and DM. A list of oral health determinants which would have an influence on the blood-glucose level of a diabetic patient and systemic factors which could impact the oral health of diabetic patients were listed out and measures and summaries were developed. A high fidelity prototype was developed to define the information hierarchy and facilitate better understanding of the interface design from a usability standpoint. Although no formal usability testing was conducted at this point, the study team did have a usability expert in formulating initial user interface design as part of this prototype development. The data for all the summaries and measures will be obtained from Marshfield Clinic Enterprise Data Warehouse and will be imported into a SQL Server database by employing the Online Analytics Processing (OLAP) cube design. ASP.NET MVC framework along with C3-JS charting library will be used to develop the front-end. The data could also be filtered based on billing type, individual dental centers, providers, and reporting periods.

The ‘Summary’ tab will display the following: a. periodontal status: provides a summary of periodontal health status of each cohort of dysglycemic patients - healthy, gingivitis and mild/moderate/severe and aggressive periodontitis, b. oral health status: provides a summary of the oral health status of each cohort of dysglycemic patients - gingivitis, periodontitis, xerostomia, dental caries, candidiasis and oral cancer, c. periodontal parameters: summarizes various periodontal parameters among different cohorts of dysglycemic patients. The count of dysglycemic patients with probing depth >=4mm in at least two probing sites, clinical attachment loss of >=4mm in 1 or more teeth, number of teeth absent >=4, bleeding on probing index and calculus index >20%, d. co-morbidities of diabetic patients: indicates the counts of dysglycemic patients with hypertension, family history of diabetes, smoking status, obesity, periodontitis and dyslipidemia, and e. dental procedures vs diabetic patients: summarizes distribution of various dental treatments received by dysglycemic patients like non-surgical periodontal treatments, complete and partial dentures, surgical tooth extractions, root canal treatments.

The ‘Measures’ tab will display the following: a. undiagnosed dysglycemic referral statistics: is a process measure which indicates the actual number of patients who followed up with a medical provider after they were screened for their glycemic index at the dental center based on the presence of certain risk factors and referred to a medical provider based on high risk. This measure will indicate the role of providers to improve the care of undiagnosed patients with risk factors of diabetes and b. change in blood glucose vs periodontal treatment: is an outcome measure which will indicate the impact of a periodontal treatment like scaling and root planning on the glycemic level of a diabetic patient.

The ‘Trends’ tab will display the monthly progression of measures and ‘Comparison’ tab would facilitate the user to compare the centers and providers with each other for a given measures.

Conclusion: This DQAD could be instrumental in providing data relevant to oral health of dysglycemic patients both at center level and provider level. This will allow dental centers to design better intervention and quality care targeting dysglycemic patients for a given oral condition and also empower dental providers with information pertaining to various oral manifestations that exist among their patient population. The next steps would be conducting usability sessions and analyzing “think aloud” thoughts and post-session usability ratings from evaluators and eliminating any design vulnerabilities and ensuring the system adaptability to address the consumer needs and preferences accordingly. Also implementing the DQAD into clinical practice by integrating it into the existing Electronic health record (EHR) or as a stand-alone system are some of the future directions.
Extracting Condition-action Statements in Medical Guidelines

Hossein Hematialam, M.S.1, Wlodek Zadrozny, Ph.D.2
1,2Univeristy of North Carolina at Charlotte, Charlotte, NC

Medical guidelines establish criteria regarding diagnosis, management and treatment in specific areas of healthcare. The most important parts of the guidelines describe actions of medical personnel to be performed under certain conditions. We propose and evaluate a supervised machine learning model extracting condition-action sentences. We establish baselines for hypertension1 and rhinosinusitis2 guidelines, as well as compare our method against previously done work on asthma guidelines.

We used part of speech (POS) tags as features in our classification models. Using POS tags instead of semantic pattern rules makes our model more domain-independent, and therefore more suitable for establishing baselines, not only for text mining of medical guidelines but also in other domains, such as text mining of business rules. We annotated part of asthma guidelines used previously by other researchers3, hypertension and rhinosinusitis guidelines to create gold standards to measure the performance of our condition-action extracting models. We classified them into three classes: condition-action, condition-consequence (effect, intention, and event) and action. ZeroR(majority classifier), Naive Bayes, J48, and random forest classifiers were applied. The results are based on 10-fold cross-validation on respective datasets. Precision for finding Condition-Action statement in asthma guidelines is 0.5 which is lower than 0.88 which was reported as Wenzina and Kaiser’s3 precision for doing the same task. The difference is due to our use of completely automated feature selection when training on an annotated corpus, and not relying on manually created extraction rules. In addition, their results demonstrate recalls on activities with specific patterns.

The results show that generally random forest classifier seems to work best in extracting Condition-Action statements. (0.84, 0.39) and (0.93, 0.43) are the (precisions, recall) pairs for extracting condition-action statements in rhinosinusitis and hypertension guidelines. Our work established baselines for automated extraction of condition-action rules from medical guidelines, but its performance is still inferior to a collection of manually created extraction rules. We are currently augmenting our model with semantic information and evaluating improvements based on “events” vs. “entities”.

Semantic Association for Literature Based Discovery

Sam Henry, M.S. and Bridget McInnes, Ph.D.
Virginia Commonwealth University, Richmond, VA

Introduction

This research explores the effectiveness of association measures at ranking the output terms of a literature based discovery (LBD) system. The amount of biomedical text published is growing exponentially and researchers are finding it increasingly difficult to keep up with new findings, even inside their area of expertise. LBD attempts to address this situation by automatically uncovering new, potentially meaningful relations between terms that could lead to new discoveries. A core challenge of LBD is that systems generate more potential discoveries than can be analyzed by a human, therefore effective ranking measures are essential.

Method

Using the traditional ABC co-occurrence model of LBD we begin with a start term, A, from which A implies B relationships are found via co-occurrences in text. Using the generated B terms, B implies C relationships are found. From these, therefore A implies C relationships are inferred to produce a list of output terms. This method generates hundreds or even thousands of C terms, many of which are uninformative and uninteresting, therefore ranking is critical. We evaluate the ranking procedures of: Average Minimum Weight, where the minimum value between each A to B and B to C is averaged over all B terms for each C term; Maximum B to C, the maximum B to C value over all B terms for each C term; Linking Term Count (LTC), where the count of unique B terms for each C term.

Generally, the co-occurrence frequency between terms is used as the “value” in these procedures; we modify them by replacing the co-occurrence frequency values with association measure values. Association measures quantify the likelihood of two terms occurring together in text versus by chance. Both the terms’ individual occurrence frequencies, and their mutual co-occurrence frequencies are taken into account. This study presents a comprehensive comparison between association measures, including Log Likelihood Ratio, Left Tailed Fisher Test, Pearsons Chi Squared, Dice Coefficient, Odds Ratio, Mutual Information, Jaccard Measure, and Phi Coefficient. We use data prior to year 2000 as the training set, and data published after year 2000 as the test set. We use the 2015 MetaMapped MEDLINE baseline as our dataset, and apply concept filtering to restrict B and C terms to specific UMLS semantic types.

Evaluation and Results

We evaluate the ranking methods with discovery replication and time slicing evaluation. Discovery replication reproduces previous discoveries, and the rank of the C term of interest is reported. The higher the rank, the better the system. We replicate three benchmark discoveries, Raynaud’s Disease - Fish Oil, Migraine - Magnesium, and Somatomedin C - Arginine. For time slicing evaluation, we divide the dataset into testing and training portions. The training portion is used to generate C terms, and the test portion is used to simulate to be discovered knowledge. 100 A terms are randomly chosen from the training set, and C terms are generated. Using the C terms generated, and the test set as a gold standard, precision and recall curves, Mean Average Precision, and precision at k (precision using only the top k ranked terms) are calculated. Table 1 shows the results of discovery replication. The results show the efficacy of using association measures, but more analysis is required. Further results and analysis are shown on the poster.

An assessment of the contribution of technology on documentation practices in an electronic health record (EHR): evaluation of the introduction of two computer-based tools in a clinical research environment

David Herion, M.D1, Matt Fred, M.D.2
1NIH Clinical Center, Bethesda, MD; 2WorkingDiagnosis, LLC, Newark, NJ

Abstract

Metrics associated with the use of computer-based clinical documentation tools can be used to assess the usability of an electronic health record (EHR)

Introduction

Usability of clinical documentation tools in an EHR is a timely and important issue. Electronic documentation of clinical practice introduced both significant benefits, as well of substantial burdens. Although it has produced improvements in the portability of patient records, as well as billing and, to some extent, improved communications among care teams, it has been shown in some cases to have a significant detrimental impact on clinicians’ work, including time management, productivity and frustration as measured by satisfaction. In response to these impacts, efforts have been made to improve the experience of clinical documentation.

Human assets, medical “scribes”, have been introduced in various clinical care environments in an effort to reduce the burden of EHR documentation. Data regarding the efficacy or negative consequences of this practice, its “usefulness”, is wanting, leaving a limited understanding of the impact of this approach on the clinical practice. Another approach has been the development of computer-based tools to facilitate documentation in an EHR.

One difficulty in assessing the usability of these tools is lack of comparator systems in a matched cohort of users. We therefore used an “experiment of nature” to assess the usability of the EHR for clinical documentation.

Methods

Two different third-party custom applications designed to facilitate clinical documentation were sequentially deployed in a single EHR over a five-year time period. Rates of user adoption and intensity of use were compared. The breadth of functionality used (the percent of modules or components accessed) was also measured as an indicator of interest of and demand for use of the application, another aspect of usability.

Results

There was a log-phase growth in the adoption of the use of the first tool and a stable distribution of intensity of use as measured by the distribution of sustained, partial and non-adopters of the technology. The second tool had a similar rate of adoption, but a lower percentage of overall intensity of use. The analysis of the breadth of use of functions was inconclusive.

Conclusion

The adoption and intensity of use of two similar technologies designed to facilitate clinical documentation provide a potential metric of the usability of an EHR.
The Experience of Students Building an Effective Clinical Data Warehouse for a Free, Student-Run Clinic

Matthew C. Hess, BS⁴, Steve Layfield, BS⁴, Timothy Kennell, Jr., BS⁴, and Seung Park, MD⁵

University of Alabama School of Medicine; Equal Access Birmingham⁴
Community Health Systems, Inc.; Equal Access Birmingham⁵

Objective:
Many free, student-run clinics depend on the availability of free or open-source electronic health record (EHR) software; however, many of these systems do not provide easy access to data for later use in research. For our student-run clinic, we developed an in-house data warehouse that would simultaneously streamline checking patients in the clinic and store this information for later use in research. This system runs alongside the clinic’s current EHR solution. Here, we discuss the design process of the system, its benefits to the clinic, and the survey responses regarding system usability after one year of use.

Materials and Methods:
After a two-week long, intensive informatics course, we analyzed the current method of check-in and data collection at our student-run clinic. We then designed and constructed a data warehouse implemented in a Raspberry Pi using a LEMP (Linux, nginx 1.11, MariaDB 10.0, and PHP 5.5.9) stack architecture. The user-interface of the data collection form was designed with web technologies (HTML5, CSS3, and JavaScript) and the Bootstrap 3.0 framework. The system allows basic retrieval of data in a CSV format; however, all data is accessible to those with credentials to pull from the database. The system is limited to the clinic’s secure, local area network and is physically locked up when the clinic is not in operation.

After one year of use, we designed a custom, 10-question survey for the current students that ran our student-run clinic. The questions covered user demographics, user satisfaction, and length and form design.

Results:
We have created a secure, customized data warehouse solution for our student-run clinic that efficiently collects data for purposes of later research and streamlines the check-in process for patients at the clinic. This system allows patients themselves to provide their own information, students to add any additional information or view the data for clinical use, and researchers to explore patterns in data collected. The use of a normalized data structure allows easier addition of new data elements to the structure. Additionally, use of the bootstrap framework allows patients to use tablets to easily fill out the check-in form.

Our survey received an 89% response rate with 88% of respondents indicating that they were very satisfied after 1 year of use. The system was designed to enhance research data collection without impairing clinic flow, and the majority of respondents (70.6%) found the system most useful to the check-in aspect of clinic flow. Despite only one year of collection so far, the data warehouse facilitated many research projects including a longitudinal study on demographic and social factors affecting patient retention in care as well as providing easily accessible data for grant applications for clinic funding. Survey respondents’ subjective comments also identified minor areas for improvement such as modifying specific intake form questions, enhancing patient interaction with the tablets, and further optimizing the use of the system in clinic workflow.

Discussion:
Our experience indicates that it is possible for students to construct a customized, usable system for assisting with workflow in a free, student-run clinic. Given the overall positive feedback from the survey, we anticipate the system to continue to be used for data collection, making it more valuable for research data as time passes. We will continue to incorporate user feedback to improve the system for the future.

Conclusion:
We have constructed an in-house data warehouse for our free, student-run clinic that has received strong indications of usability and functionality from a survey. While there are still improvements that we can make to the system, it has proven useful in its current state. This entire project was student-driven and student-engineered, allowing medical students a valuable experience in clinic and informatics administration.
Upstream Detection of Clinical Decision Support Malfunctions

Thu-Trang T. Hickman, MPH¹, Lewis Silletto², Adam Wright, PhD¹,³,⁴
¹Brigham and Women’s Hospital, Boston, MA; ²Brown University, Providence, RI; ³Partners HealthCare, Somerville, MA; ⁴Harvard Medical School, Boston, MA

Introduction
An alert at our hospital suggesting a thyroid-stimulating hormone (TSH) test for patients who had been on amiodarone, an antiarrhythmic medication, for more than a year, stopped firing. The alert logic checks whether a patient is on amiodarone but had not received TSH testing within the last 12 months, and then suggests ordering the test. The malfunction occurred when the internal code for amiodarone changed from 40 to 7099 and the alert logic was not updated to reflect this change; thus, the alert only fired for patients on amiodarone coded as 40 and not for patients on new prescriptions of amiodarone, coded as 7099. Automated techniques for identifying CDS malfunctions exist, and most rely on monitoring alert firing rates. While these can detect some malfunctions, there are delays in detecting more subtle anomalies resulting from code changes. In this example, patients who were on amiodarone prior to the code change still had 40 listed in their records. The alert still worked correctly for these patients, so the malfunction only created a gradual drop off in the rate of firing. Furthermore, it took a year for the anomaly to become visible at all because the alert only fired for patients who had been on the medication for a full year. Many CDS alerts rely on “upstream” data elements such as medication codes and lab results to be generated. As such, we hypothesized that CDS malfunctions which do not manifest in alert firing data could be detected more quickly and easily by searching for changes in these upstream data elements. We developed and tested anomaly detection algorithms which analyzed upstream prescription data.

Methods
We developed two automated techniques to detect changes in medication codes: the existing code technique and the new code technique. While our algorithms focused on medication code changes, they can be applied to any upstream input code changes (e.g. lab tests). The existing code technique searches for medication codes being replaced by other codes while the new code technique searches for medications being prescribed for the first time, which may be replacing existing codes. We developed these techniques using data from the Longitudinal Medical Record, the legacy outpatient electronic health record (EHR) system at Partners Healthcare System, as well as from Epic, the current EHR system. We collected data on all new prescriptions of all drugs between January 1, 2008 – May 31, 2015. Using the two techniques, we identified possible CDS malfunctions within the EHRs at PHS. To assess the efficacy of these methods, we performed case studies and reviewed a random sample of anomalies detected using the methods.

Results
We identified five actual code changes using the existing code technique. For example, a new extended-release form of carbamazepine was added to the EHR’s drug dictionary (other extended-release forms were already in the dictionary). A rule is in place which suggests monitoring carbamazepine levels. It identifies patients taking carbamazepine by looking to see if one of several specified carbamazepine codes is on the patient’s medication list. The list of codes in the rule was not updated, so the rule did not fire for patients taking the new form of the medication. This was a new malfunction discovered using upstream detection that was not discovered when analyzing alert firing data. Additionally, we tested the new code method against previously known malfunctions, such as the amiodarone example, and succeeded in identifying the malfunctions earlier than methods relying on alert firing data.

Conclusion
CDS malfunctions caused by internal code changes are difficult to detect by monitoring alert firing data. By analyzing “upstream” data, these types of malfunctions can be detected more quickly and easily. Thus, upstream detection can allow CDS malfunctions to be resolved earlier, ultimately improving patients’ safety.
Behavioral Health Provider Perspectives on Health Data Sharing
Megan Hiestand1, Adela Grando, PhD1,2, Anita Murcko, MD1, Hiral Soni1, Julia Varkey1, Caroline Horrow2, Michael Saks, PhD1, Richard Sharp, PhD2, Mary Jo Whitfield3, Mark Callesen, MD3, Christy Dye4, Darwyn Chern, MD4
1 Arizona State University, Arizona; 2 Mayo Clinic, Minnesota; 3 Jewish Family and Children’s Services, Arizona; 4 Partners in Recovery, Arizona;

Abstract
Integrating behavioral and physical health is the key to value-based care. Little is known about data sharing preferences and consent practices for individuals with behavioral health conditions. This study focuses on identifying behavioral health provider perceptions about patient data sharing practices, preferences and perceived impact on care resulting from enhanced patient control of record types during consent for data sharing.

Introduction
Most protected health information is currently shared under a broad consent model. The Office of the National Coordinator identified the need for patients to have more granular control of their information when sharing with providers and others. Regulations such as 42 CFR Part 2 that extend additional protections to certain types of health records containing sensitive information, oblige the behavioral health community to develop tools that allow granular control of data by patients. We are developing My Data Choices (MDC), funded by the National Institute of Mental Health, as an electronic consent tool to offer behavioral health patients more control over their medical records. To inform the construct of MDC, we are collaborating with two community behavioral health clinics: one focused on general mental illness and the other treating patients with serious mental illness (SMI.) This study summarizes our findings from interviews with 12 representative behavioral health providers about current consent processes at their facility and their perceptions about patient-driven granular data control.

Methods
Building on the lessons learned from a semi-structured interview script consisting of 15 questions was designed by our multidisciplinary research team. Data reflecting interviewee characteristics and detailed perceptions on the impact of mental health stigma, quality of life, information sensitivity and behavioral health patient-motivation for sharing data were covered by this instrument. Subjects were based on role, longevity with the facility and experience with the consent process. All interviews were conducted at the respective facilities. Interviews were recorded and transcribed. Two independent coders performed qualitative analysis using the free Coding Analysis Toolkit (CAT) and conflicts were resolved by a third coder.

Results
Six providers from each facility, completed the semi-structured interviews in 30 to 60 minutes with a mean time of 44 minutes. From the preliminary analysis of the interviews, we identified the following:
Differences in perceptions on patient-driven granular consent between medical and social work providers. Compared with social work providers (clinical coordinators, therapists, and case managers), medical providers (psychiatrists, nurse practitioners, etc.) expressed stronger concern about the potential impact on patient safety and care coordination that may result from allowing patient more control over access to medical records.
Differences in data types that providers wish to access. Medical providers were interested in full access to patients’ treatment plans and medication lists, while social work providers wanted access to patient’s history of abuse.
Stigma, sensitive data and information sharing in the context of culture, religion, and diagnosis. All providers observed that mental illness is not recognized as a legitimate medical condition by many Hispanic, Asian subpopulations and certain religions. HIV status, substance abuse history and legal history (past and present) were identified as sensitive information. Many participants stated that SMI patients feel “labeled” and more fearful of discrimination from outside providers, potential employers and others.
Need for improved consent processes and supporting tools. All providers reflected on the complexity of the process and agreed that patients probably do not comprehend each form they sign and provided support for the development of a better process and new tools.

Future Work
We are currently fielding a companion survey of 90 behavioral health patients and legal guardians on their data sharing opinions and preferences. The final analysis of the provider interviews described above will include a comparison to the patient responses. These analyses will inform the development of the MDC consent tool.

A Unified Chart Review Tool Integrating OMOP CDM and Unstructured Data
Charity A. Hilton, BA¹, Jon D. Duke, MD, MS²
¹Georgia Tech Research Institute, Atlanta, GA; ²Georgia Institute of Technology, Atlanta, GA

Introduction
Chart review of medical records is a necessary part of clinical research. Validation of clinical outcomes, for example, often requires examination of both structured data (e.g., diagnosis codes) as well as unstructured data such as clinical notes and radiology reports. Creating a unified interface to facilitate rapid review of structured and unstructured data is thus an important consideration in chart review and abstraction.¹ Furthermore, to maximize interoperability, chart review tools should support standard data models where they exist.

Methods
We developed an integrated chart reviewing tool to rapidly explore patients with data in the OMOP common data model (CDM) as well as in free text documents. Our review tool uses OHDSI (Observational Health Data Sciences and Informatics) cohorts as the point of entry for chart abstraction. OHDSI cohorts provide a common structure which can be correlated to clinical phenotypes. We used a minimalistic schema to incorporate clinical text narratives, using Apache Solr, an open source text search platform. The application organizes every data point to a cohort index date, supporting the reviewers’ ability to review data temporally. We support navigation filters for rapid traversing the chart based on index date (e.g., 365 days after index) as well as limiting content based on text found in structured and unstructured sources (the latter using Solr). The tool’s design provides visual clarity for rapidly disambiguating data domains (e.g., drugs, procedures). This tool has been used effectively in our institution for expert annotation and scanning of cohorts to assess phenotypic accuracy.

Discussion
Use of the OMOP common data model provides our chart review tool with portability across multiple institutions. Similarly, by allowing a lightweight schema for ingesting documents into Solr, we are able to link unstructured data from multiple sources flexibly. Future additions include features to better support validation of clinical phenotypes, such as structured annotations and comments.

Modeling the Cognitive Diagnostic Process, Mapping Factors Associated with Diagnostic Errors, and Analysis of Measures to Prevent Diagnostic Errors

Teruyoshi Hishiki, MD, PhD1, Rie Ichikawa, MD2,3, Jimpei Misawa, PhD2, Yukihiro Maeda, MA2, Akiko Shibuya, RN, PHN, PhD2, Yoshiaki Kondo, MD, PhD2
1Department of Information Sciences, Toho University, Chiba, Japan; Department of Health Care Services Management/2Pediatrics, Nihon University, Tokyo, Japan

Problem Addressed
Graber et al.1 reported a taxonomy of cognitive factors associated with diagnostic errors that can be classified into 25 types in the following categories: knowledge, information retrieval, information processing, and verification. They used their taxonomy to analyze individual cases of diagnostic error. We believe that, instead of making one choice from among all of the error types, it could be useful to summarize or serialize the error types, with the aim of analyzing and preventing diagnostic errors. Here, we sought to define the temporal order of diagnostic processes.

Purpose
We sought to define a cognitive diagnostic process in order to understand the cognitive factors that may lead to diagnostic errors. We also demonstrated its applicability to the analysis or prevention of decision-making errors in the diagnostic process by identifying which cognitive processes are frequently reported in the literature and identify opportunities to prevent decision-making errors in the diagnostic process.

Method
We defined cognitive functions according to the elements of the 25 cognitive factors linked to diagnostic errors in the report by Graber et al.1 We then mapped these cognitive functions according to the presumed order over time in the diagnostic process. We next searched PubMed using the index terms “Diagnostic Errors” and “Decision Making”, separated the contents of the retrieved abstracts into individual words, and counted the frequency of each of these words. Based on the results, we created a search filter to retrieve PubMed entries on decision-making errors in the diagnostic process. We used this filter to collect entries relevant to diagnostic decision-making errors for a representative disease, porphyria. We chose porphyria because it is frequently overlooked in the diagnostic process and its clinical presentation varies between patients. In addition, we expected the data management would be simpler owing to the rarity of the disease and the relatively low number of PubMed entries. We reviewed the abstracts of the PubMed entries to retrieve descriptions of factors that may hinder its diagnosis or advice on its diagnosis. Finally, we examined which cognitive processes are represented by these descriptions.

Interim Results
We were able to summarize 18 of the 25 cognitive factors into 4 cognitive processes in the information processing stage and 5 cognitive processes in the verification stage. To develop the search filter, we selected 62 words from the abstracts of 475 entries in the initial search (“Diagnostic Errors” AND “Decision Making”) and we classified the words into 4 groups: “diagnosis”, “decision making”, “error”, and “clinical”. We joined the words within the same group using “OR” and concatenated the groups with “AND” to develop the search query. When we combined this filter with the index term porphyria, a total of 250 out of 4735 entries were extracted that included the keyword porphyria and had an abstract. The abstracts of about half of these entries included descriptions to indicate that the article described the analysis or prevention of decision-making errors in the diagnostic process. We are currently analyzing which cognitive processes are related to these descriptions.

Conclusion
Plotting the cognitive diagnostic processes over time and mapping the cognitive factors associated with diagnostic errors should facilitate the analysis of decision-making errors in the diagnostic process that have been reported in the literature. We believe that the cognitive processes defined here can be used to analyze other cases of diagnostic errors, and to develop interventions aimed at preventing these cognitive errors.

Data-Driven Mobile Medical Immunization Clinic for Veterans

Christopher Hollweg, MD, MPH1, Andrew Muth, MD1, Valentin Rivish, PhD2, Pamela Garcia-Filion, PhD1, Hamed Abbaszadegan, MD, MBA2
1University of Arizona College of Medicine, Phoenix, Arizona; 2Phoenix VA Healthcare System, Phoenix, Arizona

Purpose
Despite best efforts the immunization rates among veterans remains low. Methods of routine clinical reminders for providers, annual mailings, and standing nursing orders have had variable levels of success. The use of mobile medical vehicles (MMVs) has shown to have an impact on clinical care including immunization rates, but limited work has been done with regards to optimizing the location of these mobile clinics. The purpose of this informatics project is to evaluate the use of data analytics and geomapping to mobilize a medical vehicle for immunization services to locations with the greatest underutilization of services.

Methods
The project utilized a randomized prospective design to identify residential areas with the lowest immunization rates among veterans for a community immunization event. Using the health record system at a metropolitan healthcare system, veteran location was geocoded to the centroid of the residential address on record. The intervention evaluated was a data-driven geolocation approach to optimize immunization delivery (data-driven optimized) versus a convenience location (non-optimized). The target vaccinations were influenza, pneumococcal and Tdap. Residential zip code areas were rank ordered based on lowest immunization rates. From the top 10 areas, 3 zip codes were randomly selected. Two were matched with an adjacent (top 10) zip code based on similar socio-economic statistics (i.e. median age, median household income, and median home sales price), and the third was matched with itself (as it had no adjacent top 10 zip code to pair with). Within the 3 zip code pairs, one zip code received a MMV event at a data-driven optimized location versus a conveniently located MMV event at the paired zip code. The project occurred during February 2017 over a 3 week period, and the order of scheduled events was randomized for the 6 sites. Veterans were notified twice of the event, once by mail with a letter designating what specific vaccine(s) that veteran was due for, and the other was either secure messaging via patient portal or telephone call. At events, veterans were asked to fill out a form indicating how they were contacted for the event, and which method they preferred.

Results
During the project’s course, the MMV delivered 767 immunizations to a total of 461 veterans out of a target population of 4,917. Use of a data-driven approach increased the immunization rate up to 2.4-fold [1.19 (pair-1) 2.4 (pair-2)], compared to the non-optimized approach, among areas with an adjacent zip code. For the self-paired zip code, a 4.8% increase in vaccination rate was seen from the data-driven optimized event, despite a previous non-optimized event for the same zip code. The data-driven optimized locations had 4.0% more veterans attending. All p-values were < 0.05. The average distance from the veteran to the location optimized vaccination events was 0.7 miles and 7.8 miles for the non-optimized events.

Conclusion
The results of this project indicate that a data-driven approach to MMV placement has a statistically significant impact on both veteran attendance and the amount of clinical care able to be given in the form of immunizations administered. This suggests that this model for MMV deployment and mobile clinical care is more effective than a non-data-driven approach. These methods can likely be applied to other mobile care modalities that use MMVs.
Standardization of Prescribing Data in PCORnet: RxNorm Concept Unique Identifiers in Multi-Site Research

Casie E. Horgan¹, MPH, Jessica L. Sturtevant¹, MS, L. Charles Bailey, MD, PhD², Lindsey E. Petro¹, Julia A. Fearrington, MPH¹, Juliane Reynolds, MPH¹, Jeffrey S. Brown, PhD¹, Jason P. Block, MD, MPH¹

¹Harvard Medical School and Harvard Pilgrim Health Care Institute, Boston, MA; ²Perelman School of Medicine and University of Pennsylvania, Philadelphia, PA

The National Patient-Centered Clinical Research Network (PCORnet) is a large, distributed research network (DRN) facilitating multi-site observational research and clinical studies. PCORnet uses a common data model (CDM) to standardize data across sites to allow for distributed querying. PCORnet’s CDM is based largely on the well-established Food and Drug Administration’s Sentinel Initiative CDM, with modifications to include Electronic Health Record (EHR) primary data sources and new data domains including prescribing and vital measurements. Given the PCORnet CDM is still early in its development, ongoing characterization and knowledge management will be integral to the long-term success of PCORnet.

The PCORnet Antibiotics Study (ABX)—which investigates the effects of type, timing and amount of antibiotics prescribed during the first two years of life on weight outcomes later in childhood—was the first study to use the PCORnet Prescribing table. As such, the ABX study team developed, tested, and implemented a Study-Specific Data Characterization (SSDC) distributed program to assess network data heterogeneity and usability via detailed domain and variable analyses specific to the ABX study cohort and protocol. Using SSDC, the ABX team was able to identify several key Prescribing table issues requiring remediation:

1. **Concept Unique Identifier (CUI) Missingness**: RxNorm is a clinical drug nomenclature system developed by the National Library of Medicine. The system uses CUIs to provide a standard representation for medications. Missingness was identified via checks that assess population of the RxNorm_CUI CDM variable. Among the 31 responding sites, approximately 4% of CUI codes were missing. However, missingness varied widely, from 0-95% of CUIs at individual sites. Because prescriptions (Rxs) for antibiotics with missing CUIs cannot be identified by analytic programs and would subsequently lead to misclassification of exposure, CUI missingness should, ideally, be addressed through complete mapping of Rx records from the EHR to the CDM.

2. **CUI Specificity**: CUI codes have varying levels of specificity ranging from the most granular specific generic or branded drug formulations—which include ingredient, dose, and drug form—to least granular ingredient-only codes. SSDC identified certain sites mapping exclusively to ingredient-only codes. For the ABX study, sites which used ingredient codes were typically unable to differentiate between amoxicillin and amoxicillin/clavulanate—an important distinction when comparing effects of broad versus narrow spectrum antibiotics. Researchers should ensure drugs are mapped to codes with the most granular level of specificity possible.

3. **Date Completeness**: The PCORnet CDM has three date fields in the Prescribing table—Rx_Order_Date, Rx_Start_Date, and Rx_End_Date. These variables had differential completeness across sites. To account for differential availability of these critical study variables, we had to implement a hierarchy to indicate which dates should be used to identify records. The ABX study instituted a hierarchy that relies first on Rx_Order_Date and, if Order_Date is missing, on Rx_Start_Date.

4. **Unique Prescriptions**: Examination of RxNorm_CUI frequencies suggested that some sites were using multiple codes at different levels of specificity to represent the same Rx, thereby creating duplicate records. This can cause critical issues if steps aren’t taken to de-duplicate records either in CDM formation or in analyses. To address this issue the ABX study team instructed sites to select the single code that provides the greatest degree of specificity for each Rx.

Overall, ABX investigations identified several important issues that required additional time and effort for the sites and the analytic team to resolve before the PCORnet Prescribing table could be used for the study. Knowledge management and application of lessons-learned will be essential for the long-term usability of prescribing data for PCORnet research. In the future, further characterization and exploration into different types of cohorts (adult vs. child) or medications (chronic vs. acute) will be necessary to expand Prescribing table knowledge.

Data Heterogeneity Among CMS Data Assets: Challenges and Opportunities for PCOR

Lauren Hovey, MA\(^1\), Rina Dhopeshwarkar, MPH\(^1\), Prashila Dullabh, MD\(^1\)

\(^1\)NORC at the University of Chicago

Introduction
The Learning Health System requires an infrastructure that leverages heterogeneous data for secondary research in order to generate clinically relevant insights that can be translated into practice. Given their utility for research in general and patient-centered outcomes research (PCOR) in particular, we conducted a literature review of the Centers for Medicare and Medicaid Services’ (CMS) data to examine data heterogeneity, and strategies and considerations for researchers interested in leveraging them for PCOR.

Research Objective
We define data heterogeneity as the variability among data (e.g., structure, format, terminology), given different sources, modes of collection, and intended uses. CMS data are a rich resource for PCOR, given their national reach and the diversity of data contributors. This gives rise to heterogeneity, which CMS has made significant efforts to address to increase its usability and availability for research (e.g., as part of the Open Data Initiative).\(^1\,^2\) Certain challenges remain, which we explore in more detail and couple with proposed solutions.

Study Design
We conducted a review of peer-reviewed and grey literature, targeting Medicare and Medicaid claims, marketplace data, quality reporting and assessment data, and beneficiary data under CMS purview. The search returned 355 articles, which we culled to 38 via title/abstract screening and full text review. A supplementary search and review of reference sections returned an additional 13 articles.

Principal Findings
Several specific types of issues consistently challenge the conduct of secondary research with heterogeneous data: delayed or missing data, non-standard data formatting, and state-level variation, all of which present methodological/validity challenges. Delayed or missing data results from incomplete reporting or collection, delays in availability, changes in patient eligibility for Medicare/Medicaid that truncate records, or policy changes that affect how and which data is collected. Data quality issues can be mitigated through linkages between data sets that fill gaps within a single source. Non-standard formatting arises from both provider- and source-level variation, including lack or inconsistent application of standards, and underlying differences in the fields within a data source. Electronic health records are a rich source of clinical data, therefore data element and content standards achieved via more rigorous certification criteria could address a considerable amount of heterogeneity and incompleteness. State-level variation typically arises from differences in Medicaid reporting requirements across states, and the incentives for managed care organizations involved in quality control. Statistically, imputations, attribution algorithms and risk adjustment can be applied to overcome data bias and enhance research reliability and generalizability. Finally, best practices and guidance related to building sustainable PCOR data infrastructure (e.g., distributed research networks) help orient the data collection process around secondary research, through which data heterogeneity and quality issues can be collaboratively addressed.

Conclusions
Heterogeneity among CMS data is a natural consequence of the breadth and diversity of its sources. Although heterogeneity creates challenges for conducting secondary research, CMS invests considerable time and effort in cleaning and harmonizing the data made available to researchers, and the literature reflects successful use of this data for PCOR. A close study of the underlying sources of data heterogeneity as well as practical solutions through standardization and data linkages may aid PCOR researchers to more efficiently address data quality issues.

A Dashboard to Help Clinicians Identify Hospitalized Pediatric Patients at High Risk of Medication Errors

Jonathan D. Hron, MD

Boston Children’s Hospital, Boston, Massachusetts

Introduction

Hospitalized pediatric patients are particularly vulnerable to medication errors. Factors associated with increased risk of medication errors include patient age, health literacy, number of medications, number of high risk medications and chronic conditions. While there is no consensus on what constitutes high risk medications in pediatrics, one area of concern is the need for compounding medications that are not commercially available in liquid form. Using these concepts, an interactive electronic dashboard was created to help identify hospitalized pediatric patients at high risk for medication errors.

Methods

Using the Boston Children’s Hospital enterprise data warehouse a query was created to identify all hospitalized patients. The query included all documented medications and prescriptions from each patient’s home medication list, excluding durable medical equipment and placeholders such as “no home medications.” Also included were the chronic problem list, hospital service and hospital unit caring for the patient. This report was used to create an electronic dashboard displaying a combination of interactive tables and graphs. The EDW is updated at midnight each day such that any report generated will display data for all bedded patients on the day prior. Filters for medications, chronic problems, hospital service and unit allow the user to select specific populations of patients. A sample dashboard was reviewed on March 8, 2017. The median and range were calculated for number of home medication and chronic problems. By filtering to only patients with a medication including the word “compound,” a subset of patients receiving liquid medications not commercially available were identified.

Results

The dashboard identified 286 inpatients on 43 services across 19 hospital units. In total there were 2,560 items on the patients’ home medication lists (median 6; range 1-61). Forty seven patients (16%) had more than 15 items on their medication list. There were 1,751 chronic problems recorded (median 4; range 0-44). The hospital services with the most number of items on the home medication list per patient were the Young Adult Unit (serving young adults with cystic fibrosis and other chronic pulmonary diseases) (27.8 items per patient), Pulmonary (19.3 items per patient) and the Intermediate Care Program (an ICU step-down unit) (17.1 items per patient). There were 25 patients receiving at least one compounded medication that is not commercially available (range 1-4 compounded medications per patient).

Conclusions

An interactive electronic dashboard was used to identify hospitalized pediatric patients, with filters that allow the user to quickly identify patients who may be at high risk of medication errors. While only a baseline, the data suggest a significant portion of hospitalized patients are at risk. Utilizing dashboards such as this may help clinicians and hospital administrators direct additional resources to patients in need. Future studies will attempt to correlate medication errors and adverse drug events with specific patient populations, investigate whether use of the dashboard may reduce such events as well as what types of interventions are most effective.

A System for Monitoring Stability, Usage and Data Completeness in OpenMRS Electronic Health Records in Rural Rwanda

Fraser HSF, MBChB MSc1, Mugisha M PT, MPH2, Richards J, MS, MPH, PhD3, Chelliah W MSc4, Ngenzi J, BSc PhD2, Gaju E, BSc, MSc5, Umubyeyi A MD, PhD2

1University of Leeds, Leeds, UK; 2University of Rwanda, Rwanda; 3U.S. Centers of Disease Control and Prevention, Atlanta, Georgia, USA; 4Jembi Health Systems, Cape Town, South Africa, 5Rwanda Biomedical Centre, Kigali, Rwanda

Abstract

EHR systems in low income settings can be unreliable with poor usage rates and data quality. We implemented a tool in 160 clinics in Rwanda to transmit data to central system (DHIS2) to monitor and improve EHR function.

Introduction:

In Low and Middle Income Countries (LMICs) there is increasing use of EHRs for clinical care, quality improvement, program management, disease surveillance and research. OpenMRS is an open source, modular EHR first implemented in Kenya and Rwanda in 2006[1], used in over 50 LMICs. Several countries have rolled out OpenMRS to hundreds of sites and are integrating the system into a national eHealth architecture. There are important challenges in achieving and maintaining stability, usage levels and data quality in EHR implementations in LMICs, and a lack of early warning of problems. As part of a CDC funded impact and cost study of OpenMRS use for HIV care in Rwanda, we developed tools to monitor the performance of systems in near real time.

Methods:

An OpenMRS software module was developed to track (1) server up and down time, (2) daily usage based on data entered, (3) completeness of key indicator variables. The latter include total numbers and numbers in last working day of: all patients; new patients; patient encounters; CD4 counts; and HIV Viral Load results. The first version of the Server Monitoring Tool (SMT) was field tested at 20 sites in 2014. A second version was developed in 2015 with capability to send data to the Rwanda national health monitoring system based on DHIS2[2], speeding recognition of malfunctioning sites. Uploaded data was validated against local reports in EHRs.

Results:

The SMT was successfully installed in 160 sites in September 2016. Fifty six sites automatically send updates to DHIS2 if internet is functional. 49 sent at least once per month but OpenMRS typically lacks a direct internet connection and staff copy reports from the SMT into DHIS2. Data can be viewed in DHIS2 reports. Of 25 sites reporting on 28th February 2017 mean uptime was 50.1%, range 7%-100% and 6 sites had 85% or better uptime.

Discussion:

Monitoring data is being used to rapidly detect power, network and IT problems and ensure system are functional during clinic hours. Early warning of missing data (e.g. viral loads) is important to ensure good HIV care, allow monitoring of general data quality, and assist study site selection, and will be complemented by a user survey.

Conclusions:

Despite all challenges faced in implementation sites, real time monitoring (SMT) of EHRs in LMIC is an innovative technology to support usability, user satisfaction, and data quality, and enable early interventions to address problems and improve use confidence. It is a key component in our process evaluation of OpenMRS.

Real-world Evidence for Phenotyping Chronic Diabetic Kidney Disease

Lynn S. Huang¹, Xufei Zheng², Fang-Chi Hsu¹, Jianzhao Xu³, Maggie CY Ng³, Donald W. Bowden³, Barry I Freedman⁴, Jing Su¹

¹Department of Biostatistical Sciences; ³Center for Genomics and Personalized Medicine Research; ⁴Department of Internal Medicine, Wake Forest School of Medicine, Winston-Salem, NC, USA; ²School of Computer and Information Science, Southwest University, China;

Abstract
We developed a novel algorithm to accurately and reliably identify chronic diabetic kidney disease (CKD) stages and onset time using electronic medical records. The phenotyping results demonstrated significant improvement over current diagnosis-based phenotypes and make evidence-based clinical research of the progression CKD possible.

Introduction
CKD is a major, life-threatening complication of diabetes. In 2010-2011, diabetes accounted for 44% of new kidney failure cases [1] and a third of adults with diabetes have CKD [2]. CKD is classified in severity-based stages according to the reduction in kidney function using estimated glomerular filtration rate (eGFR). Clinical research and practice require accurate and reliable identification of CKD stages and onset time, but such information is largely missing or inaccurate. Electronic medical records (EMRs) allow evidence-based CKD stage phenotyping. Previous attempts at staging CKD using EMRs have focused on CKD staging, without identifying onset time, and have relied on physicians’ written notes rather than laboratory results.

Results and Discussion
According to current clinical guidelines and practice, we developed a novel, EMR-based algorithm (Fig. 1) to accurately and reliably detect CKD stages and onset time. Renal function was estimated by eGFR according to serum creatinine level using the CKD-EPI 2009 standard [4]. CKD stages were determined by persistent evidence of eGFR reduction, in which a single below-threshold eGFR is confirmed by additional evidence in the next 1-12 months. The algorithm’s novel use of hierarchical stage definitions, where evidence of more severe CKD stages indicates the previous passage through less severe stages, allows both identification of CKD stage and onset time. This algorithm is robust against transient eGFR changes due to acute kidney diseases, trauma, medication, or clinical procedures. Nephrologists reviewed and confirmed the accuracy of the phenotyping results. We implemented the algorithm and phenotyped CKD stages for 79,434 adult type 2 diabetes patients at Wake Forest Baptist Health. Dramatic improvement was shown over the ICD-based diagnosis records. For example, among the 16,885 identified Stage 2 CKD cases, only 10.1% had the corresponding ICD documentation. On average, CKD Stage 2 diagnosis was documented 10.84±5.51 years after the detected onset time.

Conclusion
The novel EMR-based phenotyping algorithm can accurately and reliably detect CKD stages and onset times. This approach improves over current CKD staging approaches by identifying CKD stage onset time, removing the influence of temporary eGFR changes, and relying directly on laboratory results. The evidence-based phenotyping of CKD stages provides critical stage information for clinical research and patient care.

Semantic Analysis of a Nursing Home EHR for Sensor Data Annotation

Zhongkai Zeng, Mihail Popescu, PhD
University of Missouri, Columbia, MO

Abstract

Eldercare monitoring using non-wearable sensors is an emerging solution for improving care and reducing costs. However, attaching clinical significance to the large amount of data generated by the sensor network is challenging for the clinical personnel. Using electronic health records (EHR) in conjunction with a monitoring system enables sensor data annotation with clinical terms that could ease clinicians’ interpretation. The question is if a nursing home EHR contains enough clinical information to enable such a task? We performed a semantic analysis of a dataset that consisted of clinical records of 54 residents from Tiger Place, an aging in place facility, collected over five years. We found an average of 1.5 clinical terms/resident/day available for sensor data annotation.

Introduction

Sensor networks have emerged in the last decade as a possible solution to reducing cost and improving quality of eldercare. Tiger Place is an aging in place facility for seniors located in Columbia, Missouri. Each resident included in the study (54 as of September 2016) has a computer in his/her apartment that collects data from a wireless sensor (bed, motion and gait) network. The health data for each resident is stored in a home-grown nursing EHR (see more details at http://eldertech.missouri.edu/papers). We intend to use the extracted clinical terms to annotate sensor data using a “guilt by association” approach (widely used in annotation of biological sequences) in which similar sensor patterns are assumed to be produced by similar resident clinical conditions.

Methods

We extracted text from three “description” fields found in three tables of our HER: Visit, Incident and Medication Error (see Table 1). We then used MetaMapLite (https://metamap.nlm.nih.gov/ MetaMapLite.shtml) to extract 13 semantic type categories (see Table 1) from each description field that we assumed to be linked to clinical conditions.

Results

The number of terms obtained from each table and for each semantic type is shown in Table 1. We obtained a total of about 139,000 terms which translates in about 1.5 terms/resident/day. Most terms were found for “finding” (does turn, does shave, able, etc), “pharmacologic substance” (Levaquine, Calmoseptine, Xanax, etc) and “body part or organ” (foot, hip, intestines) categories. However, most useful for our purpose seem to be the “sign and symptoms” category: pain, back pain, weakness, etc. We note few problems: some terms does not seem to make sense (phsu: pharmaceutical preparations; fndg: in care) and the surprising lack of the “disease and syndrome” term category.

Annotation of Research Common Data Elements Using Clinical Terminologies

Vojtech Huser, Cynthia Burke, Minh-Diep Nguyen, Liz Amos
National Library of Medicine, NIH, Bethesda, MD

Introduction

In recent years, Common Data Elements (CDEs) have been developed to unify data collection in clinical research studies. Since 2015, a CDE repository maintained by the National Library of Medicine allows retrieval of CDEs across several initiatives. With wider availability of de-identified patient-level clinical trials’ data across research studies, organizing data elements using a hierarchical system can improve ability of researchers to discover relevant data to re-use. Free text and synonym-extended search is often used to discover data elements, however using hierarchical relationships available in medical terminologies (such as Systematized Nomenclature of Medicine Clinical Terms; SNOMEDCT) may provide better search features. We present our pilot work on annotation of CDEs using a framework that is inspired by the SNOMEDCT compositional grammar (see snomed.org/scg). In addition to cross-trial data retrieval, such annotation can also help during trial design stage or in discovering overlaps across various CDE initiatives.

Methods

From an informatics and statistical perceptive, we structured all CDEs by their data type, such as boolean, date, text or number. In selecting the CDEs to analyze, we only included initiatives that in addition to individual CDEs also distribute 100 or more pre-configured case report forms (e.g., “A questionnaire to assess migraines and headaches”). CDE initiatives that fulfilled these criteria were PROMIS, PhenX and CDEs of the National Institute of Neurological Diseases and Stroke (NINDS). We later ruled out PROMIS because their CRFs contained exclusively CDEs of value-list data type. NINDS forms were also ruled out due to ongoing development. For finding concepts, we used the official SNOMED International browser. To evaluate mapping quality, we classified CDE-SNOMEDCT_Expression mappings into classes of exact match, partial match and no match.

Preliminary Results and Conclusion

Using PhenX REDCap download option, we obtained input data on 564 forms (or possible form sections) that reflected various PhenX protocols (e.g., Sleep Apnea child protocol). These forms contained a total of 22,705 individual CDEs. In a pilot research mode, we selected the following data types: date (example: “Date chemotherapy completed?”), boolean (example: “Are you currently in treatment for substance abuse?”) and number (example: “How old was your child when he/she completely stopped breast-feeding or being fed breast milk?”). A team of annotators annotated a total of 228 data elements. An example of an annotation would be (simplified view of the full expression): “The date the sleep disorder started?” : 298059007 Date of onset (observable entity)| + 39898005 |Sleep disorder (disorder). We were able to employ existing SNOMEDCT attributes within the draft concept model for observable entities (e.g., 704318007 |property type (attribute)|, or 370132008 |Scale type (attribute)|. The poster will present detailed data on exact matches identified, SNOMEDCT compositional grammar observations, and draft CDE annotation guidelines formulated by our team. The project website at https://github.com/lhncbc/CDE contains interim results for those outputs. Our pilot study suggest that CDE annotation can facilitate data discovery and CDE quality assurance. For some CDEs, we further considered ways of using the annotations to relate case report form data to observational data formatted in a common data model (e.g., the Sentinel model). For example, the annotation for the data element ‘Year inserted permanent pacemaker?’ follows a pattern that can be automatically converted into an observational data query. During the study, we have made several new concept submissions to SNOMEDCT (US content request system) with many of them accepted. We also hope to contribute to existing IHTSDO initiatives around observable entity concepts and compositional grammar. Through our participation on the NIH CDE Task Force, we hope to provide initial input for a discussion on annotation guidelines that can optionally be adopted by the CDE initiatives.

Transformation of Disparate Terminology Standards to a Common Model

Eric Y. Hwang, MD, AMA1, S. Sarah Choi, BS, PMP1
1Deloitte, Arlington, VA

Introduction

The healthcare environment today contains countless medical terminology standards developed by disparate Standards Development Organizations (SDO), each unique and serving a specific function. To reflect the rapid evolution of medicine and technology, the content that represents these various domains is continuously updated and is released at varying frequencies and schedules. In addition, Knowledge Workers will often times create localized derivative content that is dependent on SDO content. Therefore, it is critical that this medical content is updated as soon as it is available to accurately perform quality assurance on systems consuming the content in order to support patient care.

Purpose

Storing disparate data points in a common model is vital to a terminology ecosystem1, 2. By using a common model, unrelated SDO content (e.g., SNOMED, LOINC, RxNorm) or locally created content (e.g., maps or values to support institutional requirements) represented by different data models, can share a similar construct and be stored together. Because content is continuously updated and released, it is critical for this common model to properly segregate content such that it is shielded from another content's update. This, in turn, allows systems and users to have access to the latest available content.

Approach

To simulate maintenance of SDO and local content, our solution first transformed version (V1) of disparate SDO content (SNOMED and LOINC, each released in a different format) into a common model. We then transformed the Regenstrief Institute and SNOMED International Collaboration Files (SNOMED/LOINC mapping) to simulate the injection of a map set into the same model. This native content was transformed into this common model by using code written in Java to consume individual native content source files, then parse pertinent data points to fit within the common model objects. Along with version information, each unit of content (SNOMED, LOINC, SNOMED/LOINC map) is stored together in a single database, but is also conceptually segregated from each other. We then updated V1 to the next version (V2) of SNOMED without impacting LOINC or SNOMED/LOINC Collaboration data. Subsequent queries were then executed to identify maps that were impacted due to the simulated SNOMED update to illustrate a content update. Export of each unit of content was then created to illustrate that a common query could be used despite disparate native SNOMED and LOINC formats.

Discussion

Using a common model to store and maintain SDO and local content has several technical and clinical advantages, specifically it:

- Provides a single model and single extraction mechanism to store and query against different clinical content
- Quickly generates a report of change types and newly available content for knowledge workers to assess impact1
- Allows reusable Java code in subsequent releases to transform source data into the common model as well as isolating these codes to address any source information model changes, format changes, or newly introduced information
- Uniformly exports content in a format that is defined by institutional requirements for easier downstream data consumption, regardless of the original native content format

In summary, rather than treating these released units of content as individual silos, a single common model would allow disparate content to be handled uniformly.

Unsupervised Analysis of Activity Patterns in Eldercare Monitoring

Omar Ibrahim, Mihail Popescu, PhD, James Keller, PhD
University of Missouri, Columbia, MO

Abstract

Eldercare monitoring using non-wearable sensors is an emerging solution for improving care and reducing costs. Abnormal sensor patterns produced by certain resident behaviors could be linked to early signs of illness. We propose an unsupervised method for detecting abnormal sensor patterns based on a sensor sequence clustering approach. A preliminary analysis of the method was conducted on data collected in an eldercare facility.

Introduction

Sensor networks have emerged in the last decade as a possible solution to reducing cost and improving quality of eldercare. Tiger Place is an aging-in-place facility for seniors located in Columbia, Missouri\(^1\). Each resident included in this study (37 as of March 2017) has a data logger in his/her apartment that collects data from a wireless sensor network. Each sensor network consists of several types of sensors mounted throughout the resident’s apartment, including motion and bed sensors. The health data for each resident is stored in a home-grown nursing EHR (see more details at http://eldertech.missouri.edu/papers).

Methods

For each day, the sensors firings were converted into sequences of discrete symbols where each symbol represents one sensor type. The activity (behavior) of a resident is represented by a sequence of sensor firings as it would be represented by his/her genome. In this study, we used 11 different bed and motion sensors. We split the daily sensor sequence in subsequences using a separation threshold of 30 seconds which would provide enough granularity to capture daily activities. Our pilot dataset consisted of 14 days of resident sensor data. To ground truth our approach, we employed a normal/abnormal labeling of each day based on clinically validated health alerts from our EHR. Days on which a health alert was generated by a fall or other health event were labeled “abnormal”, while days on which no alert was generated were labeled “normal”. To explore behavior patterns captured by our sensors, we clustered both the normal and the abnormal datasets using hierarchical clustering and used Calinski-Harabasz index to find the most probable number of clusters.

Results

In figure 1, we show the clusters obtained for normal (1.a) and abnormal (1.b) days projected in 3D using t-SNE\(^2\). First, there are more clusters (activities) on normal days (21 clusters) than on abnormal days (17). Second, the cardinality of some clusters, such as bed restlessness (figure 1.c and 1.d) and bathroom visits is greater on abnormal days, while the cardinality of living room activity is greater on normal days. Finally, after generating the time histogram for each cluster, the timing of activity on normal days seems to be more consistent than that of abnormal days. We use above observations to differentiate normal/abnormal days and produce more meaningful health alerts.

Clinical Informatics 101 Training in Family Medicine

Tochi Iroku-Malize MD MPH MBA1,2, Barbara Keber MD1,2
1Zucker School of Medicine at Hofstra/Northwell, Long Island, NY;
2New York State Academy of Family Physicians

Abstract

The creation of board certification in the field of clinical informatics by the American Board of Medical Specialties brought to light the need for medical education to offer earlier exposure to the subject matter so that learners would understand the options of pursuing further training, utilization in primary care as well as the potential for a subsequent clinical informatics career. We created a workshop to introduce the basics of clinical informatics which was presented at three family medicine residency programs, the departmental academic day and the state family medicine specialty society scientific assembly. We will describe the workshop developed.

Introduction

The family medicine department of Zucker School of Medicine at Hofstra/Northwell (formerly Hofstra Northwell School of Medicine) and Northwell Health, faced the challenge of introducing clinical informatics into the continuum of medical education for students, residents and physicians. This need was enhanced by the expansion of our health system, the acquisition of various electronic medical record systems, meaningful use attestation in the ambulatory settings, as well as the then impending ICD-10 activation.

Methodology

We first looked to current curriculum guidelines for clinical informatics within our specialty. The American Academy of Family Physicians had developed guidelines in 1996 with the most recent revision in 2014. They justified the need for clinical informatics training by stating that “The ultimate concern of the physician is patient welfare, yet the medical knowledge required of physicians is beyond the brain's physical capability… physicians must leverage information technology to help ensure safe, high quality care... acquisition, input, retrieval, analysis, and sharing of clinical and administrative data are crucial components of physician proficiency in this expanding field.”1 We then reviewed what was available from the clinical informatics specialty organization, namely American Medical Informatics Association (AMIA). The 10x10 course was taken by key faculty to get the latest information and to update baseline knowledge. Curriculum from graduate clinical informatics programs were reviewed and information from the Office of the National Coordinator for Health Information Technology (ONC) was put into lay terms for the introductory course.

The workshop was created utilizing a variety of learning methods that involved individual answers, team based learning and large group report outs. The timing for the workshop was 90 minutes with time left for questions and answers. The main topics covered were:

- Key definitions (audience response system)
- Resources and support tools for clinical decision making (clinical case based scenario)
- Basic computer systems and networks (hands on teambuilding activity)
- Data modeling and database systems (office based scenario regarding immunizations)
- Policies and procedures to ensure security and integrity (hospital based scenario)
- Application of clinical informatics (small group activity)
- New technologies (audience response system)

A total of 8 workshops were held (3 residency programs, department academic day and state scientific assembly) where we reached 80 medical students, 66 residents, and over 50 clinicians. A survey was given to those at the state session which assessed learner knowledge of clinical informatics, ability, formal and informal training, relevance in current or future career. There were 30 respondents of which 72% were male. 3% were medical students, 16% were residents, 7% junior attendings (<5yrs in practice) and the majority senior attendings. What follows is preliminary analytics of the data. With regards to self-rated ability in EMR utilization 38% felt their skills were excellent while 24% felt their abilities were poor/fair. In terms of utilizing decision support tools, 27.5% felt their skills were excellent compared to 20% who rated their abilities as poor/fair. These results were mirrored with regard to consulting online reference materials. The majority of respondents (regardless of year of practice) felt that formal and informal training in medical school and residency was poor, and that clinical informatics was very important for physician related tasks or responsibilities.

Conclusion

Training medical students, residents and physicians in basic clinical informatics is vital to the ability of physicians to navigate the current health care system. The goal of our program was not to create advanced learners of informatics, but rather to serve as a method of introducing the concepts. Future studies need to be done to determine the utility of the workshop in creating a difference with regards to practice and in the long term knowledge, skills and attitudes gained during the sessions.

linguistic Summarization of Sensor Data Leading to Health Events

Akshay Jain, Mihail Popescu, PhD, James Keller, PhD
University of Missouri, Columbia, MO

Abstract

Sensor networks installed in homes of elderly hold promise in helping them live independently. However, understanding the large amount of data generated by these sensors presents a unique set of challenges. One solution to this problem is to display the relevant sensor data in a linguistic format when a possible health event is detected. We present an approach for the linguistic summarization of relevant information based on Linguistic Protoform Summaries (LPS). The application of the method is illustrated with data obtained from a real eldercare setting.

Introduction

In order to help elderly population in living independently for longer periods of time, apartments at TigerPlace, an aging in place facility located in Columbia, Missouri, are equipped with motion, bed and gait sensors (see more details at http://eldertech.missouri.edu). The variety and volume of the sensor data and derived measurements produce unique visualization and interpretation challenges for clinicians. In this work, we design an eldercare monitoring system that summarizes in natural language only the part of the sensor data related to a given health event.

Methods

In a survey of 22 clinicians, we found correlations between changes in sensor measurements such as bathroom activity, bed restlessness and apartment motion and 13 clinical conditions often found in elderly. Here, we illustrate our linguistic summarization method using two Urinary Tract infection (UTI) cases. As indicated by the survey, a change in one of the activities alone may not indicate a change in overall activity pattern of a person, but if the change is present in multiple sensor feature streams, then it can be of real concern. To this end, we summarized the data comprising of multiple sensor features in natural language using Linguistic Protoform Summaries (LPS).

Results & Conclusions

We show our summarization method for two weeks of data leading to a UTI diagnosis (1,2 in Figure 1) and two previous weeks (3,4), which were considered normal based on our EHR data. The summaries that distinguished the UTI and normal days are shown in Table 1, along with their Truth Values. The Truth Values of the summaries show that, as compared to normal days, the UTI diagnosis event has more days with bathroom motion and bed restlessness being high concurrently. This can be used treated as a data summary, as well as to trigger alerts. For example, a Truth Value higher than 0.5 can be used to trigger a UTI alert for days 1 and 2 but not for days 3 and 4. Based on our clinician input, we plan to design linguistic templates for 13 chronic conditions found in elderly, as outlined in our survey.

Acknowledgment

This work was funded by the National Library of Medicine grant #R01LM012221.

Business Process Modeling in the Arden Syntax

Robert A. Jenders, MD, MS, FACP, FACMI
Charles Drew University & University of California, Los Angeles, CA

Abstract

Context: Arden Syntax encodes knowledge as Medical Logic Modules (MLMs) to deliver clinical decision support (CDS). Business processes are part of CDS, but Arden lacks formal business process constructs. Objective: Assess the need for such constructs by evaluating the presence of business processes in MLMs. Methods: A corpus of 325 MLMs was examined. Result: At least one business process was referenced in every MLM. Conclusion: Arden Syntax could be improved with formal business process constructs.

Introduction

Arden Syntax is an American National Standards Institute formalism supervised by Health Level Seven International for representation of procedural medical knowledge with the goal of sharing units of knowledge known as MLMs. A knowledge base consists of MLMs, and an MLM, which may contain business processes, consists of 3 required categories: Maintenance (software attributes of the MLM such as author); Library (with Purpose and Explanation slots for unstructured descriptions of what the MLM does); and Knowledge (with Data and Logic slots for explicit, structured encoding of executable knowledge). While Arden Syntax has a rich set of features for representation of clinical knowledge, it lacks explicit constructs for business process modeling. Vendors and implementation sites using Arden have constructed workarounds in order to represent business processes. Business Process Model and Notation (BPMN) and the related Business Process Execution Language (BPEL) have been suggested as models for representation of workflows. These formalisms represent entities such as events (things that happen, such as escalation and conditional), activities (things that are done, such as indivisible tasks) and workflows among them. The present work assesses the prevalence of business processes in knowledge bases encoded as MLMs in order to gauge the utility of introducing business process constructs in the Arden Syntax.

Methods

A convenience sample of MLMs pooled from 5 sources—3 university hospitals and 2 vendors—was examined. Business processes, either structured in the Knowledge category or unstructured in the Maintenance category of each MLM, that align with constructs in BPMN 2.0 (such as events, activities and workflows) were identified.

Results

A total of 325 MLMs were examined. MLMs concerned mainly with lab tests were the most common (137/325 = 42%), followed by clinical assessment or classification (67/325 = 21%) and medication (41/325 = 13%). The remainder addressed administrative and miscellaneous topics. These included 430 trigger mappings that could be modeled as events such as escalation or conditional events, but often with incompletely defined workflow (e.g., responsible clinician, escalation pathways, etc). The most common events were hospital admission and a laboratory test result, while ordering of a medication or a laboratory test was the most common task. In addition, 1027 output definition statements were identified, and these would align with message flows between activities and processes containing them. Further, the Purpose and Explanation slots in the Library section of nearly all MLMs referenced business processes in narrative format that typically were not represented explicitly in the Logic slot of the Knowledge category.

Conclusions

Business processes are a common feature of knowledge represented in a convenience sample of Arden Syntax MLMs. These processes are represented in part through explicit data mappings of events, activities and message output destinations. However, more nuanced processes are present only in narrative format because of the absence of specific formal constructs that would support their representation. Arden Syntax could benefit from inclusion of additional formal business process constructs, particularly conditional events, escalation, tasks and message flows.

MALTASE: a Mobile Application To improve patients’ Access to their data Sharing preference

Chao Jiang, MS, Xiaoqian Jiang, PhD, Shuang Wang, PhD, Diana Guijarro, Elizabeth Bell, MPH, Imho Jang, Gwangnho Yun, Masud Rahman, Lucila Ohno-Machado MD, PhD, Hyeoneui Kim, PhD
University of California San Diego, La Jolla, CA, USA;

Abstract
iCONCUR (informed CONsent FOR Clinical data and biosample Use for Research) is a novel web-based tiered informed consent management system (https://ctri-iconcur.ucsd.edu/). To improve accessibility to this system, we developed mobile iCONCUR application. This application allows patients to control their decisions on sharing over twenty five categories of medical and genomic data for research. Using our application, patients can create, update, and store their data sharing preferences to iCONCUR at any time.

Introduction
The goal of iCONCUR is to facilitate the process of specifying data sharing preferences in an academic medical data center for research\(^1\). To further improve accessibility and user experience with iCONCUR we developed an iOS application in addition to the existing web portal.

Methods
Our application was built on Xcode 7.3.1 with Swift 2.3. By using the latest SWIFT 3.0 framework, all the dependency packages or libraries can be easily managed by the CocoaPods, which improves the security of the application for future development and maintenance. For the convenience of integration with the web version, we are using the same database as backend for the APP. As patients might be familiar with the existing web version of the iCONCUR portal, our implementation of mobile version ensures to reproduce the user experience of the web version and makes it as user-friendly as possible on the mobile side. For example, we redesigned the layout of the questionnaire for mobile users.

There are two major efforts that we addressed in the development. One is how to dynamically interact with database and display corresponding changes; another is to deal with the limited widget functionality for the check button. We took UITableView as our major display widget, which supports dynamic content displayed and makes the application more flexible to update. Combining a third package of check button with UITableViewCell allows us customize the row of each table, which addressed main problems in our development. See (Figure 1) for a visualization of the interface. In addition to the core functionalities, we added some useful functions such as email validation, password retrieval etc. We also covered the SQL injection attack in the development of server side.

Conclusion
Using this mobile APP, patients have more options to access their data sharing preferences. Furthermore, our application is very flexible and can be easily adapted for other similar tasks such as medical questionnaire. Such extension is relatively straightforward due to the adoption of CocoaPods, which allows hassle-free maintenance and upgrade. Also our preliminary demo video of the APP is available on https://www.youtube.com/watch?v=KLRFoHk9IHY.

Teacher evaluation and its correlated factors: a case study of introductory health informatics education

Xia Jing, MD, PhD¹, Timothy Vickers, MA², Brian O. Phillips, M.Ed¹, Kathy Jefford, BS³

¹Department of Social & Public Health, College of Health Sciences and Professions, ²Center for Teaching and Learning, ³College of Osteopathic Medicine, Ohio University, Athens, OH 45701

Introduction

Teaching is one of the three pillars, along with research and service, of academic success for a faculty member. Teacher evaluation is a critical means for new faculty members to receive feedback about their teaching. In some cases, it may be the only formal evaluation of a faculty member’s teaching performance. There are a variety of factors that can contribute to a teacher’s evaluation. We selected an introductory health informatics course at a public university to analyze the correlation between the teacher evaluation results and a series of factors over the course of six semesters between 2014 and 2016.

Methods and Results

A total of 291 students were enrolled in the course over the three-year period (six semesters). During this time, there were six evaluations, which included self-rated student scores. We calculated the average and median final grades, average assignment feedback per student per assignment (word counts), survey return rates, and student attendance rates per semester. We then compared the teacher evaluation results with these factors and calculated the correlation coefficients for these factors. Our case study shows that student self-rated scores (0.82), student attendance rates (0.62), and survey return rates (0.60) have high correlation coefficients with teacher evaluation results. Figure 1 provides a summary of the main results. Students’ average grades (0.28) and median grades (0.42) have a relatively low correlation with teacher evaluation results.

![Figure 1. Results of teacher evaluation and three other aspects of teaching over six semesters](image)

Discussion

Schlenker and McKinnon¹ have demonstrated statistically significant correlations between fewer absences and more favorable teacher evaluation results. Benton and Cashin’s review shows relatively low correlations between students’ final grades and teacher evaluation results. Our case study shows the important correlation between self-rated student scores, student attendance rates, and survey return rates with teacher evaluation results in health informatics education. Attendance rate can be utilized as an early indicator of teaching effectiveness for faculty members to adjust teaching strategies early in the semester. Our results, however, should be validated across institutions and across courses, since the correlation may not be unique to this course. Our next step will be cross-course validation.

Identifying Factors Associated with Problem List Omissions in Electronic Medical Records (EMR), to Assess Underdiagnosis in Obesity

Akshat Kapoor, PhD, MS\textsuperscript{1}, Juhee Kim, ScD, MS\textsuperscript{1}, Xiaoming Zeng, MD, PhD\textsuperscript{1}, Andrew Anderson, ME\textsuperscript{1}

\textsuperscript{1}East Carolina University, Greenville, NC, USA

Introduction

Obesity is a continuing national epidemic and the condition can have physical, psychological as well as a social impact on one’s well-being\textsuperscript{1}. Consequently, it is critical to accurately diagnose and document obesity in an electronic medical record (EMR), so that the information can be used and shared to improve clinical decision making and health communication, and in turn, the patient’s prognosis. It is therefore worthwhile to identify the various factors that play a role in documenting obesity diagnosis and methods to improve current documentation practices.

Method

IRB approval was obtained prior to commencing any study activities. We used a retrospective cross-sectional design to analyze outpatient EMRs of patients at East Carolina University (ECU) Physicians. ECU Physicians is the medical practice of the Brody School of Medicine at ECU, spread across 26 locations in Eastern North Carolina. Obese adult patients who completed an outpatient visit at any of the ECU Physicians locations, at least once between 1/1/2016 and 12/31/2016 with a corresponding BMI measure, were identified. Obese patients were identified using the measured BMI (\(\geq 30\)) entry in the EMR, recorded at each visit. Patients with any pregnancy related diagnosis were excluded, in order to avoid confounding the results. Documentation of obesity in the problem list was identified using the corresponding ICD-10 codes (E66 and below). Patients were categorized into two groups (diagnosed or undiagnosed), on the basis of a documented diagnosis (or omission) of obesity in the EMR problem list. We compared the two groups, to determine differences in gender, age group, race and patient portal use by performing statistical analysis.

Results

A total of 10,208 unique patient records of obese patients were included for analysis, of which 4,119 (40\%) did not have any documentation of obesity in their problem list. Chi-square analysis between the diagnosed and undiagnosed groups revealed significant associations between documentation of obesity in EMR and age group (\(p<0.0001\)), gender (\(p<0.0001\)), race (\(p<0.0001\)) and patient portal use (\(p=0.0133\)). Results of binary logistic regression indicate that Female (62\%, 1.3 OR), Black patients (65\%, 1.6 OR) aged 65 and below (66\%, 3.9 OR) who used the patient portal (62\%, 1.1 OR) were more likely to have documentation of obesity in their EMR, as compared to patients who were Male, White, aged 66 and above and non-users of patient portal; correspondingly. Additionally, morbidly obese patients (BMI\(\geq 40\)) were far more likely (80\%, 3.6 OR) to be diagnosed as compared to other obese patients.

Conclusion

Meaningful Use Stage 1 mandated the recording of height, weight, blood pressure and BMI as core measures of vital signs, in the EMR at each patient visit. EMR designers and developers must consider investigating automated decision support techniques to populate and update problem lists, based on the existing, recorded BMI in the EMR, in order to prevent omissions occurring from manual entry. Further studies are recommended to investigate the causes that lead to a lower rate of obesity documentation for certain sociodemographic groups. Providers must also investigate patient engagement and patient portal use as potential means of improving the quality of existing problem lists, by allowing patients to review their own problem lists.

Evolution of Research Topics in MEDLINE

Andrzej Kastrin, PhD¹, Thomas C. Rindflesch, PhD², Dimitar Hristovski, PhD¹
¹University of Ljubljana, Faculty of Medicine, Institute of Biostatistics and Medical Informatics, Ljubljana, Slovenia; ²National Library of Medicine, Lister Hill National Center for Biomedical Communications, Bethesda, Maryland, United States of America

Introduction

We investigated the dynamics and evolution of MEDLINE using network analysis and co-word methodology. Here we present findings expanding on our previous work in which we initiated research on the evolution of research topics in MEDLINE¹. Our hypothesis is that the history of the biomedical domain can be summarized in a series of co-occurrences of keywords (i.e., MeSH terms) that are associated with each MEDLINE citation and that identify its important topics. We model scientific topics as evolving communities of MeSH terms over time and explore how the temporal characteristics of the MeSH network can be used to provide insight into the historical evolution of scientific thought in biomedicine. As proof of concept, we implemented a computational experiment based on over 20 million documents in MEDLINE, from 1966 through the end of 2014. To the best of our knowledge this is the first such analysis conducted on the entire MEDLINE database. In particular, this analysis is of special interest to researchers who seek to acquaint themselves with scientific topics, trends, and collaboration opportunities.

Methods

We processed all of MEDLINE up to the end of 2014, only including citations tagged with major MeSH descriptors. In the constructed network, nodes represent major MeSH descriptors, and edges between two descriptors represent co-occurrence of those descriptors in the same MEDLINE citation. To capture critical events, we converted the entire network into static subnetworks at yearly snapshots, from 1966 through 2014. These subnetworks embed the communities (groups of nodes) of MeSH terms through which their development in time can be observed. We used the Louvain community detection algorithm to identify communities of nodes in each subnetwork. After discovering communities, we computed relationships between them, in order to track their evolution over time. The Jaccard coefficient was first used to determine whether two communities match. Next, we characterized the content of each community by computing its density and centrality. Density measures both the strength of the edges that tie the cluster of MeSH terms together as well as the cluster’s capacity to develop over time. Centrality measures the degree of interaction of a cluster with other parts of the network. Finally, we created a strategic diagram for each time slot, which is a graphical representation of the structure of the particular scientific field. We can identify four types of clusters according to the quadrant in which they appear in the diagram: (i) motor themes, which are both well developed and important for a research field; (ii) specialized and peripheral themes; (iii) themes which are either emerging or disappearing; and (iv) themes which are important for a research field but are not developed.

Results and Conclusion

This study identifies the major research focuses and the current status and trends in the life sciences. It provides a description of the intellectual structure and dynamics of the entire field of biomedicine from the perspective of frequently appearing MeSH descriptors. The results of this study show that (i) using MeSH terms is plausible for tracking historical events in the biomedical domain; (ii) the evolution of MEDLINE occurs in an incremental fashion; (iii) over the years more and more diverse research disciplines are involved in the complex process of scientific evolution, and links among them become stronger; and (iv) different research areas have different dynamic evolution patterns. When compared to existing research, this work is innovative in three respects: (i) the experimental design incorporates the longitudinal framework based on dynamic communities, (ii) we provide visualization of the evolution of research topics, and (iii) we propose a simple community labelling approach based on MeSH terms.

Development and Implementation of Clinical Data Management Technology for Clinical Research

Shogo Kato, Ph.D.1, Yoshihiko Morikawa, Bachelor2, Seiji Mitsui, Bachelor1, Takeshi Kuriyama, Bachelor1, Takahisa Ogasawara, Bachelor1, Kazuyuki Saito, Bachelor1, and Naohisa Yahagi, Ph.D.3

1National Center for Clinical Research and Development, Tokyo, Japan; 2Tokyo Metropolitan Children’s Medical Center, Tokyo, Japan; 3The University of Tokyo, Tokyo, Japan

Introduction
Advances in information management technology create opportunities for researchers to more easily share information in clinical research. Such technology allows clinical research and patient care to become more integrated and interactive. Data sharing is necessary to improve the quality of healthcare and to accelerate the progress in clinical research from bedside to community.

As the Electric Medical Record (EMR) in Japan has been evolved from ordering system, items in EMR are not standardized, because it has not been designed to share data among multiple sources. Therefore, collecting, integrating and reconstructing the high quality data into a centralized system from many institutes is challenging.

This study aims to evaluate the importance and effectiveness of code mapping to assemble data for clinical research from different formats and multiple data sources into a centralized system.

Method
The Division of Data Science for Clinical Research at National Center for Child Health and Development, Tokyo, Japan, implemented clinical data management system (CDMS), which is a user-friendly, versatile, and secure network system for clinical data. The data was actually collected from 35 clinics and 11 hospitals geographically dispersed whole Japan. There was no such report before, at least in Japan.

The CDMS used a metadata-driven model that contained built-in knowledgebase to control medical terminology. It was well-constructed knowledgebase consisted of multi-indexed data such as physical examination, laboratory, diagnosis and treatment. The data dealt in HL-7 standard, however, the code for items from EMR such as drug, ICD and laboratory was various among each institute or vendor.

The items in the central database were mapped into the standard code from local codes, by one engineer in systematic method using a supporting software. In addition, items were mapped in manual processing by the engineer, through communicating with each institute and vendor, to improve and ensure the quality of clinical data. As a verification, the percentage of mapped items among actual registered data in each classification by the end of 2016 was evaluated.

Results
In the initial state, the average percentage of items with standard code of prescription, injection, laboratory and disease, among nine institutes, was 13.4 ± 14.1%, 2.9 ± 2.9%, 2.3 ± 1.3% and 95.8 ± 3.0%, respectively.

By the operation, the proportion improved to 94.8 ± 3.3%, 96.9 ± 2.6%, 73.9 ± 12.7% and 97.2 ± 2.8%, respectively.

In the actual running data, the percentage was 96.0 ± 3.1%, 98.6 ± 1.0%, 78.8 ± 5.5 and 99.6 ± 0.9%, respectively.

Conclusion
The mapping rate before operation was extremely low and it was dramatically improved by the operation both in systematic and manual processing. Development and implementation of clinical science technologies demand a close interaction between clinical research and clinical practice. The global standardized master code, which is independent from vendors or institute, should be developed to share information more easily.
Assessment of Clinical Decision Support Resolution: A Comparison Between a Generic and Targeted CDS Notification

Jessica Ken, MPH¹, Alina N. Bogdanov, MA¹, Joseph J. Vasey, PhD¹, Shruti Gangadhar, MS¹, Richard M. Loomis, MD¹
¹Practice Fusion, San Francisco, CA

Introduction

When implemented thoughtfully, clinical decision support (CDS) can improve provider experience and patient outcomes¹. Although providers find CDS useful², notification resolution remains low³. We define “notification resolution” as providers completing a clinical action, such as a screening or exam, recommended by the CDS notification. Our objective is to use large scale electronic health record (EHR) data to compare a CDS notification that displays based on patient demographics (generic) with one based on demographics plus diagnoses (targeted).

Methods

De-identified data from Practice Fusion’s EHR database between September 5, 2015 and May 31, 2017 was used to identify patients whose providers received a diabetic foot exam CDS notification (N = 1,103,252) and patients whose providers received a clinical depression screening CDS notification (N = 13,588,699). Diabetic foot exam CDS displays for adult patients with a type I or II diabetes diagnosis (targeted); the clinical depression screening CDS displays for patients ages 12 and up (generic). Descriptive statistics and logistic regression were conducted.

Results

Descriptive statistics show that resolution rate (number of patients with a resolution divided by total number of patients with a CDS notification) of diabetic foot exam CDS was significantly higher than that of clinical depression screening CDS (12.34%, 6.57%, p < 0.0001). In both cohorts, older patients and patients with a higher Charlson comorbidity index (CCI) had higher resolution rates. Patients in medium-sized practices (500-1,499 monthly patient visits) and in practices with higher technology use (e.g. electronic prescribing and lab ordering) also had higher resolution rates. Compared to other specialties, cardiologists (12.42%) and hospitalists (11.64%) resolved clinical depression screening CDS at a higher rate. Podiatrists (23.42%) resolved diabetic foot exam CDS at a higher rate. Controlling for practice, provider, and patient characteristics, a diabetic foot exam CDS is much more likely to be resolved (OR=1.367, CL=1.358-1.376, P<0.0001) than an alert for clinical depression screening.

Discussion

The large number of patients with a resolved CDS highlights the potential impact of CDS programs. Understanding how to best target a specific CDS is essential to patient care and reducing provider alert fatigue.

Conclusion

Our study suggests that providers are more likely to resolve alerts attributed to a narrower patient population or specific condition. Further, specialists related to the alert type are also more likely to resolve the alert.

Challenges Impacting Data Collection from Electronic Health Record (EHR)
Systems in Small and Medium Sized Practices in the Midwest

Pauline Kenly1, Luke V. Rasmussen1, Andy Schriever2, Faraz Shafique Ahmad1, Kathryn L. Jackson1, Richard Chagnon1, Theresa L. Walunas1, Abel N. Kho1
1Northwestern University Feinberg School of Medicine, Chicago, IL; 2Park Street Solutions, Naperville, IL

Introduction: Since its enactment, the Health Information Technology for Economic and Clinical Health (HITECH) Act has led to a widespread adoption of Electronic Health Records (EHR) systems in clinical practice. Accessibility and utilization of the wealth of information contained in EHR systems are becoming important in guiding patient care and future health research. The AHRQ-funded Healthy Hearts in the Heartland (H3) research program's goal is to work with small and medium sized practices (practices with 20 or fewer primary care providers) in the Midwest with the intention of implementing quality improvement (QI) strategies for cardiovascular care utilizing EHR data. The study focuses on evaluating four clinical measures: A spirin when Appropriate (NQF#0068), Blood Pressure Control (NQF#0018), C holesterol Management and Smoking Cessation (NQF#0028). The open-source popHealth software (https://github.com/OSERHA/popHealth) was implemented to calculate the measures and provide a central dashboard across practices for feedback and audit.

Methods: We assessed each EHR system capability to output clinical data in standard formats: Consolidated Clinical Document Architecture (C-CDA), Clinical Document Architecture (CDA) or Continuity of Care Documents (CCD) with an option to export records in batch. We also assessed if the EHR allowed custom report development or direct database export. We relied on vendor documentation to determine how patient data was structured.

Results: The study enrolled 226 small and medium practices with 21 EHR systems represented. Of the 21 EHRs, 7 were assessed for data export capability. Table 1 shows the distribution of data export capabilities for assessed EHRs. Four EHR systems allowed for data export formats in CCD, C-CDA and custom reports. The three output formats had limitations in providing complete data for measure calculations. For example, data elements such as smoking history and RxNorm codes for medications were missing in some of C-CDA data exports. Three EHR systems enabled direct database connection, allowing us to write data extraction queries against patient level data. This method provided more complete data. Of the 14 EHR systems that were not assessed, we attempted to contact vendors to identify data export options available, with insufficient responses.

Table 1: Export Capabilities from 7 Assessed EHRs

<table>
<thead>
<tr>
<th>EHR Data export capability</th>
<th>EHRs with capability</th>

<tbody>
<tr>
<td>Standard Report (CCD, C-CDA)</td>
<td>3</td>
</tr>
<tr>
<td>Custom Report</td>
<td>1</td>
</tr>
<tr>
<td>Direct Database Queries</td>
<td>3</td>
</tr>
</tbody>
</table>

Discussion: Quality EHR data not only promotes health research, it also provides reliable data for submission for quality improvement programs such as Meaningful Use. EHR data also guides patient care through coordination of care and referral documents between providers. The challenges of exporting EHR data evident in the H3 research study underscores the necessity for continued efforts towards advocating for better quality EHR data exports, formats and standards. It also highlights the need for easier access to EHR systems and vendor documentation. One such promising initiative by the Office of the National Coordinator for Health Information technology, would be to have EHR vendors enable open Application Programing Interfaces (API).

Acknowledgements: This research was supported by AHRQ grant number 5R18HS023921-02.

Leveraging Value Sets from the Value Set Authority Center (VSAC) in a Standards-Based Clinical Data Repository

Richard Kiefer¹, Luke V. Rasmussen², Jennifer A. Pacheco², Peter Speltz³, Joshua C. Denny³, William K. Thompson², Jyotishman Pathak⁴, Guoqian Jiang¹
¹ Mayo Clinic College of Medicine, Rochester, MN; ² Northwestern University, Chicago, IL; ³ Vanderbilt University, Nashville, TN; ⁴ Cornell University, New York City, NY

Introduction
The National Library of Medicine (NLM) Value Set Authority Center (VSAC) stores value sets used in Clinical Quality Measures. The Observational Health Data Sciences and Informatics (OHDSI) program offers a wide range of tools for large-scale integration and analytics of observational health data. The objective of this study is to develop an application to import VSAC-hosted value set definitions into an OHDSI repository. This will facilitate the reuse of well-defined value sets from existing value set repositories.

Value sets are groups of concept codes from one or more vocabularies, which are used to define clinical concepts. These value sets are created by subject matter experts and stored in public repositories, such as VSAC. In our ongoing Phenotype Execution and Modeling Architecture (PhEMA)¹ project, we utilize Common Terminology Services 2 (CTS2)² services, an HL7 standards-based approach that allows an application to retrieve value sets from any repository which is CTS2 compliant. OHDSI³ is a collaborative effort to create open source methods and tools to analyze observational health data. To accomplish this goal, OHDSI requires the use of a Common Data Model (CDM)-based repository. A collection of standard vocabulary concepts is stored as a concept set within the CDM Concept table, but reuse of existing value sets requires manual transcription into an OHDSI instance. By leveraging application programming interfaces (APIs) across CTS2, VSAC and OHDSI, we are able to bridge these repositories to facilitate value set reuse.

Methods and Results
A command-line utility was developed using Java to make CTS2 representational state transfer (REST) calls to access value set definitions, and parse the JavaScript Object Notation into the individual concepts contained in the value set. We used a CTS2 wrapper implemented by the PhEMA project to retrieve the value set definitions from VSAC.

We used OHDSI Broadsea to deploy the full OHDSI technology stack, which includes the OHDSI CDM and a web API to provide REST services. By sending the concept name and namespace (vocabulary identifier) to the vocabulary search service we were able to get the representation of the concept from the OHDSI repository. Mappings were made to address slight differences in the code system names. For example, where VSAC stores SNOMEDCT and RXNORM; OHDSI stores SNOMED and RxNorm respectively. Using the concept set service, we first defined the name for a concept set container. Once the container has been created and an identification number has been established, a second web service call is made to populate the concept set with the list of concepts received from the vocabulary search.

The utility was verified by migrating 40 value sets into our OHDSI instance. Two members of the study team manually verified that the concepts matched within the value sets across both systems.

Discussion
Our utility to retrieve a VSAC value set based on its OID and migrate it to an OHDSI repository for use in OHDSI tools will allow users of OHDSI to easily adopt established value set definitions from any CTS2-compliant repository. In future work, we plan to use the value set migration as part of a larger implementation to allow algorithms created by the PhEMA authoring tool to be run against an OHDSI installation to retrieve patient cohorts.

Antimicrobial Susceptibility Data Visualization Tool

Eugene Kim, MD\textsuperscript{1,2}, Larry A. Nathanson, MD\textsuperscript{1,2}, Evan Leventhal, MD PhD\textsuperscript{1,2}, Steven Horng, MD MMSc\textsuperscript{1,2}

\textsuperscript{1}Division of Clinical Informatics, Beth Israel Deaconess Medical Center, Boston, MA
\textsuperscript{2}Harvard Medical School, Boston, MA

Introduction
Increasing levels of antibiotic resistance remain a significant source of morbidity and mortality while the development of new antibiotics lags\textsuperscript{1}. The appropriate use of antimicrobial medications is critical and depends on multiple factors, such as expert recommendations, antibiograms (i.e. summaries of antibiotic resistance patterns within a population), and the patient’s clinical condition. Culture results are numerous, and patients with complex medical histories may have a wealth of previous culture data available to further tailor drug selection. There were 3,475 unique isolates grown from cultures with more than 1,464 resistant strains found at our institution from 7/1/2016 to 12/31/2016. Clinicians may find it difficult to assimilate this data into their decision-making as electronic health records (EHRs) typically spread this information over multiple pages, requiring several clicks to access each result, and do not facilitate comparison of results or analysis for trends. Our goal is to assist antibiotic selection by enabling easy comprehension of the entirety of a patient's microbiological history through an intuitive visualization tool.

Methods
Patient microbiology data were retrieved using the Caché development environment [InterSystems Corp., www.intersystems.com], the system with which the EHR at Beth Israel Deaconess Medical Center was written. Web programming tools, JavaScript, HTML, CSS, and jQuery [www.jquery.com], were used by the authors to create a graphical representation of culture results that was integrated into an EHR display. An overview of the culture sensitivity data across each antibiotic was organized in a table by test date, with the sensitivity results (i.e. 'sensitive', 'intermediate', 'resistant') color-coded. Color-coding was also used to reflect the highest level of resistance encountered for each individual test and antibiotic. Clinicians were able to click to "drill down" to reveal further information about the culture as needed.

Conclusion
We developed a novel visualization to summarize large amounts of culture data in a clinically meaningful and intuitive manner. Such overviews of data can be especially helpful in an environment such as the emergency department, where clinicians are often task-saturated and decisions need to be made quickly. Further study is planned to assess the usability and utility of the tool. Future enhancements could also assist clinicians with antibiotic selection using clinical decision support tools and by incorporating additional patient data from the EHR.

References

Abstract
Increasing levels of antibiotic resistance remain a significant source of morbidity and mortality. Use of past culture data can result in better choices of antibiotic agents, however this information is often cumbersome to access within an EHR. We developed a microbiology data visualization tool to quickly discern susceptibility patterns for individual patients and facilitate optimal antibiotic selection.
STD MIG-PGx Implementation in Clinical Trials Using Legacy PGx DB

Eun-Young Kim, MD, PhD1, Su-Yeon Park, BS2, Na-Yul Kim, MS2
Eun-Young Cha, MS2, Jae-Gook Shin, MD, PhD1,2
1Department of Clinical Pharmacology, 2Department of Pharmacology and PharmacoGenomics Research Center, Inje University College of Medicine, Busan, Korea

It has been increasing the need of pharmacogenomics data in clinical trials, which led to introduce Study Data Tabulation Model Implementation Guide for Pharmacogenomics / Genetics (SDTMIG-PGx) as a data standard. In this study, we developed an auto-converter that converts data in legacy PGx DB to standardized data format according to the guideline. This converter may be contributed to improve quality of clinical trials and to reduce time and cost of clinical trials.

Introduction
Data standardization is very important in clinical trials especially as electronic data capture technologies has been developed. A standards developing organization, Clinical Data Interchange Standards Consortium (CDISC, https://www.cdisc.org), issued Study Data Tabulation Model (SDTM) for clinical trial data standardization. The Unite States Food and Drug Administration (FDA) has asked clinical trial data submission as a SDTM format in product application process. Recently SDTM Implementation Guide for Pharmacogenomics/Genetics (SDTMIG-PGx) was introduced to guide the organization, structure, and format of gene-related data to submit into regulatory authority such as FDA (2015). Therefore we developed STD MIG-PGx implementation tool using our legacy PGx DB (http://pgrc.inje.ac.kr/) which is not compatible to SDTMIG-PGx guide.

Materials and Methods
The data standardization process is demonstrated on Figure 1. The legacy DB includes subject, sample, genetic test results, and gene information. The comparison and mapping specification between STD MIG-PGx domains and our legacy data variables were performed. The auto-converter was developed based on the work using PHP (http://php.net) and MySQL (http://mysql.com) for API. We tested it using previous clinical trial data with PGx test results.

Results
The mapping specification after comparison between data variables in our legacy PGx DB and SDTMIG-PGx domains was successfully completed. The auto-converter based on the above work was developed and it applied to generate the standard format of PGx datasets using genotype results of clinical trial subjects. It included CYP2C9 and CYP2D6 gene-related data (Figure 2).

Figure 2. The auto-converter of PGx data and the extracted standardized datasets.

Conclusion
In this study, we developed an auto-converter for SDTMIG-PGx implementation using our legacy PGx DB. It would be a useful tool for improving clinical trial data quality and strengthening competitiveness in clinical trial industry.
Guiding Principles for the Duke Connected Care Predictive Modeling Pilot

Eugenie Komives, MD\(^1\), Shelley A. Rusincovitch\(^1\), John Paat, MD\(^1\), Lawrence Carin, PhD\(^2\), Daniel Costello, MPA\(^1\), Michael Gao\(^2\), Bradley G. Hammill, DrPH\(^1\), Ricardo Henao, PhD\(^2\), N. Benjamin Neely, MS\(^1\), Ursula Rogers\(^1\), Devdutta Sangvai, MD, MBA\(^1\), Mary Schilder, MA\(^1\), Erich S. Huang, MD, PhD\(^1\)

\(^1\)Duke Health, Durham, NC; \(^2\)Duke University, Durham, NC

Introduction
Predictive modeling in healthcare is a complex undertaking. It benefits from cross-disciplinary perspectives that reflect the multi-faceted nature of risk and potential interventions. However, it can be challenging to foster these multiple viewpoints to recognize common goals and shared purposes.

Methods
In the first stages of developing a clinically-useful machine learning-based predictive model for hospital admissions, Duke Connected Care, an accountable care organization (ACO) managing a Managed Shared Savings population, assembled a diverse stakeholder group to develop a set of guiding principles that were finalized on December 21, 2016. The stakeholders represent a cross-section of expertise, including clinical care, case management, health administration, data science, information technology, translational science, and informatics. We based this activity on the approach used by the FDA Sentinel Initiative and the National Patient-Centered Clinical Research Network (PCORnet). Our intention was to form a strategic roadmap for the pilot; allow underlying assumptions, intent, and values to be recognized; create a basis for priorities to be balanced and decisions evaluated; and enable every team member to understand the underlying context.

<table>
<thead>
<tr>
<th>Table 1.</th>
<th>Stakeholder Group Guiding Principles for the MSSP Predictive Modeling Pilot.</th>
</tr>
</thead>
<tbody>
<tr>
<td>1.</td>
<td><strong>Practicality is key.</strong> Elaborate and overly complex risk prediction models may not provide strong value in actual use.</td>
</tr>
<tr>
<td>2.</td>
<td>Above all, our predictive models must generate <strong>information that is actionable</strong> and closely tied to intervention.</td>
</tr>
<tr>
<td>3.</td>
<td>The advisory role of <strong>clinicians and care managers</strong> is integral in designing and improving the predictive workflow, especially within the context of the clinical care setting.</td>
</tr>
<tr>
<td>4.</td>
<td>Careful incorporation of predictive models into <strong>clinical workflows</strong> is crucial for adoption and use.</td>
</tr>
<tr>
<td>5.</td>
<td><strong>Clear and transparent documentation</strong> is a priority, especially to capture decision points along the way.</td>
</tr>
<tr>
<td>6.</td>
<td>The <strong>“why” is important</strong> in making decisions about actionability and to understand the basis of risk. “Black-box” risk prediction, where the underlying design is not transparent, is less helpful. Understanding what drives the level of risk – particularly increasing risk – is critical to care managers and providers understanding what they might be able to do to mitigate that risk.</td>
</tr>
<tr>
<td>7.</td>
<td>Any given model <strong>may involve trade-offs</strong> (for example, more timely/less accurate vs. less timely/more accurate). Therefore, we will be open to simultaneous development of multiple models to provide multiple options where different models may be optimized for timing of deployment within clinical workflows.</td>
</tr>
<tr>
<td>8.</td>
<td>We will seek to <strong>learn from the work that already exists</strong> in predictive modeling, including published and proprietary models, but be open-minded to the new possibilities in this pilot. We will also consider leveraging and/or modifying existing tools where they exist and where permissible, especially where efficiencies can be gained.</td>
</tr>
<tr>
<td>9.</td>
<td>The <strong>lessons learned through model development</strong> may be as important as the models themselves, including new paradigms of engagement and collaboration.</td>
</tr>
<tr>
<td>10.</td>
<td><strong>Data privacy and security</strong> are critically important.</td>
</tr>
<tr>
<td>11.</td>
<td>We need to understand measures of <strong>value, quality, and cost</strong> that will allow us to monitor performance and gauge success of this predictive modeling process. Tracking and observing <strong>performance of risk prediction over time</strong> is important. It is also important to monitor the <strong>performance of interventions</strong> associated with the risk predictions.</td>
</tr>
</tbody>
</table>

Conclusion
The development of guiding principles has been a valuable foundation for our work in predictive modeling for the Medicare Shared Savings Program (MSSP) population served by Duke Connected Care. Although these specific principles reflect the uniqueness of the pilot and collaboration of the stakeholders, we anticipate that others can benefit from the value of developing guiding principles as a generalizable activity and phase of development.
Machine Learning Models to Predict Readmission for Patients with Cirrhosis
Jejo D. Koola1,3, Aize Cao2, Guanhua Chen2, Amy M. Perkins2, Samuel B. Ho3,4, Sharon E. Davis2, Michael E. Matheny1,2
1Tennessee Valley Healthcare System VA, Nashville, TN; 2Vanderbilt University, Nashville, TN; 3University of California at San Diego Medical Center; 4Dept. of Veterans Affairs, San Diego, CA

BACKGROUND: Patients with cirrhosis, a late stage of chronic liver disease, are at increased risk of hospitalization and hospital readmission. Although several studies have looked at models for predicting readmission for patients with cirrhosis, they are limited by small sample sizes, limited candidate predictor variables, and limited evaluation of discrimination and calibration.

METHODS: We analyzed a retrospective cohort of patients hospitalized nationwide in the Department of Veterans Affairs between 2005 and 2013. We included patients (age ≥ 18) with a diagnosis of cirrhosis hospitalized for any cause, and excluded hospitalizations where the patient died during the index hospitalization, was discharged against medical advice, or was transferred to another non-VA hospital. We identified patients readmitted to any VA facility within 30 days for any cause. We included 254 candidate predictor variables consisting of demographics, laboratory values, comorbidities, healthcare utilization, and medications. We evaluated four models: penalized logistic regression using Least Absolute Shrinkage and Selection Operator (LASSO), gradient boosting, random forest, and weighted random forest. Each model was run on 10 bootstrap resampled datasets. We evaluated discrimination by the area under the receiver operating characteristic curve (AUC) and the calibration by the estimated calibration index (ECI) and the observed-to-expected ratio (O/E). In addition, we ran the models on the full dataset to estimate odds ratios and variable importance.

RESULTS: There were 193,674 index hospital admissions comprising 72,737 patients. Of those, there were 43,674 readmissions within 30 days, for a readmission rate of 22.6%. On average patients were 61 +/- 9 years old, 73.6% Caucasian, and with an admission MELD score of 12 +/- 5. Etiologies of cirrhosis were 28.3% alcoholic, 18.3% viral, 33.9% alcoholic and viral, and 13.4% non-alcoholic fatty liver disease. Gradient boosting outperformed the other models in terms of discrimination and calibration (Table 1, AUC: 0.705 ± 0.003, ECI: 0.007 ± 0.002). Table 2 lists the ten variables with highest and lowest odds ratios for readmission.

DISCUSSION: Hospitals need tools to identify cirrhotic patients at high risk for readmission in order to efficiently target interventions. These data indicate that patients with ascites are at higher risk for readmission, particularly if they require albumin infusions. Prior high readmission rates and psychiatric/substance use diagnoses also were significant risk factors. In contrast, use of hospice and nursing home services were significantly associated with a reduced risk for readmission. Gradient boosting outperformed other models in terms of discrimination and significantly based on calibration. These data are useful for further efforts to develop and implement population and case management strategies to help reduce early readmission in patients with cirrhosis.

Combining Social and Behavioral Determinants of Health Questionnaires to Inform Precision Medicine in a Community Health Center Clinic
Taneya Y. Koonce, MSLS, MPH\(^1\), Sheila V. Kusnoor, PhD\(^1\), Suzanne T. Hurley, RN, APRN-BC\(^2\), Kalonji M. McClellan, MA\(^1\), Nunzia B. Giuse, MD, FACMI\(^1,3\)

\(^1\)Center for Knowledge Management, Vanderbilt University Medical Center, Nashville, TN; \(^2\)University Community Health Services, Nashville, TN; \(^3\)Departments of Biomedical Informatics and Medicine, Vanderbilt University Medical Center, Nashville, TN

**Purpose:** Precision medicine is becoming more pervasive and points to a more holistic approach to individualized patient care. We are conducting a series of detailed studies to understand how to best administer a questionnaire to assess social determinants of health prior to their routine incorporation in electronic health records (EHRs). Using an online sample, we previously evaluated a set of measures recommended by the National Academy of Medicine (NAM) for assessing health-related social and behavioral needs\(^1,2\). Here, we explore in-person administration of a hybrid instrument to collect social and behavioral determinants of health in a community clinic setting, to gain further insight into data collection methods and to guide standards for EHR implementation.

**Methods:** For this pilot study, a convenience sample of patients ages 18 and older was recruited at the Vine Hill Community Clinic, a health center providing medical care for Nashville’s underserved population. Patients were asked to complete a social and behavioral determinants of health questionnaire developed specifically for the community clinic population, called the Protocol for Responding to and Assessing Patient Assets, Risks, and Experiences (PRAPARE)\(^3\) in combination with a subset of items from the NAM questionnaire which were not addressed in PRAPARE, and the Federal Reserve Board’s Survey of Household Economics and Decisionmaking (SHED)\(^4\).

**Results:** One hundred participants completed the study. The median age was 38 (interquartile range = 26.5-56.5; n=100), and the gender distribution was 67% female, 30% male, and 3% transgender (n=100). The median questionnaire completion time was 11 minutes. The questions that were most commonly unanswered included those about household income and race, which were not answered by 40% and 7% of participants, respectively. Results from descriptive analyses indicated that the most prevalent social and behavioral needs were in the domains of physical activity, financial and material security, education, and social integration and support.

**Conclusion:** This study supports the feasibility of administering a hybrid social determinants of health instrument in the community clinic setting and provides insight on what questions are most likely to be answered. Our data suggest that inferences can be made based on patterns of unanswered questions, and data interdependencies may be used to overcome voids in data collection. The findings regarding unanswered questions also suggest an opportunity for future research on better approaches for assessment. Use of a hybrid questionnaire, incorporating elements of PRAPARE, NAM, and SHED, allows providers to obtain a more complete assessment of patients’ social and behavioral health factors, which is a necessary component for truly achieving precision medicine. The results from this study will help to establish standards for routinely collecting information about social and behavioral determinants of health via electronic health record systems. Future efforts are planned to study how to best connect patients with appropriate public health and community-based resources and evaluate their effectiveness in addressing identified social and behavioral needs.

Combined approach to Lyme disease surveillance using text mining and structured data elements available in Electronic Health Record

Rajesh Koralkar, MSHI¹, Elham Sagheh Hossein Pour, MS¹, Jennifer Meece, PhD¹, Anna Schotthoefer, PhD¹

¹Marshfield Clinic Research Foundation, Marshfield, WI;

Introduction:
Lyme disease and other tick-borne diseases have been on the rise in Wisconsin (1). Early diagnosis and treatment of Lyme disease patients are currently the most effective ways of preventing severe illness and development of secondary sequelae, such as Lyme arthritis and neurologic abnormalities (3). However, diagnosis of Lyme disease is made difficult by the non-specific symptoms found in early stages of the disease and the absence of a confirmatory laboratory test. Collecting data on these patients, in the form of a Lyme disease registry, is needed to better understand the disease. One of the difficulties in developing such a registry is identifying patients most likely to have the disease. To achieve this goal we developed an electronic surveillance tool which incorporates regular expression (Regex) text mining and structured data elements available in electronic health records (EHR) to identify Lyme disease cases.

Methods: This study was approved by the Marshfield Clinic Institutional Review Board. The overall aim of this work is to develop a Lyme disease registry. Patients who visited the Marshfield Clinic Health System from January 2014–December 2016 were included in the study. We screened the electronic health record clinical narratives for terms and structured data elements listed in Table 1. We used a stepwise approach to evaluate the accuracy of adding additional elements to the screening tool. We manually validated 10% of the patient data from each group and calculated the algorithm’s predictive positive value for detecting patients with Lyme disease.

Results: We identified 2086 patients who had positive mention of Regex terms; of these, 691 patients were tested for Lyme serology, 463 had ICD code in EHR and 1279 received Lyme specific treatment. Based on these findings, patients were divided into 4 groups as shown in Table 2. Group A had .35 PPV, group B had .65 PPV, and group C and D achieved .95 PPV.

Discussion: Using multiple data sources, we were able to develop a highly predictive EHR-based phenotyping algorithm to identify patients with Lyme disease. Our results are similar to the experience of others in that the more phenotyping approaches and data sources used tended to increase PPV [3]. Regex alone achieved 35% accuracy as we did not consider negation and location of text in patient history section. Adding laboratory test data improved the PPV and finally combining Regex with treatment and ICD diagnosis code achieved the best results. Regex text mining is easy to setup with minimal infrastructure.

Conclusion: This is an example of a combined text and structured data mining application for identifying Lyme disease patients with minimal infrastructural development.

Evaluation and Adoption of Security Standards to Improve Information Security in Healthcare Administration Systems

Prashansa Rao1, MS and Gunes Koru1, PhD
University of Maryland Baltimore County

Abstract Information security has become crucial in healthcare information systems as high-profile data breaches have increased in the last decade. Unfortunately, the lack of adherence to current information security standards and practices is an important contributing factor. This research identified a number of information security standards and guidelines whose application proved to be useful in determining a large number of security vulnerabilities in a real-life healthcare administration system. This approach and the lessons learned could contribute to further minimizing security breaches in various healthcare administration systems.

Introduction Preserving the security of information stored in the healthcare information systems is becoming an increasingly important yet a challenging target as the utilization, size, and complexity of these systems constantly and substantially increase [1, 2]. This research investigated the relevance of various generic standards and guidelines which can be used to improve the information security in large-scale healthcare administration systems and evaluated the applicability of these security standards in identifying security vulnerabilities in a specific healthcare administration system.

Methodology In this research, we first performed an extensive literature review of the current generic information security standards to healthcare administration systems. The identified security guidelines (e.g., vulnerability scanning) were applied to a real-life healthcare administration system. This system is used by Medicaid providers to attest to the meaningful use of their electronic health records systems. The system maintains meaningful use data for the Medicaid providers in one of the states in the US. Based on the identified guidelings, a prioritized security evaluation plan was prepared to evaluate the system for different vulnerabilities such as Uniform Resource Locator (URL) manipulation, session hijacking, and cross-site scripting (XSS).

Results Four major information security standards, namely, Centers for Medicare and Medicaid Services (CMS) Information Security Acceptable Risk Safeguards, International Organization for Standardization and International Electrotechnical Commission’s (ISO/IEC) 27000 Series, National Institute of Standards and Technology (NIST) Special Publication (SP) 800 series of Computer Security Publication, and Health Insurance Portability and Accountability Act (HIPPA), were identified through the literature review. Twelve security tasks were established which should be followed to secure sensitive information. Application of these in identifying a large number of security problems. Almost 1,000 security warning were found using various software code analyzers which included warnings of potentially malicious code and SQL injection vulnerabilities. The prioritized security evaluation revealed that the healthcare information system was highly vulnerable and susceptible to attacks. During evaluation for URL manipulation vulnerabilities, approximately 1,600 URLs were found to be leaking highly sensitive data, such as names and social security numbers. Lack of documentation of procedures and policies followed for the security increased the overall complexity and aggravated the difficulty of security evaluation and the effort it required.

The Accuracy of Monitoring Stress from Wearable Devices

Maciej Kos, MA, MS1, Christine M. Gordon, MPH2, Xuan Li, MFA3, Iman Khaghani-Far, Ph.D.4, Misha Pavel, Ph.D.5, and Holly B. Jimison, Ph.D., FACMI6

123456College of Computer and Information Science & Bouvé College of Health Sciences, Northeastern University, Boston, MA, United States

Introduction

Continuous monitoring of behaviors as well as physiological and mental states is increasingly considered to be a key prerequisite for optimizing health interventions. The recent influx of affordable wearable sensors may enable continuous and unobtrusive assessment of individuals’ health in ambulatory settings. If such sensors provide data of sufficient quality, we will be better equipped to help individuals improve or maintain quality of life.

Stress has important implications for a wide variety of health conditions1. Hence, there is a clear need for new tools to monitor stress in real time to provide tailored and timely interventions. Although feasible in a clinical setting, ambulatory stress monitoring (ASM) still proves challenging. Even short instruments, like the 10-item Perceived Stress Scale, would be too burdensome for patients to complete multiple times a day. Of great promise in ASM are heart rate variability (HRV) and electrodermal activity (EDA). While numerous studies demonstrated that HRV and EDA are biomarkers of stress and emotion regulation2, relatively few have attempted to use such data obtained from wrist sensors in ASM. As the efficacy of this data capture method hinges upon the quality of obtained measurements, the focus of this poster is on assessing the quality of data collected by two wrist sensors and proposing new algorithms to improve it enough for these sensors to be viable sources of ASM data.

Study design

Physiological data was collected in a laboratory setting using Firstbeat Bodyguard 2 (FB) (interbeat intervals, or IBI), Microsoft Band 2 (MB) (IBI, EDA), Empatica E4 (IBI, EDA), and J&J Engineering I-330-C2+ instrument (EDA). IBI were collected using pulse photoplethysmography sensors (MB and E4) and ECG chest electrodes (FB). Eight participants were led through cycles of relaxation (listening to relaxing music in a dark, quiet room) and stress (viewing International Affective Picture System photos, performing Stroop and mental arithmetic tasks, and engaging in physical exercise) to elicit physiological changes.

Results

Our preliminary results suggest that despite a significant degree of agreement between HRV data collected by wrist sensors and an ECG sensor in a laboratory, there is a relatively high level of dependency of the inferences on context and activity levels. To attenuate these effects, we developed an algorithm based on generative-model that uses singular spectrum analysis (SSA) of the RR interval sequence to separate the low-frequency components of HRV from the disturbances due movements as recorded by the accelerometers. SSA method generates a Toeplitz matrix from the RR sequences and then computes four principal components with the highest eigenvalues. We will describe this analytic process that makes it possible to fuse the accelerometry and the photo plethysmographic data to improve data accuracy. This poster will describe these novel approaches for extracting more precise stress information from noisy bio-signals. We will discuss the advantages of the model-based algorithms in capturing individual-level trends and differences in HRV and EDA over traditional population-based approaches.

Conclusion

Data collected by wearable sensors in a laboratory setting are of high quality, but new algorithms are required to make them useful for ambulatory stress monitoring.

An Exploratory Analysis of the Excessive Administration of Seasonal Influenza Vaccinations in Minnesota

Samuel J. Kozloff, MD¹, Miriam Muscoplat, MPH², Zeke J. McKinney, MD, MHI, MPH³
¹New York University, New York, New York, ²Minnesota Department of Health, ³HealthPartners Occupational and Environmental Medicine, Saint Paul, MN

Introduction
Seasonal influenza illness is associated with significant morbidity, mortality and concomitant healthcare spending. The influenza vaccine is known to reduce these undesired outcomes. The complicated logistics of manufacturing and distributing influenza vaccine coupled with variable patient demand can lead to occasional shortages or delivery delays. Excessive influenza vaccine administration may increase healthcare cost and decrease immunization availability. The Minnesota (MN) Department of Health maintains an immunization information system, the MN Immunization Information Connection (MIIC), which includes data submitted by 4,972 vaccination providers, despite no legal requirement except for pharmacists administering vaccines. This research adds to the sparse literature investigating the prevalence of excessive influenza vaccination and identifying targets for intervention.

Methods
The MIIC was queried to generate a dataset of influenza vaccines administered between July 1st, 2009 and June 30th, 2016 to individuals of all ages. Influenza seasons were defined as starting July 1st and ending on June 30th of the next year. Influenza vaccine appropriateness criteria were based on historical Advisory Committee for Immunizations Practices’ (ACIP) guidelines.¹ Inappropriate administration of an influenza vaccine was defined as receiving more than one vaccine per influenza season for individuals nine years and older, and as receiving more than two vaccines in a given influenza season or having multiple seasons in which two or more vaccines were administered for those between six months and eight years of age. All vaccines given to those under six months of age were considered inappropriate. Cost estimates were obtained using Archived CDC Vaccine Price Lists.² An algorithm was created to accurately classify vaccines as appropriately or inappropriately administered, allowing for analysis of excessive vaccination patterns that was otherwise not easily possible with the MIIC data.

Results
The cohort comprised 4,137,453 individuals and 13,339,584 immunizations. 278,700 individuals received inappropriate influenza vaccines (6.56% of all individuals). A total of 332,041 inappropriate vaccines were administered (2.43% of all vaccines). Of individuals who received inappropriate vaccinations since 2009, 84.9% received only one dose more than the number recommended. These influenza vaccines were reported to MIIC by 2,009 different organizations. Ten clinics accounted for 30.3% of all inappropriate vaccinations. Individuals who received multiple inappropriate vaccinations in an influenza season more commonly received these vaccines from multiple clinics. The age group that received the most inappropriate vaccinations was six-month-old infants, followed by middle-aged adults (57 years). The cost of inappropriate administration was estimated to be $4,213,469.

Conclusions
Inappropriate administration of influenza vaccines is not an insignificant issue in MN. Most instances of excessive administration involved one inappropriate dose, and most cases occurred when vaccination was administered from multiple clinics in a given influenza season. The study results suggest populations for informatics-based interventions, including clinics and age groups with the most frequent inappropriate administrations. A known limitation of this data is primarily voluntary data submission to MIIC. More reliable reporting of vaccine administration to MIIC and better incorporation of MIIC into existing clinical workflows could reduce the incidence of vaccine overutilization, thus reducing unnecessary healthcare spending, decreasing the potential for adverse vaccine reactions, and potentially maintaining local availability of immunizations.

References
Introduction

Behavior and lifestyle habits play an important role in defining long-term health outcomes of an individual. This is especially true for an individual burdened by a chronic condition, whose behaviors may directly impact the management of the condition. The recent rise in popularity of digital health devices, activity trackers and apps has created the opportunity to quantify behavioral patterns with the ultimate goal of identifying those that are associated with specific health outcomes. In this study, we consider a population of patients with digital activity trackers who self-reported as diabetic. Research has shown that individuals with type 1 or type 2 diabetes have a higher risk of developing mental health illnesses (MHI) such as depression and anxiety than individuals without diabetes. However, many individuals with diabetes experience undiagnosed MHIs due to inadequate screening or diagnosis. The goal of this study is to understand whether there are significant digital activity tracker-based behavioral characteristics that can help identify individuals with MHI symptoms in a population of individuals with diabetes. Early identification of MHI comorbidities may enable interventions to prevent poor diabetes management and progression of MHI.

Methods

Members of an online health community that use activity trackers and apps were invited to participate in a survey that included self-reports of diagnoses and symptoms, ratings of perceived overall health status, physical health, and mental health, and characteristics such as age and gender. We used the members' activity information recorded from activity trackers and apps over the past 12 months to compute per-individual daily features that indicate the tracking rate, consistency, and intensity of step counts and sleep duration. When comparing digital activity tracker-based behavioral characteristics between individuals with diabetes and individuals with diabetes and MHI, we conducted nonparametric tests and t-tests, and examined the false discovery rate.

Results

A total of 1,330 members reported a diagnosis of diabetes, and 336 (25.3%) of those individuals reported having MHI symptoms in the last year. Of those who reported MHI symptoms, 259 (77.1%) reported having anxiety symptoms and 237 (70.5%) reported having depression symptoms. Among individuals diagnosed with diabetes, those with self-reported symptoms of a MHI walk on average 1,469 steps per day less than individuals without MHI symptoms (p<0.001). Those who reported MHI symptoms had significantly lower frequency of tracking steps than individuals without symptoms (p<0.001). These individuals also had significantly less frequent days with high activity (more than 10,000 steps/day) and more frequent days with low activity (fewer than 500 steps/day) compared to individuals with no reported MHI symptoms (p<0.01). Despite similar mean sleep lengths between both groups, individuals experiencing MHI symptoms slept for longer durations (more than 9 hours/day) significantly more frequently than individuals without symptoms (p<0.01).

Conclusion

Our preliminary results indicate that digital activity tracker data can help identify behavioral traits associated with self-reported symptoms of MHI in a population of individuals with self-reported diabetes. Traditionally, clinicians use self-reported data to screen and measure the progression of MHI. Digital activity tracker-based behavioral data may enrich and supplement this self-reported data, and can potentially help detect MHI and track MHI symptoms. Further research should focus on detecting behavioral markers of onset of and progression of MHI symptoms in individuals with diabetes as soon as they begin to develop.

Mapping U.S. FDA National Drug Codes to Anatomical-Therapeutic-Chemical Classes using RxNorm

Fabrício S. P. Kury, MD¹, Olivier Bodenreider, MD, PhD¹
¹U.S. National Library of Medicine, U.S. National Institutes of Health, Bethesda, MD, USA

Background

The U.S. Food and Drug Administration National Drug Codes (NDCs) are the official identifiers for drug products in the U.S. and therefore commonly appear in large drug prescription datasets from this country. To analyze these datasets from a clinical perspective, it is often useful to abstract away from details such as manufacturer, dosage form and packaging information, and to group prescriptions by drug classes. The Anatomical-Therapeutic-Chemical¹ drug classification system provides a 5-level aggregation scheme for drugs. However, neither WHO nor FDA provides a map from NDC to ATC. Here we demonstrate how to use the U.S. National Library of Medicine RxNorm² application programming interface (API) to automatically create such a map. We apply this by mapping 71,309 NDCs found in 1.015 billion Medicare Part D claims from 2006 to 2013, and 134,580 NDCs found in a commercial all-payer claims dataset from Partners Healthcare© from 2011 to 2012.

Methods and Results

We produced an R script and made it freely available under a Creative Commons Attribution-NonCommercial-ShareAlike 4.0 International license in the GitHub repository at https://github.com/fabkury/ndc_map. The script uses caching and parallel processing to greatly improve efficiency. The script ingests a list of NDCs, queries the RxNorm API to obtain their RxNorm Concept Unique Identifiers (RxCUIs), then queries the API again to obtain the fourth-level ATC class or classes (ATC-4) of each RxCUI. Therefore, our mapping can fail at two stages: when NDCs are not recognized by RxNorm, and when an RxNorm drug has no associated ATC-4 class. Tables 1 and 2 provide statistics about the mapping of the two datasets under investigation.

Discussion and Conclusion

Medicare claims contained a smaller set of NDCs which were proportionally better covered by RxNorm. In the Medicare dataset, only 77.9% of the NDCs were mapped to at least one ATC class, but those NDCs represented 97.6% of all claims. From an informal analysis of the Medicare data, the majority of the non-mapped claims were for over-the-counter medications or non-drug supplies (e.g. syringes, gauze). In both datasets, individual NDCs were ambiguously associated with up to 21 ATC-4 classes for two reasons: some drugs have more than one active ingredient with different ATC classes; and ATC can provide multiple classes for the same ingredient depending on its usage. For example, miconazole has 6 ATC level 4 classes across oral use, gynecological use, otological use, and so on. If not addressed, the NDC-to-ATC ambiguity can create issues in analyzing prescription datasets. Conclusion: Our approach leveraging RxNorm provides a simple and scalable solution for mapping NDCs to ATC classes. The ambiguity of some mappings is the biggest concern for researchers using the NDC-to-ATC map.

Rapid Low-Cost Usability Engineering: Can We Demonstrate the Cost-Effectiveness of the Method for Ensuring Usability of Health IT?

Andre W. Kushniruk, MSc, PhD, FACMI1, Elizabeth M. Borycki, RN, MN, PhD1

1School of Health Information Science, University of Victoria, Canada

Introduction

Worldwide there are increasing reports about the poor usability of health information technology (HIT) being deployed. This has included concerns about electronic health record systems (EHRs), decision support systems, mobile applications and other types of HIT applications. To address this, we describe an approach we have developed known as rapid low-cost usability engineering and present a cost-benefit analysis case for its application.

Methods

The authors have been involved in the development and refinement of an approach to usability engineering in healthcare they have termed rapid low-cost usability engineering. The approach argues that studies can be conducted in-situ, at low cost and rapidly in real clinical settings. The approach typically involves recording the providers’ interactions with systems in a real or simulated environment. Screen recordings of all computer interactions are captured and integrated with audio transcripts to facilitate rapid coding of the data using coding schemes that can be adjusted to the application being tested. The protocols are coded to identify and statistically summarize usability issues and previous studies have shown that the method can be applied rapidly. In order to determine the cost-effectiveness of the approach, data from studies were re-analyzed where total costs of applying the method were calculated (e.g. costs of equipment, participant remuneration, costs of analysis etc.) in order to document the costs of applying the approach. After analyzing the usability data for usability problems, estimates were made (using tables of software costs) to determine the cost of fixing identified usability problems, in order to estimate tangible benefits of applying the approach to catch usability problems. The cost-benefit ratio was then calculated.

Results

From analyses of the results from several usability studies where the rapid low-cost usability engineering approach was applied (and the costs and benefits calculated as described above), it was determined that benefits outweighed costs for applying the approach in all cases, with percent cost savings ranging from 36.5% to over 200%. Furthermore, the total cost for conducting the studies was typically well under $10,000 USD per study. In addition, the methodology also detected errors that would not be considered usability problems, including programming bugs, safety issues and technology-induced errors (that would have otherwise not have been detected prior to widespread implementation). The approach was therefore found to be useful in detection of both usability problems and technology-induced error.

Discussion

We have developed an integrated approach to detect serious usability problems that can serve as a safety net for catching problems. In order to provide evidence that the method is cost-effective we conducted analyses of several usability evaluations to determine the benefits of the approach. Future work will include plans for knowledge translation and wider dissemination of the method through educational initiatives and design of training programs.

Reach and Impact of an EHR Pain Care Clinical Decision Support Program
Steven Labkoff, MD, FACP, FACMI 1, Christopher Bond, PhD1, Lee Kallenbach, MPH, PhD2, Nam Nguyen, MS2, Shruti Gangadhar, MS2, Dan O’Brien2
1Purdue Pharmaceuticals, Stamford, CT; 2Practice Fusion, San Francisco, CA

Introduction
Pain care is one of the top reasons for ambulatory office visits in the US. Assessment of pain is a critical step to providing good pain management. To further both general and chronic pain care management, a manufacturer of pain medications engaged an EHR vendor to implement a clinical decision support (CDS) program aimed at pain care.

Methods
Based on current evidence-based clinical guidelines three pain care-related CDS alerts were deployed July 5, 2016 on the Practice Fusion EHR platform (PF-EHR)1. The PF-EHR is cloud-based with practices in all 50 states facilitating over 5M office visits per month representing 6.7% of US ambulatory care. CDS alerts are displayed on the PF-EHR in real-time when a provider opens a patient chart for editing that meets specified logic. The program includes three CDS alerts: 1) document a pain score in the vital signs flowsheet view for adult patients without chronic pain; 2) complete a brief pain inventory (BPI) assessment for patients with chronic pain; and 3) document a pain care plan for patients with a recent pain score or BPI. The CDS program consisted of matched test and control practices with data evaluated for a six-month period prior to program initiation. Data for the first six months of the program are reported.

Results
Alerts were displayed to 103,717 health care professionals (HCP) during 24,820,820 office visits for 8,355,683 patients at 18,896 practices. Most alerts were for entry of pain scores with the remainder for completing the BPI or for documenting a patient pain care plan. Response to alerts was sustained throughout the 6-month period. (Figure 1).

Figure 1. Pain Care CDS Program Alert Responses by 2-Week Intervals.

Impact of the program is noted by an increase in pain score documentation for an existing EHR data element and by number of BPIs and care plans entered for new EHR data elements. Compared to control practices, test practices entered pain scores, BPIs, and care plans 1.2, 341, and 777 times as often, resulting in 123,662, 38,218, and 29,466 patients with responses attributable to the program, respectively.

Conclusion
Provider acceptance of pain care plan prompts on the PF-EHR platform was positive with completion of prompted actions sustained over six months. CDS provides a method for increased documentation of pain-related care data. Further work will evaluate the impact of this additional data on patient level care and clinical outcomes.

Assessment of pain is critical to providing good pain management. Based on evidence-based clinical guidelines three pain care clinical decision support alerts were deployed on the Practice Fusion cloud-based EHR platform. The program design consisted of matched test and control practices. Provider acceptance of pain care prompts was positive and sustained over six months with completion of prompted actions including pain scores, brief pain inventories, and care plans higher in test than control practices.
Substance Use Extraction in Cancer Patients' Clinical Notes

William Lane, MS¹, Spencer Morris, MS¹, Emily Silgard, MS¹
¹Fred Hutchinson Cancer Research Center, Seattle, WA

Introduction

The development of software systems that can reliably extract clinical events from free-text clinical notes could prove of immense value to clinicians, health care management personnel, as well as medical researchers. The task is a challenging one, and much work has been done around extracting smoking status information, particularly in the context of the 2006 i2b2 shared task¹. The intervening years have seen much success for researchers applying NLP to smoking status detection. This work expands on those efforts by attempting to extract not only smoking status, but also alcohol use status as well as the relevant attributes of the particular substance use. Extracting substance quantities like “pack-years” in smoking², for example, are important for categorizing more fine-grained exposure.

Data and System Structure

The data set consists of 1,450 clinical notes annotated on the sentence level for alcohol and tobacco status (Current, Former, User, Non), as well as for each substance type’s associated attributes (e.g. amount, duration, quit date, and time ago quit) belonging to patients treated at the Fred Hutch/University of Washington Cancer Consortium between 2010 and 2015. Our system takes a batch of clinic notes as input and first filters sentences for alcohol or tobacco-related references according to an extensive library of regex patterns. We implicitly label sentences not containing any hits as an “unknown” status for the particular substance type. The remaining sentences are fed to a linear SVM and classified as alcohol or tobacco related. All sentences classified as relevant to tobacco or alcohol use are put into a multi-class linear SVM where lexical features are used to classify the substance use status. The set of sentences is then passed to the attribute extraction module, where attributes related to the substance use event and status are extracted using a CRF. The final module uses another SVM to match attributes with their appropriate substance event and status, using a combination of lexical and contextual features. Document-level status values were determined by organizing status values into a hierarchy. Attributes were selected on a document level by selecting the attribute value for a particular field which had the highest confidence score output by the CRF calculation.

*Results of status classification and attribute extraction in 5-fold cross validation

The performance of the system varied depending on the attribute being extracted, and some attributes' performance suffered greatly due to overall sparsity in the training set. For example, it is far less common for a clinician to report on alcohol cessation dates than to report on tobacco cessation dates, and the performance gap between those two figures demonstrates the limitation of a system driven purely by supervised learning. Error analysis on the system output showed that the CRF component was actually quite effective at extracting general amounts and dates, but that the final numbers were significantly diminished by the final SVM classification step which assigns attributes to substance events. In future work, we plan to enhance the machine learning approach with domain-specific and situational logic to mitigate the effect of a single weak link in the process propagating errors to subsequent layers.

New MetaMap Features for Processing Numerical Tables
François-Michel Lang, MSE, Dina Demner-Fushman, MD, PhD
US National Library of Medicine, Bethesda, MD

Abstract
A recent project using MetaMap to identify adverse reactions in drug labels encountered two serious problems: long runtimes and low precision. Analysis revealed that tables containing many numbers caused both problems; we present two MetaMap enhancements that substantially improved MetaMap's runtime and precision with no loss in recall.

Introduction
The US National Library of Medicine (NLM) collaborated with the FDA’s Center for Drug Evaluation and Research on an evaluation of 476 Structured Product Labels (SPL) sections provided by FDA in XML format. NLM's contribution consisted of (1) Creating a Gold Standard via manual annotation of the 476 label sections to identify adverse reactions (ARs); (2) Running MetaMap1 on the ASCII text extracted from the 476 sections, restricting results to UMLS concepts having Semantic Type(s) in the Disorder Semantic Group2; and (3) Evaluating MetaMap's performance relative to the Gold Standard. This poster describes two new optional MetaMap features that greatly improve MetaMap's runtime and precision.

Methods
SPLs contain many numerical tables, such as the following small example:

| Rash | 1 0 6 | 0 0 |
| Pruritus | 2 0 5 | 0 0 |
| Alopecia | 10 0 0 | 5 0 |

- **Runtime problem:** MetaMap’s phrase chunker discovers no internal syntactic structure in such text, because it is simply a noun pile with interspersed numbers. Consequently many tables are analyzed as a single long phrase, requiring extensive processing time. To solve this problem, we modified the chunker to force a phrase break after encountering two consecutive numerical tokens. The much shorter resulting phrases led to far shorter runtimes.

- **Precision problem:** MetaMap is a named-entity recognition (NER) application that maps text to UMLS concepts; however, many numerical strings, such as those in the above table, appear in the UMLS, but contribute only noise, thereby severely degrading precision. We substantially improved precision via the ability to ignore concepts (1) containing no alphabetic character and (2) consisting of ≥50% numeric characters.

Results
- **Runtime improvement:** We observed an overall 2.2x speedup; 9 files showed >10x speedup, and 2 files containing very long tables improved by >50x.

- **Precision improvement:** We observed an increase of 35% in precision (from 31% to 42%), with no loss of recall. 17 files showed a doubling of precision, and one a quadrupling. Even so, MetaMap's precision on this project was far lower than normal, because although a vast majority (>97.5%) of ARs identified are in CUIs with a Disorder SemType, many disorder concepts are not ARs: E.g., in “Do not administer to patients with infections”, infections is a disorder concept, but not an AR. These results demonstrate that AR recognition needs processing beyond NER (e.g., semantic analysis)—although NER could be a good first step as it provides good recall. An ancillary benefit of this enhancement was an improvement in the performance of NLM’s Medical Text Indexer (MTI)3, which should result in ~1,000 additional correct MeSH recommendations each year.

Conclusions
These new features show that special-purpose processing in MetaMap can substantially improve the processing of tables, regardless of whether created via screen scraping or automated extraction from markup such as XML.

Leveraging Clinical Decision Support Tools to Improve Early Recognition and Treatment of Pediatric Sepsis

Michael E. Lang, MD, MPH\textsuperscript{1}, Anna Keller, RD\textsuperscript{1}, Robert S. Heidersbach, MD\textsuperscript{1}, Heidi Flori, MD\textsuperscript{2}

\textsuperscript{1}UCSF Benioff Children’s Hospital Oakland, CA; \textsuperscript{2}C.S. Mott Children’s Hospital Michigan, Ann Arbor, MI

Abstract

Septic shock is an important cause of morbidity and mortality for pediatric patients. As part of a quality improvement project, we implemented clinical decision support tools (CDS) to help clinicians recognize signs of sepsis and to direct them to follow our sepsis clinical practice guideline (CPG). While our outcomes were not statistically significant, length of stay (18.2 to 15.6 days) and mortality (13.4% to 7.1%) trended towards improvement post-CDS intervention.

Introduction

Worldwide, sepsis is responsible for greater than 1,000,000 deaths per year and is one of the top ten causes of death in children in the U.S. (mortality ranges from 4-11%)\textsuperscript{1}. Studies have shown that early recognition and treatment of sepsis improve mortality rates\textsuperscript{2}. We embarked on a five-year process improvement project, funded by U.S. Army Medical Research and Material Command Grant W81-XWH-10-01-0682, to determine if CDS tools in our EHR can help guide clinical practice to improve sepsis outcomes.

Methods

Our project was divided into three phases: Phase 1, Baseline Assessment (7/2010 – 12/2011); Phase 2: CPG Education (1/2012 – 11/2013); Phase 3: CDS Intervention (11/2013 – 12/2015). We used the International Consensus Conference on Pediatric Sepsis\textsuperscript{3} as a basis for our CPG and study inclusion criteria. Patients admitted to the UCSF Children’s Hospital Oakland PICU for severe sepsis/septic shock were enrolled in our study. Clinicians (physicians, mid-level providers, and nurses) received education on the new CPG (Phase 2). In Phase 3, we created an alert that appears when clinicians open the chart of a patient meeting criteria for severe sepsis/septic shock. The alert presents ordering providers an order set modeled after the CPG, thus encouraging them to adhere to the CPG. We obtained feedback from clinicians throughout all three phases, leading to a rebuild of the alert in 7/2015.

Results

For each of the three phases, the numbers of patients meeting severe sepsis criteria were 50, 67, and 56, respectively. Process measures and clinical outcomes were determined in each phase. None of the results were statistically significant; however, our data showed a trend towards improvement in length of stay (18.6, 18.2, and 15.6 days) and mortality (10%, 13.4%, and 7.1%) through the three phases, respectively. Clinicians reported too many false positives for the alert. The alert discrete triggering parameters and display were adjusted in 7/2015, which led to anecdotal reports of improvement.

Conclusion

Although our process improvement project failed to improve sepsis outcomes, our post-CDS intervention length of stay and mortality were lower than pre-intervention.

Understanding Ovarian Cancer Symptoms from Patients’ Perspective: A Topic Modeling Approach

Young Ji Lee, PhD, RN1,2, Albert Park, PhD4, Mary Roberge, BSN, RN1, Heidi Donovan, PhD, RN1,3

1School of Nursing; 2Dept. of Biomedical Informatics; 3Dept. of Obstetrics, Gynecology & Reproductive Sciences, School of Medicine, Univ. of Pittsburgh, PA; 4Dept. of Biomedical Informatics, Univ. of Utah, Salt Lake City, UT

Introduction: Ovarian cancer is the fourth leading cause of cancer-related deaths in women in the United States1. Patients with ovarian cancer often experience multiple symptoms that adversely affect their quality-of-life2. To manage cancer- and treatment-related symptoms more effectively, we must understand symptoms from the perspectives of the patients. Social media has created new opportunities for gaining understanding of the patient experience through not only large volumes of data, but also the nature of information that is distinct from data obtained in clinical settings1. However, to date, no studies have utilized data gathered from social media data in this way to understand symptoms among ovarian cancer patients. The purpose of this study is to understand major topics of communication (e.g., social, informational, management advice) related to the symptoms frequently discussed on social media by women and family members affected by ovarian cancer.

Materials and Methods: The data was collected from the online forum of a peer-support community sponsored by the American Cancer Society: Cancer Survivors Network (http://csn.cancer.org). For this study, we used posts from January, 2006 to March, 2016. To identify symptoms discussed in the online forum, we developed a dictionary that includes a list of ovarian cancer symptoms using consumer health vocabulary. After pre-processing data, we selected the top 5 most frequently discussed symptoms and extracted and analyzed postings that mentioned any of those five symptoms. Then, we conducted Latent Dirichlet Allocation using R.

Results: In total, we used 50,626 postings made from 1,947 users. 52% of users (n=1,009) and 25% of postings (n=12,802) mentioned at least one symptom. Among 28 symptoms, pain, nausea, anxiety, fatigue and skin rash were the top five most frequently discussed symptoms in the forum (n=4536, 1296, 967, 878, 657 respectively). Topics of the postings differed across the symptoms. Our analysis resulted in 20 topics that could be further classified into 11 categories: social and spiritual support, communication with doctors, decision about treatment, fear of recurrence, stories about diagnosis and treatment, returning to normal life, complications, adjusting to treatment, chemo-related side effects, symptom management, and miscellaneous.

Figure 1. The distribution of topics in the pain postings.

Chemotherapy-related side effects were most likely to refer to fatigue, nausea, and rash while discussions of spiritual and emotional support were likely to refer to anxiety, and discussions of diagnosis and treatment were often referred to pain.

Conclusion: Text mining has shed new light on health research by identifying useful information from unstructured text. Our results showed that users with different symptoms addressed different topics in the forum. Our next study will address the influence of additional factors (e.g., age, cancer stage, time) on topic discussion to refine our approach and reflect contextual factors.

Meeting Common Health-Related Needs Through a Pediatric Inpatient Engagement Consultation Service

Authors: Daniel J. Lee MD, Robert M. Cronin MD, Jamie Robinson MD, Kim Unertl PhD, Shilo Anders PhD, Katherine Kelly BS, Gretchen P. Jackson MD PhD

1Departments of Urology, 2Biomedical Informatics, 3Internal Medicine, 4Pediatrics, 5Surgery, 6Anesthesiology, 7Pediatric Neurosurgery, Vanderbilt University Medical Center

Background
Engaged patients actively involved in their health care have greater satisfaction with care, decreased costs, and improved outcomes. Patients are increasingly using technologies for their health care. Access to electronic health records, online resources, and other technologies may promote engagement by providing tools to review health information and participate in their care. Hospitalizations offer opportunities to engage patients and caregivers in their child’s care. In 2014, we developed a Pediatric Patient and Family Engagement Consultation Service at the Monroe Carell Jr. Children’s Hospital at Vanderbilt to assess the health-related needs of the caregivers of hospitalized patients and to promote engagement and meet needs with educational or technology interventions. Consultations focus on supporting families with new diagnoses and chronic illnesses using internet-based or mobile resources, the My Health at Vanderbilt (MHAV) patient portal, or other technologies to assist with education, disease monitoring, behavior change, or emotional support.

Methods
We sought to describe the most common needs identified and the technology recommendations provided by this service. We examined 22 consultations from a retrospective and a prospective study. Both studies were approved by the Vanderbilt University Institutional Review Board. The analysis aimed to determine the most common health-related needs identified in the pediatric hospital setting. Each health-related need was classified according to a validated taxonomy of consumer health needs, and the technology recommendations for each need were described.

Results

NEED #1: Need for Provider Contact Information. NEED TYPE: Logistical-Contact/Communication. A health-related need expressed by nearly every parent seen by the consult service is the need for a means to contact multiple healthcare providers for follow up and ongoing care. RECOMMENDATIONS: Parents were registered for the MHAV patient portal and a link to the child’s health information was established. New providers were encouraged to send messages with contact information to the parent through the portal prior to discharge. Extensive time was spent teaching parents to navigate the MHAV patient portal so that they gained experience with messaging providers, checking pertinent test results, and looking up or changing appointments.

NEED #2: Recognizing Common, Benign Versus Concerning Symptoms. NEED TYPE: Informational-Problem-Clinical Presentation. Another common need was distinguishing normal or benign symptoms of infancy or childhood (e.g., baby spit ups) from concerning signs or symptoms of the patient’s medical problems. Parents often had difficulty identifying trustworthy resources online and were often left confused by the breadth of information from a Google search. RECOMMENDATIONS: The consult service educated the parents on how to identify trustworthy sources, such as the American Academy of Pediatrics website, and helped provide easy access to sites by bookmarking them on their mobile devices.

NEED #3: Remembering Questions for Rounds. NEED TYPE: Logistical-Contact/Communication. Another common need was remembering and keeping track of questions for hospital rounds or the answers provided by the care team. RECOMMENDATIONS: For this need, the consult team recommended utilizing NotePad apps or voice recording features present on nearly all the smartphones and tablets. Most parents used such devices frequently, but had not thought of utilizing these tools for health.

Conclusions
The parents of hospitalized patients share several common health-related needs that can be addressed by technologies. An inpatient Engagement Consultation Service can identify and meet needs and promote engagement with health information technologies.
Predictive Modeling for the Prevention and Surveillance of Adolescent Substance Abuse and its Implications for Nursing

Mikyoung Lee, PhD, RN1, Dawn Murphy, MS, RN, CPNP1, Suzanne Gillson, MSN, RN2, Leolin Castillo, PMHNP, RN1 & Anila Simon, MSN, RN1
1Texas Woman’s University College of Nursing, Denton, TX, USA; 2Houston Baptist University, Houston, TX, USA

Introduction
Substance abuse in adolescents is a significant population health concern and a risk factor for other health problems and mortality in adolescents1. Predictive analytics have served as a useful tool for healthcare decision-making, and the value of such a process is more recognized with emerging big data science2. It is valuable to review significant predictors related to substance abuse in adolescents so that nurses can transfer the knowledge into actions for prevention and management of substance abuse and relevant health issues. This systematic literature review aimed to identify what predictive analytics have been used and what predictors have been statistically significant to predict the onset and trajectory of substance abuse and subsequent health issues in adolescents.

Methods
The databases of CINAHL, PubMed, and Child Development & Adolescent Studies were searched with the following use of Boolean operations and keywords: ['Substance use' OR 'Substance abuse'] AND ['adolescent*' OR 'Teen*' OR 'Youth*'] AND ['nurs*' OR 'health*'] AND ['predict*' OR 'forecast*' OR 'modeling*']. The search was limited to peer-reviewed articles published in English between 2012 and 2017. 131 articles were found. The duplicates (n=39) were excluded. Studies irrelevant to the study aim, qualitative studies, editorial/commentary, and review articles were excluded after a quick view of the abstracts; 46 articles were reviewed using a pre-determined review table.

Results
Common data sources were national data sets, such as the National Longitudinal Study of Adolescent Health, National Survey of Drug Use and Health, followed by research data, school-level data, and state-level data. Sample size ranged from 154 to 126,764 participants. The major predictive analytic methods were logistic regression analysis, structural equation model, and latent growth curve modeling. Popular predictors with statistical significance for substance abuse were age, gender, family dynamics, peer substance use, and peer networks. Early onset or prior experience with substance abuse significantly predicted later substance abuse. The common health issue related to substance abuse was mental health, including depression and self-esteem. An interesting predictor identified was cyber-bullying.

Conclusion
This literature review identified the multifactorial complexity of substance abuse in adolescents and the strong need for multifactorial approaches to them. With the identified predictors, nurse clinicians, educators, and researchers can develop programs targeted adolescent substance abuse. Health education should be directed to adolescents, their peer groups, and other significant relations. It is important for nurses to assess adolescents with regard to their network of social interactions and engagements. As social media use becomes more prevalent in adolescents, the assessment and interventions with peer networks using social media will be a promising strategy. This review recognized the importance of assessment and intervention of substance use and relevant mental health issues in the early adolescence to prevent sustained or worsen substance abuse in later adolescence or young adulthood. Nurses should also consider family dynamics while designing and implementing preventive and therapeutic programs for adolescent substance abuse. This literature review also identified a lack of nursing-focused studies in relation to predictive analytics and substance abuse in adolescents. It is recommended for the nursing profession to apply predictive modeling to data from public and nursing-driven sources to create substance abuse prevention/surveillance programs for adolescents.

Analyzing Patient Data Entry Patterns of Free Text based Family History Disease Concepts

Jaehoon Lee, PhD¹², Nathan C. Hulse, PhD¹², Stacey Knight, PhD¹²
¹Intermountain Healthcare, Murray, UT; ²School of Medicine, University of Utah, Salt Lake City, UT

Abstract

In this study we used a patient-facing family health history (FHH) tool to analyze free-text based reporting of diseases to understand common patterns of data entry of patients. From 6,132 patients, we retrieved 28,982 reported disease of which 2,094 (7.2%) were free-text entries. The key findings from manual analysis of the free-texts were 1) significant number of typos (13.7%) 2) and differences in data entry patterns by age group and gender.

Background

FHH reported by patients has been recognized as valuable information for genetic risk assessment and patient-facing FHH tools that capture these data in a non-clinical setting are desirable. However the data quality of these FHH reported diseases may be questionable due to the patient’s lack of clinical knowledge, especially with free-text reporting. Understanding the free-text entry patterns in FHH collection tools will help enhance existing FHH data model, and improve user interface of the tools to capture correct FHH.

Method

OurFamilyHealth is a web-based FHH tool developed at Intermountain Healthcare and allows patients to enter their FHH interactively with a graphic pedigree drawing tool. Patients can enter diseases for family members by two methods; one is to choose from predefined list of 552 diseases that are linked to standard terminologies; the other is to enter the diseases of family members as free-text. Using descriptive statistics, we analyzed the entry pattern from 6,132 FHH records captured through OurFamilyHealth from 2009 to 2016.

Results

From the 6,132 FHH records there were 28,982 reported diseases of which 2,094 (7.2%) were free-text based entries. The free-text reporting was most often done by female patients and by patients between the ages of age 30-50 years old. The most frequently entered free-text disease were Lupus (44, 2.1%); Endometriosis (40, 1.9%); Skin cancer (39, 1.9%); High blood pressure (29, 1.4%); and Hypothyroidism (27, 1.3%). Of the free-text entries 287 (13.7%) contained typos and 1,225 (58.5%) of the entries matched to a Systematized Nomenclature of Medicine (SNOMED) term. There are differences in free-text reporting by sex and age (Table 1), with rates of typos increasing with age and matching to SNOMED concept tending to be higher in the younger age groups.

Table 1. Descriptive statistics of free text based FHH disease entry by gender and age group.

Conclusion

Among patients using a web-based FHH tool, we found that females and younger patients use free-text based entry more actively and with less typos. More than half the free-text entered diseases could be mapped to the standard terminology. In future research we will enhance our disease list by adopting frequently entered disease concepts and improve our tool to support patients with user interfaces to prevent or autocorrect typos.

Spanish Text Simplification Using Term Familiarity: Applying Principles from English Text Simplification

Gondy Leroy, PhD1, Brianda Armenta Navarrete1, Sonia Colina, PhD1, David Kauchak, PhD2
1University of Arizona, Tucson, Arizona; 2Pomona College, Pomona, California

Introduction
Health literacy is important for patients; text simplification is one tool to help facilitate the comprehension of information provided to them. Previously, we have developed and validated several features for simplifying English text. We report here on one such feature Term Familiarity, and how it applies to Spanish text simplification.

Simplifying Spanish Text Using the Term Familiarity Algorithm
We manually simplified four Spanish texts based on Term Familiarity (Table 1). We identified difficult words based on low term familiarity (low frequency in the LexEsp corpus) and either 1) replaced them with a higher frequency synonym or, when none was available, 2) added an explanation of the word. We integrated short explanations in the text, but added longer explanations between parentheses. We adjusted gender agreement as necessary.

Table 1. Text Statistics

</tbody>
</table>

Pilot Study and Results

Study Design: We recruited six native Spanish speakers without a medical background. Each read two easy and two difficult texts (Table 1) that were randomly assigned and in random order. On average, twelve (8+4) words were simplified in the texts. For example “En este artículo se repasan …” was replaced with “En este texto se revisan”. We measured perceived difficulty with a Likert scale (lower is easier), actual difficulty (accuracy) with 10 multiple-choice questions per text (after reading the text), and total reading time.

</tr>
</tbody>
</table>

Conclusion and Lessons Learned: Similar to English, term familiarity can be used as the guiding principle to reduce difficulty of Spanish text. While encouraging, there were important lessons learned. In Spanish, increasing overall term familiarity is difficult, i.e. changing one term requires often adjusting other terms for gender and, as a result, the average term familiarity sometimes decreased. Furthermore, the lexicon has enormous impact. In prior studies, we used a smaller lexicon and were unable to simplify text. Finally, adding explanations may weaken improvements in term familiarity. Our approach requires more fine-tuning and the best version will be included in our future online text simplification tool.

A Pilot Study on the Coverage of ICD and SNOMED CT of Problem List Terminologies Used in a Large Healthcare Institute in China

Yuxi. Li, MD 1, Jie. Jiang, MD1, Yan. Zhang, MD1, Jianping. Li, MD1, Yong. Huo, MD1
1Cardiology Department, Peking University First Hospital, Beijing, China

Introduction

Standardized problem list terminology (PLT) plays an important role in medical informatics while in China the only available standard terminology system is the ICD-9-CM Chinese Edition. Furthermore, most healthcare institute do not have local PLTs, besides synonyms and homonyms are very common in Chinese, which result in many different words for the same meaning during daily clinical practices. Previous studies1, 2 have shown SNOMED CT CORE Subset may be the best terminology in clinical health records. We performed this pilot study to evaluate the coverage of ICD and SNOMED CT CORE Subset and identify a subset of concepts based on standard terminologies that occur with high frequency in problem list data to facilitate the standardization of PLTs.

Methods and Results

We analyzed 165,959 structuralized problem list items without standardization from electronic health records database including 17,437 unique terms since 2011 August to 2016 July among patients discharged from the Cardiology Department of Peking University First Hospital. Figure 1 shows the percentage of unique terms (vertical axis) required to cover a certain percentage of total usage (horizontal axis), which shows the distribution of a small proportion of commonly used terms and a long tail of rarely used ones.

Firstly, we sorted all the unique terms according to the frequency. Secondly, we mapped items with exact match to ICD-CM Chinese Edition, which covers 32.61% of all terms. Finally, data scientist designed regular expressions using Python re Module for each term based on the rules provided by physicians to standardize and map terms into ICD and SNOMED CT CORE Subset, a teamwork revision was performed based on full list of distinct original items matched each expression. As shown in figure 2, even though there is no standard Chinese SNOMED CT available, compared with ICD, it covers those standard Chinese terms used in the hospital quite well (54.03% vs. 44.60%, p<0.0001).

Conclusion

SNOMED CT Core Subset is better than ICD-9-CM for covering PLTs for clinical needs in China.

End-to-End solution to improve user experience of tranSMART: From data curation to advanced data analytics

Haiqing Li PhD, Eric Jiang, Ajay Shah PhD, MBA
Research Informatics and Systems, Center for Research Informatics and Data Science, Beckman Research Institute, City of Hope, Duarte, CA

Introduction

tranSMART is a web-based open source translational and clinical research platform that integrates OMICS data with clinical data and biological knowledge[1]. Once the data are curated and loaded into tranSMART data warehouse, tranSMART simplifies the data management and data analysis through the graphical user interfaces. However, researchers still face two barriers to fully utilize this system. First, curating external clinical and omics data for tranSMART is time-consuming. Second, users are limited to the analysis tools provided by tranSMART. In this work, we developed three systems to seamless user experience from data curation to external analytical features integration.

Method

We designed and implemented three components to improve the tranSMART user experience by breaking down the two barriers mentioned previously. Figure 1 shows our implementation architecture (the three implementations are highlighted in blue). First, we designed a guided data curation tool with graphic user interface. It can guide the user to convert the external data to tranSMART friendly format step by step. The system generates the all raw data file, mapping data file, and/or reference file in right formats with right names. And those data files are ready to be loaded into tranSMART data warehouse. Second, we implemented a customized ETL package to integrate over 115k de-identified patients data from our i2b2[2] cohort identification system with tranSMART. The patient data includes complete demographic information, ICD-9 diagnosis data, ICD-O tumor registration data, and sample status. The data is updated weekly with automatic dataaudit. Third, we designed and implemented a web services plug-in – “tranSMART Connector”, which extends tranSMART analysis capacity. Instead of re-implementation of the existing analysis features from other analytical systems, tranSMART Connector links the tranSMART with the external system. Researchers still use tranSMART’s data explorer feature to generate a cohort for analysis. Once the cohort is selected, the information about dataset for analysis is seamlessly transferred from tranSMART to external analytical system with a unique data identifier. With this solution, we successfully add machine learning analysis feature to tranSMART by link it with our machine learning analysis system, SPIRIT ML [3].

Results:

We designed and implemented a guided graphic data curation tool which simply the complex data curation procedure. This feature speedups the data collection and avoids user operation errors introduced by copy-and-past. The researcher can add the data they are interested in themselves without the assistance from data curators. The customized ETL demonstrates the integration solution for i2b2 and tranSMART. Finally, the “tranSMART connector” allow end users to hook up tranSMART with an external analytical system for advanced analysis features without re-implement them in tranSMART. We demonstrate two use cases to show the end-to-end user experience enhancement in tranSMART using these three features. The first one is to conduct a biomarker discovery study for Pediatric Brain Cancer by re-using public dataset from GEO. We retrieved the clinical information and gene expression dataset from GEO, and curate them using our guided curation tool. Then load it to tranSMART for Biomarker analysis using tranSMART advanced workflow. The scientific researchers can perform all the data management and analysis procedures by themselves. The second use case is to conduct a breast cancer recurrence factor study in tranSMART using Machine Learning features that are implemented in an external analytical system.

Conclusion

By adding these three systems, tranSMART can provide an end-to-end translation research solution for end users. It powers the scientific researchers the independence to utilize the data integration and analysis capacity of tranSMART. The Scientific researcher can have full control of tranSMART, from the sources of data to analysis tools.

Correlation Between End-User Experience and Clinical Effectiveness of a Clinical Decision Support Tool for the Management of Uncontrolled Hypertension

Victor S. Lin, MD, MS1, Andrew J. Holdaway, MD1, Neris M. Nieves-Robbins, MD1, Robert C. Marshall, MD, MPH, MISM1, Keith D. Solveson, MS1, Robert D. Highley, MD2, MPH, Leilani A. Siaki, PhD1
1Madigan Army Medical Center, Tacoma, WA; 2Analytics4Medicine, Kirkland, WA

Abstract
Clinical decision support (CDS) systems can greatly enhance patient care quality, but their success may depend upon positive user experience. We will present the results of an ongoing pilot study investigating the correlation between the end-user experience and the clinical outcomes of a web-based CDS system designed to aid clinicians in the management of uncontrolled hypertension.

Background
Clinical decision support (CDS) systems can greatly enhance the quality of patient care by assisting clinicians with the assimilation of clinical information and adherence to clinical practice guidelines. The successful adoption of CDS systems is generally associated with a positive end-user experience. A web-based CDS tool has been developed by Analytics4Medicine (Kirkland, WA) to aid clinicians in the management of uncontrolled hypertension. This tool analyzes and categorizes hypertension based primarily on the patients’ blood levels of renin and aldosterone. Approximately 15% of patients with hypertension have hyperaldosteronism, which only responds to aldosterone antagonist medications. These are not included as first-line agents in the current Joint National Committee (JNC 8) guidelines. Personalized recommendations for appropriate medication treatment, based on the sub-category of hypertension, are then generated by the CDS tool. This web-based tool has both provider and patient-facing portals. A funded, Institution Review Board-approved pilot study entitled Technology Assisted Management of Uncontrolled Hypertension (TEAM-HTN) is currently ongoing to assess the clinical effectiveness of this CDS tool, as well as the end-user experience with this tool.

Methodology
In this prospective within-subject pilot study, 160 patients with uncontrolled hypertension, and who are currently on three or more medications, will be enrolled along with 16 providers. Patient data, including laboratory results for renin and aldosterone levels, as well as demographical data, are entered into the CDS tool at the beginning of the study. The patients are provided a digital home blood pressure monitor to collect blood pressure readings and enter those readings into the CDS website. The providers will then manage the patients’ hypertension with the aid of the CDS tool. The rate of blood pressure control will be assessed at the end of the six-month study period. In addition, provider satisfaction with the CDS tool will be assessed using pre/post questionnaires evaluating end-user perception of feasibility, efficacy, and usability. Each questionnaire incorporates validated questions from the Technology Acceptance Model (TAM). The post-questionnaire will also incorporate questions from the validated End User Computing Satisfaction (EUCS) model. Patients will complete a post-questionnaire consisting of TAM and EUCS questions.

Results
Preliminary data obtained during CDS development showed that 85% (n=73) of patients achieved blood pressure control on at least 70% of their blood pressure readings, and on fewer medications. This is a significant improvement compared to the 2014 National Health and Nutrition Examination Survey (NHANES) results demonstrating that only 53% of hypertensive patients were controlled. Additional results from this ongoing study are expected by October, 2017. The hypertension control rates will be correlated with the end-user experience as measured by the pre/post questionnaires.

Conclusions
Uncontrolled hypertension is a significant clinical problem with devastating consequences. Personalizing hypertension management with this CDS tool may positively impact morbidity and mortality, and reduce the cost of care. End-user satisfaction with CDS systems is expected to play a significant role in achieving these outcomes.
Integrating Smart Pump Infusion Data with Electronic Health Record Data to Analyze Medication Administration Alerts

Todd Lingren, Yizhao Ni, Eric Hall, Matthew Leonard, Eric Kirkendall*, Kristin Melton*
Cincinnati Children’s Hospital Medical Center, Cincinnati, OH *Equal contribution

Introduction
Smart pumps are designed to deliver continuous medication infusions in hospital settings like the neonatal intensive care units (NICUs). Unlike standard infusion pumps, smart pumps are programmed with standardized medication libraries, rules, and alerts to facilitate administration of appropriate drug concentrations and infusion rates\(^1\). Although the pumps may prevent some potential errors\(^2\), they are still vulnerable to technological and nursing behavioral factors as well as data entry errors\(^3\). Furthermore, drug administrations are communicated wirelessly to local databases and the lack of smart pump integration with the electronic health record (EHR) hampers medication safety efforts\(^4\). As part of a larger study on NICU medication safety\(^5\), we seek to evaluate smart pump errors, perform alert statistics, quantify high rates of errors, and identify potential causes. Here we describe initial efforts to match medication order and medication administration records (MARs) in the EHR with smart pump records (SPRs).

Methods
We selected all EHR medication data and SPRs from the Cincinnati Children’s Hospital Medical Center (CCHMC) NICU in 2016. We identified medications delivered continuously including parenteral nutrition, lipid, intravenous fluids, narcotics (morphine and fentanyl), insulin, milrinone, dobutamine, vasopressin, dopamine, and epinephrine resulting in a data set of 19,614 medication orders, 154,459 MARs and 437,474 SPRs. MARs are initiated at the bedside by scanning a patient and medication barcode, but there is no similar integration for manually-programmed smart pumps. SPRs have a manually-entered patient id field, which typically captures the patient medical record number (MRN), but no EHR medication order field. We developed algorithms to link corresponding medication orders, MARs, and SPRs. First, we linked records using matching patient ids. Next, exact orders were linked with MARs and SPRs using medication name, time, and date of administration.

Results
Smart pump data contained 486 unique patient ids. Of these, 345 matched MRNs from EHR data and 31 matched encounter ids. Non-matched ids included 1) seemingly random numbers (e.g. 0, 999999999), 2) numbers matching the format of MRNs, but not matching MRNs in the EHR data set, 3) alpha characters (e.g. A, C, last names), and 4) one typo (PP was added to an MRN). MRN and encounter id-matched records accounted for 74.5% (325,909/437,474) of SPRs. Of the 325,909 records matched using patient id, 11.8% (38,544) matched exact MARs (medication name and time, within 10 minutes); a further 42.9% (140,103) matched MARs with the same medication on the same day. Only 8.3% of alert events in the SPRs were matched (2,911/34,953). Overrides to CCHMC’s pre-programmed medication library complicate matching: 95,763 (21.9%) of SPRs had medication name Unknown and 87,563 SPRs (20.0%) with Unknown as a patient id. Of these, 19,330 (4.4% overall) have both Unknown as an id and a medication name.

Conclusion
We described algorithm development to match SPRs with EHR medication information for the purpose of analyzing errors and alert events. Matching non-integrated medication administration information remains a challenge, given data entry errors and standard pump programming overrides. Further work includes physician chart review to develop more robust rules in order to refine the matching algorithms.

Using Machine Learning to Predict Hospital Acquired Sepsis

Xinran Liu, MD1, Greg McKelvey, MD2, James Marquardt, MS3,
Rosemary Grant, BSN, RN, CPHQ4, David Carlbom, MD5
1, 4, 5 University of Washington, Seattle, WA; 2, 3 KenSci, Seattle, WA

Problem addressed

Hospital acquired sepsis (HAS) accounts for 11-15% of all cases of sepsis. HAS is associated with higher mortality (19.2% versus 8.6%), costs ($38,400 versus $8,800), and length of stay (17 days versus 6 days), compared to community acquired sepsis1. At Harborview Medical Center (HMC), there are about 270 cases of HAS per year, with about 70 deaths/year (26% mortality). HMC has its own sepsis screening algorithm (SePSIS), which looks for trends and absolute values of temperature, heart rate, respiratory rate, white blood count, systolic blood pressure, lactate, shock index, bicarb, and fractional of inspired oxygen. While this algorithm is very sensitive (95%+), it is not very specific (~13%), which leads to a high false positive rate (low positive predictive value). There are about 2000 triggers from this algorithm per month, which leads to alert fatigue for both bedside nurses and providers.

Aim

Our goal is to create a predictive model that can identify hospitalized patients who are likely to develop sepsis. This will allow these patients to receive treatment earlier, which could decrease mortality rates as it has been shown that every 1 hour delay in starting antibiotics leads to 7.6% decrease in survival.3 Specifically, we hope to create a novel predictive model built on top of the current SePSIS screening algorithm. This model would essentially act as a “filter” to the SePSIS screening algorithm, and would be designed specifically for the HMC patient population. This should decrease the number of false positives, which will also decrease alert fatigue.

Methods

This will be a retrospective study in which clinical data extracted from the electronic health record will be used to train a machine learning model to predict hospitalized patients who are at risk for developing HAS. The population will be patients 18 or older who are admitted to HMC in a 5 year retrospective timespan. Time spent in the ICU will be excluded. Four years of data will be used to train the model, and 1 year of data will be used for validation. The model will be trained to predict sepsis based on the sepsis-3 criteria, which is suspected infection and signs of organ dysfunction. During the training phase, data elements (i.e. temperature, heart rate) for the model will be selected bases off literature review and clinical input. Data elements will also undergo feature engineering to create more novel features to be used in the model. Examples of feature engineering include monotonically decreasing/increasing values, adjustments for conditions or medications that affect vitals or labs (i.e. adjusting HR for patients on beta blockers), polynomial expansions, threshold discovery, categorical variable grouping, etc.

We propose to run our data through multiple different machine learning models such as boosting models, bagging models, neural networks, and regression based models, etc. Once training is complete, we will then validate the models on the validation data set. Our outcome metrics will be sensitivity, specificity, positive predictive value of identifying patients who develop sepsis in the validation set. We will work with the data science company KenSci to create and run machine learning models on this data and expect to have preliminary results before November of 2017. The KenSci platform has already been used to create predictive models on topics such as: surgical outcomes, inpatient deterioration, patient mortality, sepsis in the outpatient setting, readmissions, etc.

Number of Citations of Structured and Unstructured Abstracts in PubMed

Fang Liu, MS; Paul Fontelo, MD, MPH
National Library of Medicine, Bethesda, MD

Abstract

Structured abstracts are more informative so some may rely solely on abstracts to inform decisions. We wanted to know whether articles with structured abstracts would be cited more often than unstructured abstracts. We reviewed citations data for 11 terms in PubMed. We found that unstructured abstracts outnumber structured abstracts by more than 2:1. However, we found no significant difference in the number of citation between structured and unstructured abstract.

Introduction

Because structured abstracts are labeled with tags, readers can discover key elements in papers more easily. In recent years, around 30% of newly added publications in PubMed were structured abstracts. Our goal in this study is to find if there is a difference in the number of citations between publications with structured abstracts and those with unstructured abstracts. Although PubMed has a filter for structured abstracts, it does not provide the number of citations for journal articles but PubMed Central (PMC) does.

Methods

We selected 11 queries from the askMEDLINE database. Search algorithms were developed to retrieve and process data through E-Utilities, an API tool for PubMed and PMC. We searched PubMed with an abstract-type filter (structured abstract versus unstructured abstracts) and a publication-year filter (yearly from 2007 to 2011) for each term to allow adequate time for articles to be cited. We retrieved the PubMed ID (PMID) for each query with different abstract types yearly then searched PMC database to retrieve the number of cited-by publications in PMC.

Results

From 2007 to 2011, the total number of no-abstract, structured abstracts and unstructured abstract was 642992, 980996, and 2465968 respectively. Table 1 shows the yearly average citations for structured (S) and unstructured (U) abstracts. Figure 1 shows the average number of citations for all the 11 search terms. The average number of citations for structured and unstructured abstracts were 14.9 and 16.6 in 2007, and 9.5 and 10.5 for 2011, respectively.

Table 1. Average number of citations in PMC.

</tr>
</tbody>
</table>

Conclusion

Our data does not seem to support the hypothesis that structured would be cited more often than unstructured abstract. However, we discovered that unstructured abstracts outnumber structured abstracts by a ratio of 2.5:1. Although, no difference was found in the absolute number of average citations, the almost equal average number of citations may favor structured abstracts despite the higher number of unstructured abstracts. However, it could also simply mean that structured and unstructured abstracts have equal chances of being cited in future publications.

Detection of Weight Data-Entry Errors

Jing Liu, MS\(^1\), Laura E Brown, PhD\(^1\), Judith W Dexheimer, PhD\(^2\), S Andrew Spooner, MD\(^2\)
\(^1\)Michigan Technological University, Houghton, MI; \(^2\)Cincinnati Children’s Hospital, Cincinnati, OH

Introduction

Errors in weight data are recorded into patient’s Electronic Health Records at a small, but not insignificant rate. For pediatrics, where weight-based dosing may be used, the importance of recognizing a weight data-entry error is critical to avoid over- or under-dosing a patient. Also, pediatric patients are at high risks for adverse drug events due to the rapid weight change over a short period, therefore, they may be more vulnerable to the effects of these errors\(^1\). In this work, we examine methods to predict a patient’s weight given their historical data. This is the first step in the aim to build an automated system to identify, alert, and mitigate weight data-entry errors in real-time practice settings.

Methods & Results

Patient weight data was collected over a three-year period Jan. 1, 2013 – Dec. 31, 2015. The analysis examines a subset of 1525 patients (643 female and 882 male), aged 0 to 36 months, who have at least 10 historical weight data points. The weight data is pre-processed using the lambda, mu, and sigma (LMS) power transformation\(^2\). The methods use the records of weights, age, and gender for prediction. For each patient, all historical data except the most recent weight is used to train the methods and tested on the last data entry. The first prediction method is a percentile classification algorithm (Perc.), where the Chebyshev distance between the training data and percentile growth curves\(^3\) classify the patient into a percentile rank whose smoothed LMS parameters predict the weight. Double exponential smoothing regression (DE) is applied so as to take both individual patients’ trend and the level into account, discounting less recent data. A non-linear least square regression model (NLS) matching expected growth curve functions is trained and tested. Lastly, due to the significant bias of outliers, a robust regression method (RR) is used. The mean absolute prediction error measuring the absolute distance between predicted and actual weight is shown below (Table 1). Overall, the double exponential smoothing has the lowest prediction error. Each method has strengths on specific data patterns, e.g., percentile classification works well when the data follows a percentile rank; double exponential smoothing works well when there is a regularly sampled, recent data available; robust regression is good at removing outliers. Large prediction error, e.g., males age 12-24 months for the NLS and RR methods, can be attributed to extreme errors in weight entry in the training data; we plan to address in future work. Some data patterns such as recent data paucity, extreme overweight/underweight patients, sawtooth patterns, etc. are challenging for all methods\(^4\).

Conclusion

This work is the first step to create automated alerting system for pediatric weight monitoring. In the future, we plan to explore other variables embedded in patients’ data such as, department, diagnoses, and medications, and create ensemble models by integrating and leveraging the strengths of each model mentioned above to improve predictions.

Building an Obesity and Cancer Semantic Web Knowledge Base

Juan Antonio Lossio-Ventura, PhD¹; William Hogan, MD, MS¹; François Modave, PhD¹; Amanda Hicks, PhD¹; Yi Guo, PhD¹; Zhe He, PhD²; Mirela Vasconcelos, BS¹; Jiang Bian, PhD¹
¹University of Florida, Gainesville, FL; ²Florida State University, Tallahassee, FL

Introduction: Obesity is associated with increased risks of cancer, as well as a wide range of other chronic diseases. On the other hand, access to health information activates patient participation and improves their health outcomes. However, existing online information related to obesity and cancer, is heterogeneous and often presented as free-text data. A formal knowledge representation and a semantic web knowledge base could help to manage and deliver quality health information. Ontologically-structured knowledge base construction can be achieved using natural language processing (NLP) and machine learning (ML) methods. Nevertheless, current ontologies describing obesity, cancer and related entities are not designed to guide automatic knowledge base construction from heterogeneous information sources. In this work, we developed a novel framework (see Figure 1) to build an obesity and cancer knowledge base from PubMed abstracts.

Methods: Our framework consists of four main steps. First, we developed an approach for named-entity recognition (NER) to extract biomedical entities from abstracts of scholarly articles. Our method leverages both linguistic and statistical characteristics of biomedical entities. Compared to existing methods, our approach can automate the knowledge base construction process with more fine-grained entities (e.g. be able to identify "type 2 diabetes" rather than simply "diabetes" from a sentence), and new entities¹ (i.e., entities that do not exist in current terminology services such as those in the Unified Medical Language System). Second, we used a similar statistic- and linguistic-based method to extract predicates from the text. Third, we developed a binary classifier to detect whether a pair of biomedical entities and a predicate form a meaningful relationship (i.e., relation detection). Fourth, we built a multi-class classification model to identify the specific relation between the pair of entities, and mapped the predicate to 12 classes in the relation ontology (RO). Overall, our framework is capable of extracting semantic triple statements (i.e., the subject-predicate-object expressions, such as “obesity is a risk factor of cancer”) from free-text PubMed abstracts.

Results: We evaluated the four steps in the framework separately. First, we used two datasets to evaluate the proposed NER approach: (1) a set of 214 manually annotated sentences extracted from 23 PubMed abstracts related to obesity and cancer; and (2) the well-known NCBI disease corpus. We compared our method with several state-of-the-art biomedical NER applications, including MetaMap and BioPortal annotator. Our method achieved the best performance with an F-measure of 90.1%. Second, we compared the performance of our predicate extraction method to a state-of-the-art application, Reverb, obtaining a better precision (62.5%). Third, our relation detection method obtained an F-measure of 98.6%. Finally, the multi-class classification model achieved an F-measure of 85.3% when we classified the specific relations to RO classes. The two classification models are built with 51 statistical, lexical and semantic features. We also experimented with a wide range of well-known supervised learning algorithms in these classification tasks, and found that the Random Forests model performs the best for both tasks.

Conclusions: We have developed a framework for building an obesity and cancer knowledge base. The steps in the proposed framework are important building blocks towards automating construction of an ontologically-structured knowledge base from large, free-text datasets. We presented an improved biomedical NER model and a predicate recognition model incorporating both linguistic and statistical characteristics of the text. Moreover, we used two supervised learning methods to: (1) predict if two biomedical entities and a predicate in a sentence are related, and then (2) classify the kind of relationship between them. Our initial testing of the proposed framework on a small, manually-curated gold-standard dataset shows promising results.

Characterization of Information Collected from Decision Support Request Forms in Academic Medical Centers

Jean F. Louis¹, MIM, Guilherme Del Fiol¹, MD, PhD, Rachel L. Richesson², PhD
¹Biomedical Informatics, University of Utah, Salt Lake City, UT, ²Duke University School of Nursing, Durham, NC

Introduction
In academic medical centers, requests for new Clinical Decision Support (CDS) tools can involve a lengthy and sometimes inefficient process of soliciting functional and data requirements from clinicians. Characterizing the type of information that different organizations collect in their CDS request forms can help in developing a more effective and productive CDS request system. We analyzed the information collected from the CDS request forms of three academic medical centers in order to create a set of categories of information collected in all three forms.

Methods
Three informatics experts (the authors) independently created categories for each question in two of the three CDS request forms. Next, discrepancies were reconciled through consensus, yielding a master set of categories along with definitions. Last, the three experts assigned the categories to the questions on the third form. Collectively, the experts have extensive experience in CDS, terminologies and standards, public health, and information management.

Results
We evaluated 78 questions from the three CDS request forms (34, 17, and 27 questions for forms 1, 2, and 3 respectively), which were assigned to 11 categories. The table lists the categories with definitions along with the number of questions per category in each of the three forms.

Discussion
As organizations update their CDS request forms, the collection of information from these categories can improve how organizations prioritize CDS requests and define requirements. Our research enhances our knowledge of the CDS request process while working toward a standard platform to submit CDS requests that can be shared and reused across organizations. This project will help streamline communication between experts and CDS requesters. It may reduce time spent in CDS meetings by soliciting CDS functional and data requirements from requesters before meeting with CDS committees. Ultimately, we plan to implement a logic-based CDS request form in REDCap to be used across institutions and evaluate additional institutions as part of our future work.

Enhancing LexSynonym Features in the Lexical Tools

Chris J. Lu, PhD1,2, Destinee Tormey1,2, Lynn McCreedy, PhD1,2 and Allen C. Browne1
1National Library of Medicine, Bethesda, MD 2Medical Science & Computing, LLC, Rockville, MD

Introduction

Concept mapping is vital to natural language processing (NLP) for bioinformatics. Query expansion using synonyms for subterm substitutions is an effective technique to increase recall when no direct concept mapping can be found through normalization. For example, no concept can be found by direct mapping through normalization if the source vocabulary is “calcaneal fracture”. By substituting the subterm “calcaneal” for its synonym, “heel bone”, the matched UMLS concept [C0281926, fracture of calcaneus] is found. In this example, “calcaneal” and “heel bone” are element synonyms while “heel bone fracture” is the expanded term. The effectiveness of this technique relies on the completeness and quality of both the element synonyms and the UMLS synonym thesaurus in the query expansion pipeline of UMLS concept mapping (Figure 1).

Figure 1. Query Expansion Pipeline of UMLS Metathesaurus Concept Mapping

Enhanced LexSynonym Features in the Lexical Tools

A systematic approach to LexSynonym acquisition from the UMLS Metathesaurus and the Lexicon was developed to meet two necessary properties, commutativity and transitivity, for quality element synonyms [1]. LexSynonyms are synonymous (multi)words in the Lexicon, such as “calcaneal” and “heel bone” in the above example. 190,844 LexSynonyms are acquired in the Lexicon.2017. They are integrated in the Lexical Tools (2017) for synonym retrieval. The synonym flow component (-f:y) is enhanced to include synonyms, POS and source information. A sophisticated algorithm is implemented in the recursive synonym flow component (-f:r) to preserve precision based on the source types. In addition, the synonym source option (-ks) is added to restrict the results by source type (CUI, EUI, NLP), or any combination of the above. These new features provide needed information for downstream NLP processing. For example, the size of the fruitful variants flow component (-f:v, using recursive synonym features), that is used in various NLP projects (Sophia, MMTx, Custom Taxonomy Builder) for better recall, has been increased from 8.9M (2016) to 9.9M (2017) due to the enhancement of LexSynonyms.

Test, Results and Conclusion

The UMLS-CORE project assigned CUI(s) to terms (13,076) that are within the top 95% usage and mappable to SNOMED CT [2]. 2,755 of these terms (with 2,756 CUIs) that do not have direct mapped concepts in UMLS.2016AB are used to test the performance of LexSynonyms for query expansion. Three different synonym sets are tested through the Sub-Term Mapping Tools (STMT) [3]. The results show improvements in recall (4.97%) and F1 (0.05) from both the 2016 and 2017 LexSynonyms with the STMT synonym set (Table 1) [1]. Precision is slightly increased (0.26%) due to the high quality of LexSynonym 2017 (71.04% precision in this test). The set of LexSynonyms and enhanced features are distributed in the Lexical Tools.2017 with UMLS by NLM via an Open Source License agreement. Improvements in performance can be anticipated for NLP applications that use these enhanced features of LexSynonyms.

Current Practices in Integrating Social and Behavioral Data into Patient Care at a VAMC

Cherie Luckhurst, PhD, MS¹, Michael Weiner, MD, MPH¹-³

¹VA HSR&D Center for Health Information and Communication, Indianapolis, IN; ²Indiana University School of Medicine, Indianapolis, IN; ³Regenstrief Institute Inc., Indianapolis, IN

Study Rationale
Research conducted over the last several decades has firmly established that social and behavioral (S&B) factors influence physical health. Recently, the Institute of Medicine recommended that such data be collected from every patient, and it proposed that S&B data will aid in recognizing, diagnosing, and treating medical problems¹. However, some VA care providers do not see the usefulness of such data in their clinical practices. As a result, these data are rarely collected and, when collected, they are used inconsistently²; a mechanism has not yet been developed to integrate such data into clinical workflow and decision-making³.⁴ Before developing such a mechanism, however, the principles of informatics direct us to examine current practices.

Design
This study uses mixed methods to understand current use of S&B data in the diagnosis and treatment of medical issues at the Roudebush VAMC. Personnel in many VHA clinics, including primary care, social work, and mental health/psychology will be recruited to participate. We will interview 24 clinicians who serve in a variety of roles (e.g., primary care providers, nurse practitioners, care-coordinators, technicians). We will also administer a short survey that includes demographic and practice-focused questions that explore a care provider’s perspective on the usefulness of S&B data in his or her medical practice. Quantitative data will be analyzed using descriptive statistics; qualitative interviews will be analyzed inductively based on the grounded theory approach.

Timeline
Interviews of 24 clinicians are being conducted in March and April of 2017. Thematic analysis will be conducted in May and June 2017, with poster preparation to follow.

Outcome
The work described here is the first step toward development of new procedures to collect and use S&B data across services and departments in a VA medical center. We hope, through a multi-disciplinary collaboration, to fulfill the IOM’s promise of improved diagnosis and treatment of medical problems by incorporating psychosocial data into clinical practice, thereby bridging the current gap between research and practice.

Computer Vision-based Approach to Maintain Independent Living for Seniors

1Zelun Luo, 1Alisha Rege, 1Guido Pusiol, 2Arnold Milstein, 1Li Fei-Fei, 2N. Lance Downing
1Stanford Vision Lab, Stanford University, 2Department of Medicine, Stanford University

Introduction

As the first baby-boomers begin to reach retirement age, the U.S. has begun to experience a shift in the age demographics of its population that has significant implications for Medicare spending and the federal budget. Thus far, computer vision has not had significant application in healthcare but holds significant potential for automation and augmentation in the monitoring and recognition of health and healthcare behaviors1. In this work, we introduce a computer vision-based system to allow seniors to live independently at home. Depth and thermal sensors are used as they hold advantages over wearable sensors and RGB cameras: they do not require daily wearing, provide richer information, avoid personal identification, and operate in different lighting conditions. Our prototypes are lightweight and easy to install, requiring only power source and internet access. We introduce a new open-source dataset: Thermset2, which contains 214 hours of thermal video collected at senior bedrooms. A convolutional neural network (CNN) is used to detect five clinical states: background, people present, standing, sitting, and sleeping. These states are important on their own and necessary to identify more complex activities that are more likely to be actionable by caregivers.

Methods

We trained a CNN-based feed forward network on Thermset (Figure 2) to detect whether an activity occurs in a video frame. Our network is inspired in AlexNet3, and it consists of five convolutional layers. Each layer is followed by a ReLU nonlinearity layer, a batch-normalization layer, and a dropout layer. The output is the multi-label classification of the target activities, obtained with a softmax function. At training stage, 21,960 frames (4,392 from each category) were used. For evaluation, we do not include any frame of a scene that appears in the training set.

Results

Figure 1 shows the confusion matrix for the algorithm. The matrix shows that an average 76% correct classification rate on the five aforementioned clinical states. We were only recently able to begin collecting data from depth sensors so do not have results to present here. As we add data diversity by collecting more data and using depth data, we expect a much more robust system in the future.

Conclusion

This work shows the viability of using thermal signals for monitoring elderly citizen, and can potentially allow for them to receive the care that they require from the comfort of home. In our future work, we plan to train a model that recognizes a wider range of clinical states, including day and night reversals, eating, falls, slowed movements, unstable transfers, front door loitering, chair and bed immobility, urinary frequency, restlessness, and fever. By detecting these clinical states, we aim to identify elder patients who are at risk for requiring long-term care, and to provide feedback to caregivers that would support their safe and independent living.

Meaningful Use Stage 3 Safety-Enhanced Design: Third Time’s a Charm?
New Certification Criteria, Insights and Lessons Learned

Andrea Mahnke MS¹, Gabrielle Falkey BS², Elise Ewers BS²
¹ Marshfield Clinic Research Foundation, Marshfield, WI
² Marshfield Clinic Information Services, Marshfield, WI

Introduction

The Office of the National Coordinator (ONC) for health information technology (HIT) is driving implementation of electronic health record systems with advance decision support in order to improve and monitor care quality and increase patient safety¹. The health care environment is dynamic and complex and therefore HIT can be successful only if systems are designed taking human technology interaction in mind and integrating them well into clinical workflows. The ONC has again required EHR developers to conduct summative usability evaluations and submit results as part of Stage 3 certification. The 2015 edition (170.315) for Stage 3 certification includes the same test criteria as the 2014 edition, but also introduces several new test criteria including additional CPOE requirements, demographics, problem list and implantable device list. Test results of all systems will be made public on the ONC website. This will allow both consumers and developers to review and assess the usability of systems to help steer purchasing and design revisions to other systems. Experience from two previous rounds of certification helps to prepare us for Stage 3. We discuss methods, results, lessons learned and proposed changes based on findings.

Methods

MCIS Clinicals V6.2, the Marshfield Clinic home-grown EHR, was used for the summative validation testing and resided on dedicated testing environment. Physicians, physician assistants, nurses and medical assistants were recruited as they represent user groups of the EHR. Recruited participants had a mix of backgrounds and demographic characteristics. Participants were scheduled for 90 minute sessions and all completed the same set of tasks. Two non-patient seeing staff was recruited to perform two administrative tasks. A number of tasks were constructed that would be realistic and representative of the kinds of activities a user might do with this EHR. Tasks matched requirements for ambulatory certification as identified by the Test Procedure for §170.315(g)(3) Safety-enhanced design certification criteria. Measures assessed system effectiveness, efficiency and satisfaction. They also served to identify usability issues that, if left unaddressed, could result in errors that could potentially lead to patient harm².

Results & Conclusion

Pending data collection and analysis scheduled for summer 2017. Reported results will include: task success, task failures, task deviations, task time, task difficulty rating, System Usability Scale score and, usability issues and errors that could potentially lead to patient harm.

Repurposing Software Built for Large Clinical Trials for Use in Small Trials
Nilla Majahalme, BSE1; Stephen J. Miller, MPH1; Andrew Zimolzak, MD, MMSc1,2; Jason L. Vassy, MD, MPH, SM1,3
1VA Boston Healthcare System, Boston, MA; 2Boston University School of Medicine, Boston, MA; 3Harvard Medical School, Boston, MA

Statement of Problem
Point-of-care (POC) clinical trials, which can enable a learning healthcare system, rely on the integration of electronic health record (EHR) data with other study data. Data must be presented to the study team in a usable manner, especially when the data drive study decision logic for patient enrollment, outcome monitoring, or safety events. This integration is often resource-intensive and not readily available for small, budget-constrained studies. We recently launched a POC randomized trial called the I-PICC (Integrating Pharmacogenetics in Clinical Care) Study. The pharmacogenetic association between the SLCO1B1 gene and simvastatin myopathy is well validated, but the clinical value of its use in patient care is unknown. The I-PICC Study will enroll 400 statin-naive patients with elevated cardiovascular disease risk and determine whether clinical use of SLCO1B1 testing improves patient outcomes. The limited budget of the I-PICC Study does not support extensive custom informatics development.

System Purpose
We leveraged existing components originally built for the 13,500-enrollee Diuretic Comparison Project (DCP) to support the I-PICC Study. DCP is supported by full back-end automation featuring web services to process data on demand and scheduled execution of complex jobs. For the resource-limited I-PICC Study, we used the same front-end components (ProjectFlow and workflows) but created a simpler back-end using SQL stored procedures to consume EHR data and manage decision logic. ProjectFlow is an open-source workflow application originally developed in collaboration between the Massachusetts Veterans Epidemiology Research and Information Center and the VA Informatics and Computing Infrastructure. The browser-based application connects to a database server, enabling but not requiring real-time access to data from the EHR and other sources. Data displayed in ProjectFlow are decoupled from the workflow itself, allowing not only the reuse of workflow definitions but also full customization of data displayed to the end user. The application tracks workflow sequences, prompting users to complete a next step when available. Workflows are represented by XML files built using a third-party Business Process Model and Notation (BPMN) 2.0 workflow editor. ProjectFlow applies a user interface (UI) to the workflow and uses a BPMN 2.0 engine to track progress of “clinical elements” (e.g., patients) in workflows. Data are populated into ProjectFlow through a database view, with one view driving each type of clinical element. The view is queried on each page load, giving the user a real-time view of the data. Over time, a view can be modified, with the constraints of maintaining a unique ID for each row and never removing existing data fields. The UI can be modified to display only relevant data.

ProjectFlow stores user-input data in the database in nearly human-readable form, enabling easy data retrieval from the system by any SQL programmer. For the I-PICC Study, we built a simple SQL back-end by defining 11 stored procedures to retrieve and manipulate data entered into ProjectFlow. The stored procedures can be invoked either manually or by scheduled execution on the server. We implemented a state machine of patient progress through the study by testing for conditions found in the EHR and ProjectFlow data. Patients meeting certain criteria (for example, consent call complete and an eligible lab found in the EHR) were allowed to proceed to the next state. ProjectFlow was configured to invoke a specific workflow for each patient in a particular state. Thus, new workflows are invoked and displayed to study personnel as patients progress through the study.

Seven workflows were built for I-PICC: 1) recording provider consent, 2) tracking patient mailings and consent, 3) asking providers to order the genetic test, 4) reminding providers about orders if necessary, 5) sending the lab specimen, 6) reporting genetic results, and 7) withdrawing a patient from the study. Development effort was ~3 days to build workflows using a 3rd party open source BPMN editor and ~1 month to create SQL stored procedures.

In summary, we have reused “trialware” components from a large funded study and implemented a simpler back-end to automate a state machine and decision logic for a resource-limited trial, simulating real-time data updating. ProjectFlow is being applied to other projects including the VA Precision Oncology Project. We demonstrated that if trialware is built in a modular fashion, it can be scaled for use in both small and large trials.
Optimizing Parameters of word2vec for a Text Classification Task

Vincent Major, ME1, Alisa Surkis, PhD2, Yindalon Aphinyanaphongs, MD PhD1
1Department of Population Health, NYU School of Medicine, New York, USA;
2Health Sciences Library, NYU School of Medicine, New York, USA.

Introduction

Machine learning text classification models often rely on empirical parameter optimization to identify classifier settings that are highly performant (for example, support vector machines optimize the C parameter). word2vec1,2, a recent method that uses neural networks to build word embeddings, has several key parameters. However, prior works select word2vec parameters against an internal measure of semantic similarity rather than an external measure of utility, such as performance in a classification task. Word embeddings are vectorized representations of words such that similar meaning words such as “strong” and “powerful” are in the same general Euclidian space. Representing words as vectors allows text classification models to learn concepts, rather than simply word occurrences. In theory, using embeddings results in improved model generalizability. In practice, incorporating word embeddings have demonstrated state of the art performances. In this poster, we optimize the utility of word embeddings to classify MEDLINE articles into their translational stage of T0, T1/T2, or T3/T43. One metric for success of a translational research grant is how quickly a concept or method develops from basic science through animal and human studies and into clinical practice. A model that could classify translational stage could be used to map research trajectories and evaluate return on investment.

Methods

Word embeddings were constructed using titles and abstracts from 10.5 million MEDLINE articles published between January 2000 and December 2016. The following word2vec parameters were optimized in a naïve grid search: model = {continuous bag-of-words, skip-gram}, optimization = {hierarchical softmax, negative sampling}, dimension = {50, 100, 150, 200, 300}, and context window lengths = {4, 5, 6, 8, 10}. These word embeddings are then used with a state of the art classification algorithm called fastText4 to learn and predict on a manually labeled dataset (updated from our prior work3) consisting of 542 manually labeled MEDLINE abstracts classified into 3 categories: T0 (n=281), T1/T2 (n=109), and T3/T4 (n=152). We assess predictive performance using the area under the receiver operating characteristic (AUC) in 5-fold cross validation.

Results

The baseline performance from our prior work3 (using a support vector machine) in T0, T1/T2, and T3/T3 classes are: AUC(%) [range] = 94 [93-96], 84 [76-98], and 92 [90-94]. Many of the 100 parameter combinations result in AUCs comparable to or marginally greater than the baseline.

Discussion

The comparable performance to baseline suggests that learning text semantics in a large dataset results in models that are comparable but likely more generalizable. Across the 3 classes, the skip-gram model outperformed the continuous bag of words model, as previously reported5,6, with hierarchical sampling marginally outperforming negative sampling. The number of dimensions and context window length do affect classification performance however; the effect size is small everywhere except the extremes. These data suggest that expensive optimization may not be necessary for some tasks. However, for performance critical tasks the expense may be warranted.

Guideline Based Recommended Therapies in PAD Patients

Identified by NLP: A Quality Assessment Project

Vishnu Priya Mallipeddi, MBBS, Naveed Afzal, PhD, Iftikhar J. Kullo, MD, Hongfang Liu, PhD, Rajeev Chaudhry, MBBS, MPH, Adelaide Arruda-Olson, MD, PhD

Mayo Clinic, Rochester, MN, USA

Introduction
Patients with peripheral artery disease (PAD) constitute a high-risk population. Evidence-based management strategies for secondary prevention have been recommended by PAD clinical practice guidelines. However, prior studies have demonstrated a substantial gap between guideline recommendations and clinical practice with low proportion of PAD patients using these strategies. We previously developed a natural language processing (NLP) algorithm for identification of PAD cases from narrative clinical notes, which had a higher accuracy than billing code algorithms. We applied this NLP algorithm for PAD case identification to conduct a quality assessment project to evaluate the use of 4 distinct guideline-recommended risk modification strategies in PAD patients from the community.

Methods
We applied a NLP based PAD algorithm to a cohort of patients evaluated at the Employee Health Clinic, Mayo Clinic, Rochester. For validation, we compared the NLP results with the gold standard manual abstraction of the medical records by two abstractors. Baseline demographic characteristics and use of each one of the four guideline-recommended strategies within 6 months of PAD diagnosis were also manually abstracted from EHRs. These strategies were: abstinence from smoking, use of moderate or high intensity statin therapy, use of aspirin and use of angiotensin-converting inhibitors (ACEI) or Angiotensin Receptor Blockers (ARB).

Results
There were 73 patients (26% women, mean age 72.87 ± 11.4 years). The NLP algorithm had positive predictive value (PPV) of 97% and sensitivity 99% for PAD case identification, compared with the gold standard. Guideline recommended therapy within 6 months of the PAD diagnosis included the use of Aspirin in 63 (86%), statin medications in 47 (64%), ACEI or ARBs in 35 (48%) and abstinence from smoking in 49 (67%) patients. The figure shows distribution of combined use of guideline recommended strategies for PAD risk modification.

Conclusions
In this pilot study, an NLP algorithm applied to clinical notes had excellent PPV and may be used to support quality assessment projects. The use of guideline recommended therapies in PAD patients remains limited. Our results indicate a need to develop automated clinical decision support tool to facilitate further implementation of guideline-recommended risk modification strategies for PAD patients. As a next step, we are planning to conduct a provider survey to assess potential need for clinical decision tool to facilitated discussion of guideline-recommended risk modification strategies in patients with PAD at the point of care.

Abstract

Automated laboratories analyze thousands of blood samples every day. Some samples may become contaminated due to improper collection, producing incorrect results. Identification of such samples is critical but often requires a labor intensive expert review. We present a set of machine learning algorithms that efficiently analyzes Big Laboratory Data in Hadoop and Apache Spark. We compared performance of each model using 13,945 blood samples. Our best model, Random Forest, achieves 86.5% sensitivity and 99.9% specificity.

Background: The study objective was to evaluate the accuracy, validity, and clinical usefulness of detecting laboratory errors with machine learning algorithms in Hadoop distributed computing systems. We present a machine learning approach that can be integrated into a high-throughput automated laboratory system.

Materials and Methods: Test results were extracted from an automated laboratory system for 13,945 blood samples, of which 194 were contaminated. A rule-based classifier and the clinical judgment of physicians were used to identify contaminated samples. A basic metabolic panel with eight commonly measured analytes was incorporated into our models. We compared performance of four algorithms: a decision tree, a random forest, an elastic net logistic regression, and an artificial neural network. We split each dataset into training, validation and test sets (60-20-20). All models were tuned with Bayesian optimization, selecting hyper parameter settings with the highest AUC for the validation set. We also used a larger synthetic data set (2,013,945 samples) to demonstrate scalability. These samples were synthesized by a generative model, specifically a Gaussian mixture model with 7318 components. All experiments were performed on a four-node 2.2 GHz quad-core Hadoop cluster.

Results: Each model included eight analytes from a basic metabolic panel: blood urea nitrogen, calcium, chloride, bicarbonate, creatinine, glucose, potassium, and sodium. When validating the performance of four models on the test data set, specificity was above 99% across all models. Our final Random Forest models showed best discrimination, with areas under the receiver-operating-characteristic curve of more than 0.90. Random Forest model showed the highest sensitivity of 86.4%. Comparing the experimental results with several state-of-the-art methods, such as rule-based and decision tree methods, revealed that the proposed method outperforms previous methods.

Conclusions: Machine learning models based on a basic metabolic panel can be used to accurately detect contaminated samples and assist in clinical interpretation of results. Machine learning algorithms combined with clinical judgment could be applied in daily practice. Our work is the first to apply machine learning at this scale for detecting contaminated cases.

Figure 1. Performance of machine learning algorithms, receiver-operating-characteristics curves, for 2,789 samples in the test dataset (A) and for 2,2013,945 synthetic data points (B).
Implementing Data Event Triggers with Standard-based Document Exchange to Improve Timely Communication for Referring Providers

Darren K. Mann, BS¹, Shan He, PhD¹, Jennifer Nelson, RN¹, Gary Anderson¹, Sidney N. Thornton, PhD¹,²
¹Intermountain Healthcare, Salt Lake City, UT; ²University of Utah, Salt Lake City, UT

Introduction
Communication between primary care physicians (PCPs) and specialists for referrals and consultations is often incomplete due to unreliable communication methods and time constraints. Referring providers need to receive consultation reports and test results back from specialists in order to provide optimal coordinated care. However, the common practice for sending results to referring providers is through phone, fax or secure email, which is resource-intensive and error-prone. A study reported that 80% of specialists said they “always” or “most of the time” send consultation results to the referring PCP, but only 62% of PCPs said they received such information. At Intermountain Healthcare we repurposed an automated electronic data delivery system to link referrals to the creation and transmission of an electrophysiology report from the Heart Institute to the referring providers.

Methods
To enable automated electrophysiology report delivery, we implemented clinical event based triggers in our Electronic Health Record (EHR) system. The trigger was fired when an electrophysiology report was finalized and stored to the EHR by a heart rhythm specialist. We implemented an HL7 Consolidated Clinical Document Architecture (C-CDA) document generator that embedded the electrophysiology report in the Assessment and Plan section of the progress note template after the trigger was fired. The C-CDA document was then automatically routed to the referring provider via the Direct protocol. A dashboard report from the transmission audit records facilitates the measurement of timely and complete communication of the referrals.

Results
Using trigger-based document transmissions, the Heart Institute sends finalized electrophysiology reports immediately to referring providers without any manual processing. Previously, clinical staff spent 4 hours per day facilitating the transmissions. Automating this process also increased the percentage of results that were successfully sent back to the referring providers. The Direct receipt acknowledgment increased the reliability of the consultation results arriving at the referring provider.

Discussion
The advantage of using Direct to exchange documents among healthcare providers is the ease of configuring the providers’ Direct email address. However, without a national provider directory each organization has to collect and maintain the Direct email addresses for its Direct exchange partners. As a result, the effectiveness of our implemented solution for the Heart Institute relies on the information of the referring provider collected during registration and their Direct email address existing in the local provider directory. For future work, we plan to accommodate other industry standard delivery methods preferred by referring providers such as Cross-Enterprise Document Reliable Interchange (XDR) and FHIR. Currently we embed the free-text electrophysiology report in the C-CDA document with discrete patient demographic information. We plan to improve the semantic interoperability of our document when additional standard-based exchange specifications become available that support additional structured and coded data elements for an electrophysiology report.

Conclusion
Using automated and standard-based document exchange improves the efficiency, effectiveness, and security of the communication between referring providers and specialists. Our implementation for the Intermountain Heart Institute can be generalized to other clinical use cases that require timely and reliable patient data exchange.

Evaluation of the Surveillance, Epidemiology, and End Results Data Management System (SEER*DMS) to support efforts in enhancing U.S cancer surveillance

Marina Z. Matatova, MA1, Paul A. Fearn, PhD1, Eric B. Durbin, DrPH2, Gary M. Levin3, 
Frank J. Manion, MS4, Patrick M. Mergler, MBA5

1National Cancer Institute, Rockville, MD; 2Kentucky Cancer Registry, University of Kentucky, Lexington, KY; 3University of Miami, Miami, FL; 4University of Michigan Comprehensive Cancer Center, Ann Arbor, MI; 5University Hospitals Seidman/Case Comprehensive Cancer Center, Cleveland, OH

Introduction
The Surveillance, Epidemiology, and End Results (SEER) Program at the National Cancer Institute (NCI) is an authoritative source of information on cancer incidence and survival in the United States representing approximately 30 percent of the US population. To improve on patient outcomes SEER is actively employing innovative approaches to augment and automate data acquisition and processing, such as natural language processing (NLP) techniques for data extraction. The SEER Data Management System (SEER*DMS) has been utilized since 2005 by central cancer registries to process and submit cancer data to the SEER program. To ensure that the system is optimally positioned to handle and is configured to seamlessly integrate machine-learning technologies for information processing. SEER contracted with health informatics experts (ED, PF, FM, PM) to methodically evaluate SEER*DMS.

Methods
The evaluation process began with an initial meeting with SEER program leadership to identify goals and objectives. After initial assessment, the health informatics committee met with staff from Information Management Systems (IMS) Inc., company contracted to design and develop SEER*DMS, in order to obtain an overview of the system. The committee proceeded to collect field observation data by visiting four SEER registries including, Iowa, Louisiana, Georgia and Seattle. The registry visits were apportioned among the committee members and yielded insights into central registry characteristics, operations, and registry user feedback of SEER*DMS. The findings were compiled by the committee members, analyzed, and organized into a comprehensive report. The team extracted nine key recommended areas of improvements and delivered a final summary report intended to support current and future goals of the SEER program. The program leadership reviewed each recommendation with IMS in a joint effort to align understanding of the proposed enhancements to SEER*DMS.

Results
The summary report provided nine key areas recommended for enhancement: (1) increasing automation of linking multiple tumor case records related to the same cancer diagnosis, (2) consolidating data elements from different records to create a complete summary of patient and tumor information, (3) developing an integrated web portal to support submission files from reporting facilities to the SEER registry, (4) developing an integrated report writer with functional and user friendly features that would support registry operations and research needs, (5) developing and supporting a natural language processing infrastructure within SEER*DMS to augment and enhance data extraction, (6) performing a system-wide usability assessment of SEER*DMS through a cognitive approach aimed to improve functional and ergonomic needs of the registry user community, (7) a redesign in the change control board for SEER*DMS and to improve communication between NCI, IMS, and the SEER registries, (8) improvements and updates to system architecture, performance, security, and sustainability to ensure SEER*DMS employs the latest technologies and methodologies to support the scale of nationwide operations, and (9) developing a strategic roadmap to prepare SEER*DMS for future trends in molecular/precision medicine which will produce a greater volume and variety of health information.

Conclusion
A systematic evaluation of SEER*DMS by health informatics experts yielded key areas of enhancements to the system that would support current program needs, central registry operations, and position the system to seamlessly integrate innovative approaches, such as natural language processing, to modernize U.S cancer surveillance with the aim of enabling current and future research to improve patient outcomes.
A Data-driven Framework for Sub-Typing Stem Cell Transplant Recipients at Risk for Infection

Anoop Mayampurath PhD $^{1,2}$, Jonathan Matthews ME$^3$, Samuel L Volchenboum MD, PhD, MS$^{2,4}$ and L. Nelson Sanchez-Pinto MD, MBI$^4$

$^1$ Computation Institute, $^2$ Center for Research Informatics, $^3$ Pritzker School of Medicine, $^4$ Department of Pediatrics, The University of Chicago, Chicago IL 60637

**Introduction**

Advances in hematopoietic stem cell transplant (HSCT) treatment have significantly improved outcomes for diseases that were often fatal. However, infection remains one of the top causes of mortality in HSCT recipients, especially in the early post-HSCT phase.$^{1,2}$ Because early identification of life-threatening infections can improve outcomes, identification of HSCT recipients at high risk for severe infection *prior to transplant* and consequent increased surveillance after transplant could be lifesaving. In this paper, we devise a computational paradigm that utilizes both unsupervised clustering and supervised-classification techniques to define different sub-types of HSCT recipients that are prone to different risk of infection due to pre-HSCT factors.

**Methods**

*Setting and study population:* We conducted a retrospective study of all allogeneic HSTC recipients from 2009-2015 at the University of Chicago Medicine. *Outcome and features of interest:* The primary outcome of interest was bacteremia, as identified by a positive blood culture within the first 100 days of HSCT. The features of interest are from a three-month pre-HSCT time period and included variables related to patient demographics, diagnosis, HSCT/donor factors, prior inpatient stay, prior infection and antibiotic use, and routine laboratory test results prior to transplant. *Analysis:* In order to detect sub-types of patients with differential risk *at time of HSCT for infection post-HSCT*, we built a computational framework using three successive steps. First, we performed hierarchical clustering on all pre-HSCT features using the Gower distance (since the data is of mixed-type) to detect patient groupings in the population in an unsupervised manner. Next, we compared rates of the primary outcome across groups and used chi-squared testing to determine if any observable difference was significant ($p < 0.001$). This allows us to detect sub-types of patients with differential rates of post-HSCT infection. The last step is to utilize classification and regression tree (CART) models to determine the variables that primarily drive the sub-type differentiation.

**Results**

Out of 425 patients that received allogeneic HSCT, 151 (35%) developed bacteremia infection. Hierarchical clustering of pre-HSCT variables in the allogeneic population revealed four distinct groups of patients (Figure 1), of which one group showed higher rates of infection compared to other groups (Table 1, $p < 0.001$). The direction and strength of association between each pre-HSCT feature and the grouping is currently being studied.

**Conclusion**

Our novel computational framework detected sub-types of patients with different risk of infection based on characteristics prior to transplant. This allows for patient risk stratification at transplant as well as incorporation of a baseline risk score in prediction models that use post-transplant variables. The framework can be easily applied to other scenarios in which determining the baseline risk for infection prior to high-risk medical or surgical intervention might be beneficial.

HealthPro: An integrated web application for essential health data and biological specimen collection in the Precision Medicine Initiative

Kelsey R Mayo, Ph.D.¹, Robert J Carroll, Ph.D.¹, Jason Tan, M.S.¹, Rebecca L Johnston, M.S.¹, Celecia M Scott¹, Joshua Denny, Ph.D.¹, Paul Harris, Ph.D.¹
¹Vanderbilt University Medical Center, Nashville, TN, USA

Abstract

A critical opportunity and challenge within the Precision Medicine Initiative (PMI) is standardized health data and biospecimen collection for one million or more participants across diverse national enrollment sites. The HealthPro web application was developed to facilitate data standardization and communication between healthcare provider organizations and PMI data consuming nodes. Furthermore, HealthPro integrates with MayoLINK®, the Mayo Clinic’s universal test management solution, to enable a nationally scalable system for biospecimen collection.

Introduction

One primary goal of the All of Us Research Program, formerly known as the Precision Medicine Initiative Cohort Program, is to create a broad, representative public resource to advance the health of all Americans¹. To achieve this goal, All of Us will recruit one million or more participants through healthcare provider organizations (including regional medical centers, federally qualified health centers, and Veterans Affairs) as well as through direct volunteer enrollment site networks (e.g. Walgreens, EMSI, QTC). The number and diversity of these enrollment centers presents a unique challenge to the successful execution of the All of Us Research Program. To meet this challenge, the Data and Research Center (DRC) developed HealthPro, a novel tool to securely collect and transfer baseline health data and biospecimens as part of the All of Us initial core data set.

Results and Discussion

The DRC applied an iterative, user-centered design process to prototype, develop, and refine the HealthPro web application. Initial functional requirements were elicited through collaboration with All of Us Working Groups and Principle Investigators (PIs), and trained staff (e.g. nurses, research coordinators, phlebotomists) at All of Us enrollment sites were identified as HealthPro target users. In October 2016, prospective users and PIs (N=22) rated a prototype on usefulness and usability of the following core functionalities on a 5-point Likert scale from “Strongly Disagree” to “Strongly Agree”: 1) providing standardized online data capture tools for collecting and transferring participant’s baseline health data and 2) integrating with MayoLINK® to create and manage orders for collected biospecimen. Overall, responses were positive, with HealthPro usefulness and usability ranking a median of “Agree” (4) on the Likert scale. Based on feedback from this early user testing, HealthPro’s core functionalities were updated to include: 3) providing training reminders and capturing protocol deviations in a structured manner.

From November 2016 to March 2017, the All of Us enrollment sites (N=47) ran exercises using HealthPro for baseline data collection and biospecimen collection, processing, and shipment to the All of Us Biobank. Feedback from these practice exercises catalyzed development of new functionality: 4) providing a “Work Queue” for operational data (ex. date of consent and contact information) to enable enrollment workflows. 94.7% of users (N=38) reported that the Work Queue prototype was “Very Important” (N=14) or “Absolutely Essential” (N=22) to every day operations.

Final testing of the production version of HealthPro, integrated with the production versions of MayoLINK® and the All of Us Research Program database, successfully concluded in May 2017. Since the official launch of the All of Us Research Program on May 30, 2017, HealthPro has enabled participating organizations to successfully enroll, capture baseline health data, and collect biospecimens from more than 250 participants across the nation, growing daily.

Conclusion

User-centered design and innovative integration with clinical biospecimen management software resulted in HealthPro - a scalable solution for secure, standardized health data and biospecimen collection in support of precision medicine.

Electronic Health Record Safety: Identifying Measures for Clinical Decision Support Quality

Allison B. McCoy, PhD1, Adam Wright, PhD2, Hardeep Singh, MD, MPH3
Marie Krousel-Wood, MD, MSPH1, 4, Dean F. Sittig, PhD5

1Tulane University School of Public Health and Tropical Medicine, New Orleans, LA,

DeBakey Veterans Affairs Medical Center, Baylor College of Medicine, Houston, TX, 4Tulane University School of Medicine, New Orleans, LA, 5The University of Texas School of Biomedical Informatics at Houston, Houston, TX

Introduction
Recent reports have highlighted potential challenges and unintended consequences of electronic health records (EHRs), which are implemented to improve patient safety and reduce healthcare costs. Effective measurement of potential hazards may help healthcare settings detect unsafe system conditions and implement interventions to prevent medical errors. We sought to develop measures for EHR safety based on a previously described health information technology safety (HITS) framework and the National Quality Forum (NQF) report on prioritization and identification of HIT patient safety measures, focusing on the clinical decision support (CDS) key risk area.

Methods
We used the potential measure concepts proposed by NQF as a starting point and, through a consensus process, expanded each into a list of operational measures. Study team members (AM, AW, HS, MK, DS) independently reviewed each measure for implementation feasibility (i.e., measure is easily defined and computed, and the data are easily accessible in an existing, electronically available format) and usefulness (i.e., measure will be useful in assessing EHR safety). We generated a combined score by summing the median of reviewers’ feasibility and usefulness scores. We ranked the measures by the combined score and described factors that contributed to each measure’s scores.

Results
From the 6 NQF potential measure concepts, we identified 41 operational measures. Table 1 shows the three highest and three lowest scoring measures. Most measures with low implementation feasibility were difficult to define or required chart review or clinical judgment to implement. Some measures were recurring and could be recalculated over time to observe changes in CDS use, while others were one-time measures (e.g., institutional practices), often with a binary outcome (i.e., true/false), that were not likely to change over time. There was no apparent correlation between these characteristics and the resulting ranking, or between implementation feasibility and usefulness.

Conclusion
The NQF potential measure concepts served as a good starting point for identifying measures, but many of the concepts were too broad or imprecise and required discussion to translate into one or more measures, and many of the resulting measures were neither feasible nor useful. Further research is underway to refine and better rank the measures for CDS through an improved review process, and to identify additional measures in other key risk areas, including system downtime and patient identification.

Engaging Bedside Nurses in the EHR Change Request Process

Jacquel J. McDonald, MSN,RN-BC, Kimberly C. Burress, MIS,BSN,RN-BC
Children’s Hospital of Philadelphia, Philadelphia, PA

Introduction

Children’s Hospital of Philadelphia, had an established well process for handling EHR change requests generated from inpatient nursing. The process began with one analyst, supporting over 2200 requestors from the Department of Nursing (inpatient) and meeting with every requestor to define workflow requirements. The workflows were subsequently review by a group of practicing bedside nurses with expertise in the EHR [Epic Nursing Clinical Champions (ENCCs)] who often suggested significant redesign. The analyst began the cyclical process of meeting with requestors and the ENCC team until final design requirement were finalized. This methodology was labor and resource intensive for the analyst, caused delays in ticket initiation to completion rates, and requestor dissatisfaction.

Goals of this project were to: 1) 10% increase in nursing satisfaction with the Epic change request process 2) 10% increase in the number of Epic requests completed monthly 3) 10 % decrease in ticket initiation to completion rates

Methods

Starting in September 2016, a nurse who submits a change request receives a follow-up email requiring the completion of a scoring tool. The weighted prioritization scoring tool requires the nurse to evaluate the request based on the IOM’s six domains of health care quality and include quality effectiveness, productivity, work effort, patient safety, financial impact, clinician, and patient scope. Each scored request is validated by the informatics nurse specialist and Epic analyst. Based on the score and level of complexity an ENCC is assigned to meet with the requestor(s) and define the clinical and business requirements. The ENCC presents the final requirements to the team for feedback and approval. With the approval process complete, the change request is transitioned to the analyst who focuses on the build.

Results

![EHR Request Data]

Figure 1. Tickets open before the model change in September and two months of post data.

Conclusion

The ENCC participation in the request process decreased time required to complete a ticket from 201.6 to 139 days, on average (30% reduction) and decreased average ticket open time from 160 to 138.2 days (13% reduction). Initial outcomes indicate faster response times to nursing requests for EHR documentation changes and reflects increase in time the Epic analyst now has on completing request. Based on our pre and post model change, we have also increased overall end user satisfaction by 5%.
SMARTenAPP: The Development of a Web-Based Application as an Antimicrobial Stewardship Intervention: A Pilot Project

Richard Medford MD FRCPC¹, Siddhartha Srivastava MSc MD FRCPC², Gerald Evans MD FRCPC³

¹ Department of Clinical Informatics, Stanford School of Medicine, Palo Alto, California, United States
² Division of General Internal Medicine, Queen’s University, Kingston, Ontario, Canada
³ Division of Infectious Diseases, Queen’s University, Kingston, Ontario, Canada

BACKGROUND: Antimicrobial stewardship programs (ASPs) are useful in promoting appropriate antimicrobial use while maximizing patient safety and minimizing cost. Many institutions have implemented such programs but have faced challenges secondary to lack of clinical resources and time and economic constraints. In the era of advancing technology and increasing use of mobile health resources, it is important to look at this avenue as a possible stewardship tool.

OBJECTIVES: To develop and evaluate the utility of a web-based application (app) as an antimicrobial stewardship intervention.

METHODS: A web-based app to assist prescribers with selection of antimicrobial therapy based on local resistance data was developed. The app utilizes four main headings to direct prescribers to the pertinent sections: Clinical Condition, Microbiology, Antibiotics and Location. In March 2014, the app was introduced on to the Internal Medicine Clinical Teaching Units (CTUs). We looked at the uptake and use of the app using web-based statistics. We then did both a comparative and “before/after” analysis of the usage (Defined Daily Doses/1000-patient days) of two targeted antibiotics: piperacillin/tazobactam (TZP) and vancomycin (VAN) on surgical and medical floors at our hospital the year before and after our intervention.

RESULTS: From March 2014 to February 2015, there were 3110 sessions, 16,442 page views, 57.7% returning users and 42.3% new users. There were 5.28 page views and 2.31 minutes per session. Comparing targeted antibiotic usage rates on medical to surgical units from our intervention period - March 2013-February 2014 vs. March 2014-February 2015: utilization of VAN was 21% lower on the medical floors (p=0.0001), while TZP showed a non-significant increase of 7% (p=0.4222). This correlated to a decrease in DDD/1000 patient days of 66 to 55 for VAN and an increase in TZP from 35 to 42 DDD/1000 patient days.

DISCUSSION: A web-based application is a practical, accessible tool for prescribers to aid in antimicrobial selection. Our data suggest a reduction in use of targeted antibiotics is achievable and sustainable, especially in low-resource settings. Future directions include evaluating the usability and impact on local antimicrobial resistance patterns over extended time periods.
Cross-species Mapping of Human and Mouse Craniofacial Structures

Jose LV Mejino Jr. MD¹, Landon T Detwiler, MS¹,², Timothy C Cox, PhD³,⁴, and James F Brinkley, MD, PhD¹,²

¹ Department of Biological Structure, ² Department of Biomedical Informatics and Medical Education, University of Washington, ³ Division of Craniofacial Medicine, Department of Pediatrics, University of Washington, ⁴ Center for Developmental Biology and Regenerative Medicine, Seattle Children’s Research Institute, Seattle, WA, USA

The Ontology of Craniofacial Development and Malformation (OCDM)¹ is an OWL application ontology for use by the NIH-sponsored FaceBase consortium, as well as by the larger craniofacial research community. The purpose of FaceBase is to collect and integrate data ranging from genomic to clinical in order to understand the causes and possible treatments of craniofacial birth defects such as cleft lip and cleft palate. The purpose of the OCDM is to provide the terminology standards, as well as the relationships (e.g. parts, developmental lineage, associated malformations), to associate and correlate disparate FaceBase data pertaining to the craniofacial complex by formally representing multi-species canonical anatomy, embryological development, malformation, and cross-species anatomy homology mappings.

Understanding development and malformation requires knowledge derived from research on model organisms, such as mice and zebrafish, that cannot directly come from human subjects. The wealth and availability of information from these organisms can be leveraged and utilized to advance research at the human level. In previous work on the OCDM we have provided comprehensive representations, not only of human, but also of mouse and zebrafish craniofacial anatomy. In the work reported here we investigated homology correspondences between human and mouse craniofacial structures, and represented them in the Craniofacial Human Mouse Mapping Ontology (CHMMO), one of several sub-ontologies of the OCDM.

Mappings include developmental entities from the zygote to perinatal structures at progressive stages of development, with emphasis on embryonic precursors of components of the musculoskeletal system of the head (muscles, bones, cartilages, skeletal ligaments and joints). Despite overtly apparent differences between mice and humans, these organisms are closely related mammals and share very similar biology. The structural similarity between the two organisms is the basis of much translational research. We initially carried out provisional mappings based on existing nomenclature, incorporating similar names, and then validated these, through consultation with domain experts and the literature, for homology evidence, either based on direct molecular studies or inferred vertebrate Bauplan. Bi-directional one-to-one and uni-directional one-to-null mappings were recorded using a Protégé mapping plugin we developed (Figure 1). Except for the very early stages of development (zygote to germ layers), mappings were largely implemented at the gross anatomical level.

These mappings (and mappings in-progress relating human to zebrafish) will facilitate ontology-based searches of FaceBase model organism data, such as gene expression studies, that can give insight into the causes of clinical conditions such as cleft lip or palate. Funding: NIH DE24417.

Use of an iPad Program to Improve Access to Physical Therapy Services for the Management of Chronic Low Back Pain

Brittany L. Melton, PhD, PharmD1, Zoe Lai1, Neena Sharma, PT, PhD2
1University of Kansas School of Pharmacy, Lawrence, KS; 2University of Kansas Medical Center, Kansas City, KS

Abstract
This study sought to evaluate the impact of a home-based iPad program on chronic low back pain and associated psychological factors. Participants completed a 6-week program that provided pain education and exercises. Pain, fear, depression, and other factors were assessed at baseline and completion. Participants had a significant reduction in pain and improved energy. These results can be used to expand the program and improve access to physical therapy.

Introduction
Low back pain (LBP) is one of the leading causes of disability in the United States and is estimated to cost up to $635 billion annually.1,2 While exercise is the standard of care for chronic LBP, it does not address the psychological issues associated with chronic pain which can negatively impact patient quality of life.3 Less than a third of patients see a physical therapist for chronic LBP, and a home-based program which addresses both the exercise and psychological factors of chronic pain could improve access to care while improving patient outcomes.4 The objective of this study was to evaluate an iPad program’s impact on chronic LBP patient pain and functioning.

Methodology
Participants were given an iPad pre-loaded with pain education and exercise programs which incorporated stretching, strengthening, and aerobic exercises. Each session was an hour or less, and participants were instructed to follow the session recommended activities three times a week for six weeks, to reflect traditional physical therapy sessions. After two weeks, participants had a virtual visit via the iPad with a study investigator to answer any questions and ensure exercises were done correctly. Participants completed validated surveys related to fear avoidance, disability, and pain at baseline, two weeks, and at program completion. Three months after completion, participants were contacted about their LBP and exercises. Participant questionnaire responses were assessed for changes in participant pain and associated outcomes using Wilcoxon Signed Ranks Test. The study was approved by the Institutional Review Board.

Results
Twelve pilot participants were mostly female (72.7%), with a median age of 37 years, and median duration of current pain episode of 30 months. There was a significant reduction in pain (median 8.5 vs 4, p=0.005), and increase in energy (median 1 vs 0, p=0.007) after completing the program compared to baseline. Participants generally reported that the program was easy to use, and felt it gave them access to therapy they would not otherwise have. At the three month follow-up, some participants reported still performing the exercises without the presence of the iPad and some asked if they could continue to have access to the information and exercises because of the perceived benefit.

Conclusion
A pilot iPad program to educate and guide participants in chronic LBP management was effective, while also being usable. These findings will be used to refine and expand the program to increase rural access to physical therapists.

Research on the Accessibility of Parks Based on GIS in 8 districts of Beijing

Yujie Meng, MD, Xiaopeng Qi, PhD, Songwang Wang, MD, Qiang Chen, MD, Rui Zhang, MD, Huan Zheng, MD
Chinese Center for Disease Control and Prevention (China CDC), Beijing, China.

Introduction
Parks are the main part of urban green infrastructure, they have recreational function and can provide the most common places for population-level physical activity. The urban planners and policy-makers widely took park area per capita etc. as the key indexes to guide urban planning. They pay few attention to spatial accessibility and utilization of parks. Good park access is associated with increased physical activity1.

Methods
We measured residential population’s potential spatial access to parks by population-weighted distance (PWD) to parks using the method developed by Zhang and colleagues2. We selected 1 km population grids as basic geographic neighborhood unit of analysis and used centroids of 1 km square grids to measure geographic location more accurately. Firstly, 1 km grid level PWD to nearest parks for the population in that grid is calculated, and then the PWD for the population in larger geographic units than 1 km grid (counties) to visit nearest parks is aggregated.

Results
We drew the distribution and per capita park area for 8 districts of Beijing (see figure 1 and 2). Darker green means more park area per capita in figure 2. The county in the edge have more park area per capita than the county in the center. Chongwen district has the highest per capita park area. We also calculated the PWDs for 8 districts of Beijing. People in the 8 districts of Beijing are expected to travel 0.85 mile on average to access their local neighborhood park. Figure 3 depicts the county level PWDs to parks in 8 districts of Beijing. Darker green means better potential spatial access to parks for local residents. Chongwen District has the best access to local neighborhood parks with PWD of 0.38 miles. Haidian District and Shijingshan District have the largest PWDs of 1.03 and 0.97 miles, respectively. In summary, Chongwen District is the best location for these two indicators.

Conclusion
This study adopted a GIS approach to aggregate potential spatial access to parks from 1 km grid level to county level. Counties in the center part of Beijing have significantly better spatial accessibility to parks than the urban-fringe counties. The result in PWD is different from per capita park area in some districts. The accessibility of parks is a great supplement for per capita park area. It will enrich the key index system for assessing parks. The study evaluates the potential spatial access to parks and environment justice in Beijing. It could be informative for health professionals and policy makers to improve the availability and accessibility of public parks.

Introduction

Data-driven machine learning systems have the potential of revolutionizing healthcare by leveraging large data sets to automatically derive the patterns and knowledge needed to accurately augment the work of clinical professionals. Though these systems may eventually be capable of surpassing human levels of performance for certain tasks, their fundamental need and limitation is the availability of large annotated data sets that can be utilized as training data for generating the required knowledge. Many domains that have seen machine learning algorithms exhibit high levels of performance, such as object recognition in images and games of strategy such as chess, have readily available training data that is straightforward to obtain with little associated costs in terms of human labor. Obtaining high quality, large volume, annotated data sets within the medical field, however, is a more challenging endeavor due to the higher labor costs of annotators because they must possess sufficient medical knowledge and training. To alleviate this bottleneck, we have developed a pattern-based NLP tool with an intuitive web-based GUI that is capable of boosting the productivity of annotators by automatically pre-annotating documents with high precision.

Methods

We leveraged an existing information extraction (IE) system that uses multiple sequence alignments (MSAs) to automatically generate extraction patterns from annotated training documents [1]. Our working hypothesis is that these patterns can be used to identify specific data elements from within free text with high precision when trained on smaller training sets. Based on this, we designed a web application that provides a case report form (CRF)-based interface to clinical users for facilitating chart review and data abstraction workflows. The user can abstract data from documents into a CRF using only a point-and-click input device. This results in the capture of both structured data values and annotations that are used to train the MSA algorithm. The backend IE system utilizes user annotations to produce extraction patterns, determines which patterns exhibit high precision levels, and then applies the high precision patterns to documents that have not yet been seen by the user.

For this preliminary study, we leveraged a corpus of 100 de-identified lung cancer screening reports from the UCLA Healthcare System and designed a CRF containing a set of salient data elements based on direct input from thoracic radiologists who have experience reading lung cancer screening cases. This study focused on the annotation of four particular data elements: patient age, patient gender, the existence of a previous comparison exam, and smoking status. The reports were ordered arbitrarily and the annotator was instructed to fill out the four chosen data elements from the corresponding CRF for each report, moving from one report to the next sequentially. As each report was annotated, the backend IE system automatically annotated reports downstream from the user’s current position. Our results showed that the system was able to automatically annotate the four data elements in new documents at a level of 95% precision and 40% recall.

Conclusion

The results of this study show the potential of using pattern-based NLP to boost the efficiency of clinical annotators. The fact that the results exhibited high precision levels was important because it reduces the amount of manual effort needed to correct the system’s errors. On the other hand, a recall of 40% enabled the system to locate almost half of the cases that the user would have had to manually annotate, saving overall time and effort.

Reflecting on Diabetes Self-Management Logs with Simulated, Continuous Blood Glucose Curves: A Pilot Study

Elliot G. Mitchell¹, Matthew E. Levine¹, Dave J. Albers¹, Lena Mamykina, PhD¹
¹Department of Biomedical Informatics, Columbia University, New York, NY

Introduction
Continuous Glucose Monitors (CGM) are a powerful intervention to support patients with diabetes in better managing their condition – using a CGM significantly improves glycemic control in individuals with diabetes.¹ However, CGMs can be uncomfortable to wear, and are too expensive to be standard care for type 2 diabetes.² We hypothesized that viewing computationally generated, continuous blood glucose curves can yield similar benefits to reviewing CGM data, like improved reasoning and reflection, without the cost and discomfort of a physical monitor.

Methods
Participants were 5 adults (3 female) with diabetes who had recently completed a trial of GlucOracle, a diabetes self-monitoring smartphone application for recording meal logs, with nutrition and pre/post meal blood glucose readings. We conducted a mixed-methods, within-subjects pilot study to compare the experience of reviewing blood glucose as single point measurements, or with a continuous curve. All participants reviewed summaries of their meal logs (Figure 1) with blood glucose represented as pre/post points (Figure 2), or with a continuous curve (Figure 3). The curves were generated using a physiology-based computational model, trained on each participant’s individual data.³,⁴ After reviewing a set of meals, participants also completed a prediction task with another set of meals in which they estimated blood glucose readings after their meals. Participants drew their estimate on the graph using either a single point or a continuous curve, matching the format they had just reviewed. Baseline prediction was assessed before reviewing any meals, and meals were presented in a random order.

Results and Conclusion
All five participants preferred viewing their data with simulated curves. Whether or not they had used a CGM in the past, they thought the continuous representation was intuitive, and that it provided more information than a single post-meal finger stick reading. Many participants mentioned that a single reading lacks information about what happened leading up to the reading, or which direction blood glucose is trending.

While there was no significant difference in the mean squared error of estimates between point and curve conditions, the small sample size of our pilot study limits our power for statistical inference. Counter to our hypothesis, baseline performance was actually slightly better than performance after reviewing meals. This underscores the notion that predicting blood glucose change after a meal is difficult,⁵ and suggests that reviewing individual meals may not improve estimates, and could actually make estimates worse.

Clinical Informatics for Precision Cancer Medicine: Computational Methods for Interpreting Individual Whole Exome and Transcriptome Tumor Sequence Data

Nathanael D. Moore, BS1,2,3,4, Brendan Reardon, BS1,2, Eliezer M. Van Allen, MD1,2,5
1Dana-Farber Cancer Institute, Boston, MA; 2Broad Institute of MIT and Harvard, Cambridge, MA; 3Howard Hughes Medical Institute, Chevy Chase, MD; 4Indiana University School of Medicine, Indianapolis, IN; 5Harvard Medical School, Boston, MA

Introduction

Precision cancer medicine seeks to improve cancer care by tailoring treatments to individual patients’ alteration profiles. Towards this end, we have developed PHIAL (Precision Heuristics for Interpreting the Alteration Landscape), a heuristic clinical interpretation algorithm, and TARGET (Tumor Alterations Relevant for GEnomics-driven Therapy), a knowledge base of clinically actionable alterations. Combined, PHIAL and TARGET can help to inform cancer treatment decisions at the point of care. Our current work involves greatly enhancing and reimplementing PHIAL and TARGET to provide individualized treatment recommendations with greater accuracy.

Methodology

PHIAL was originally designed to analyze somatic whole exome sequencing data. While it was able to extract meaningful alterations from patient tumor data, it was unable to distinguish the relative actionability of variants, did not consider somatic-germline interactions, and was limited to first-order genomic relationships (e.g., BRAF V600E → RAF/MEK inhibition). TARGET began as a catalogue of putatively actionable alterations, but lacked specificity beyond the gene level and was unable to denote the relative confidence of each clinical assertion.

We made several improvements to increase PHIAL’s predictive abilities. PHIAL was revised to predict actionability based on the presence of SNVs, indels, SCNAS, and fusions derived from transcriptome data, by matching the presence of these alterations to information stored in several alteration-action databases. PHIAL also assesses global features (e.g., context-specific mutational burden) for possible clinical relevance. TARGET was redesigned to allow representation of multiple feature types at varying levels of specificity (“assertions”) and to incorporate indicators of clinical confidence (“predictive implication levels”) for each assertion. Finally, 215 new alteration-action relationships were added to TARGET and the resource was made publicly accessible through a web portal.

Results

We applied the original (PHIAL1) and updated versions of PHIAL (PHIAL2) to a cohort of 255 patients with whole exome and transcriptome sequencing data (146 castration-resistant prostate cancer and 109 metastatic melanoma samples). PHIAL1 identified 1,342 putatively clinically actionable/biologically relevant events across the cohort, with a median of 3 events per patient (95% of patients had at least one event). PHIAL2 identified 2,508 events, with a median of 6 events per patient (98.5% of patients had at least one event). Of these events, TARGET associated 8.12% with an FDA-approved therapy and 2.09% with a clinical trial.

Conclusion

Our improvements allowed identification of a greater number of putatively actionable alterations in our patient cohort. PHIAL successfully transitioned from a variant-based to a feature-based approach, and was able to leverage the additional information recorded in TARGET to make more meaningful clinical suggestions. This strategy could inform future use of whole-exome/transcriptome sequencing in the clinical setting, and help identify clinical actions in cases where there is no clear single alteration associated with oncogenesis.

A Comparison of Stroke Classifiers Leveraging Hospital Billing Codes versus Natural Language Processing

Danielle L. Mowery PhD MS1,2; Brent Hill PhD3; Mingyuan Zhang MS4; Wendy W. Chapman PhD1,2; Lisa Cannon-Albright PhD MStat5; Jennifer J. Majersik MD6

1IDEAS Center, George E. Wahlen Veteran Affairs Medical Center, 2Biomedical Informatics, 3Clinical Neurosciences Center, 4University of Utah HealthCare, 5Division of Genetic Epidemiology, 6Division of Vascular Neurology; Salt Lake City, UT

Introduction

In large-scale epidemiological studies, ICD-9 billing codes can misclassify many non-stroke patients as stroke cases resulting in varied precisions (ischemic: 66-95% and hemorrhagic: 65-89%)1. More precise classification might be achieved using information extracted from the clinical notes using natural language processing (NLP) and machine learning. Therefore, we developed an NLP-powered stroke classifier and compared its performance to a classifier using ICD-9 billing codes. This is a first step toward NLP-powered stroke phenotyping to support large-scale pedigree studies leveraging the electronic health record (EHR) and the Utah Population Database.

Methods

For this Institute Review Board-approved pilot study, we randomly selected 400 patients hospitalized in the Neurocritical Care Unit at the University of Utah Hospital from 2008–2015 with hand-adjudicated discharge diagnoses based on EPIC EHR data by two domain experts. This dataset consists of three classes: 50% ischemic stroke, 25% hemorrhagic stroke, and 25% acute neurological disorders (other). We compared the performance of an NLP-powered stroke classifier (linear support vector machine) trained using n-grams (1-4 word features) from radiology notes compared to a stroke classifier trained using ICD-9 billing codes. The NLP classifier was trained with non-stop word features occurring more than twice and ranking in the top 1% using Chi-square feature selection (n=620 features). Each classifier was trained and tested using 5-fold cross-validation (average scores below).

Results

Our NLP stroke classifier produced comparable recall and promising precision for each class.

<td>85.3</td>
</tr>
<tr>
<td>Other</td>
<td>87.7</td>
<td>95.3</td>
<td>81.2</td>
</tr>
</tbody>
</table>

Conclusion

The NLP stroke classifier produces precisions within known performances of epidemiological studies1, but a more complex approach is required to produce comparable ICD-9 precisions, which performed better than anticipated. Given the ICD-9-based precisions are not likely to precisely identify pre-EPIC stroke cases locally and stroke cases at other institutions, we are enhancing our NLP stroke classifier to leverage features from a stroke ontology2.

Developing a Biomedical Information System for the geo-spatial analysis of California Office of Statewide Health Planning and Development (OSHPD) Data among minority population in Los Angeles

Sukrit Mukherjee, PhD, Paul L. Robinson, PhD
1Charles R. Drew University of Medicine and Science, Los Angeles, CA, USA

Abstract
At Charles R. Drew University of Medicine and Science, researchers analyze large secondary dataset called OSHPD using existing ArcGIS software for geo-spatial analysis. But due to limitation in labeling capabilities, role based logins, customized screens and dependence on GIS personnel in ArcGIS, we developed an alternative web-based tool to access, retrieve and analyze OSHPD data from geo-spatial perspective contributing towards an enhanced effort in translational research for removing health disparities at Los Angeles.

Introduction
At Charles R. Drew University of Medicine and Science (CDU), researchers are involved in translational research activities involving minority population in Los Angeles with a goal of removing health disparities. At CDU’s Urban Health Institute, researchers need to study OSHPD data for clinical, epidemiological and health services research. The Institute used to have a license of an ArcGIS software for geo-spatial analysis of OSHPD data and the operation of the ArcGIS needed a GIS person on board to help researchers to run the data through ArcGIS. Our current version of ArcGIS has no labeling capabilities. The role-based security features provided in ArcGIS is also very limited. Although ArcGIS provides some good user interfaces, they are more geared towards sharing data within an organization. They are not really designed to share analysis and study with our collaborators. On top of that, there is very limited support available for developers to customize the screens and analysis algorithm as long as geo-spatial analysis is concerned. These factors justified the background of development of a biomedical information system called ‘OSHPD Geo-Spatial Analysis System’ to load, access, retrieve and analyze OSHPD data for geo-spatial analysis for the study of minority population in Los Angeles.

Methods
OSHPD Geo-Spatial Analysis System was designed and developed after an initial feasibility study which involved carefully analyzing the requirements for our geo-spatial analysis, the existing process of studying OSHPD data and the usage of the data with ArcGIS. The current research strategy in place was used to develop initial conceptualization for the new system including algorithms, functionality, featured interfaces and the expected customized behavior of the system so that researchers could operate the system themselves without turning to GIS personnel for their analysis and processing of OSHPD data.

Results
The pilot implementation of the system was designed with web-based front end designed with ASP.Net and C# and MS SQL Server as backend with clinical, epidemiological and health services researchers in mind. The users specify search criteria including demographics, diagnosis, type of care, admission types, payment, etc. There is an ETL (Extract, Transform and Load) module embedded within the system that loads multiple years of OSHPD data into an optimized SQL Server Enterprise Edition database from flat files media. An automatic parser module located next to the ETL module verifies for the correct syntax of the input data and creates appropriate database schema. The system processes the user input, performs calculations, retrieves data and generates reports either (i) to feed as user specified format to other data analyzing software e.g. SPSS or (ii) to analyze the report online. The ultimate goal of the analysis report or the downloadable file is to act as an efficient aid for the geo-spatial analysis of the minority population belonging to SPA 6 region in Los Angeles.

Conclusion
We addressed the limitations of the ArcGIS software and created a pilot version of a customized solution to access, retrieve and analyze OSHPD data for geo-spatial analysis of the minority population in SPA 6 of Los Angeles. When the system will be deployed on its full scale, this system carries potential to increase the productivity of translational research at CDU thus contributing towards an enhanced effort of removing health disparities at Los Angeles.
Global HIV Case Surveillance Using Electronic Medical Records (EMR) Data
Lisa A. Murie, MSc, Eric-Jan Manders, PhD, James Kariuki, MPH, Mahesh Swaminathan, MD, Xenophon Santas, BA
Centers for Disease Control and Prevention, Atlanta, GA, USA

Introduction
The global HIV epidemic remains a major health challenge in low and middle-income countries (LMIC). Approximately 37 million people are living with HIV globally, 46% of those eligible for treatment receive it, and an estimated 2.1 million new infections occur every year1. The United Nations Programme on HIV/AIDS (UNAIDS) set an ambitious global target that aims to diagnose 90% of all people living with HIV, 90% of whom would receive sustained treatment, and 90% of those on treatment would achieve viral suppression by 20202. To measure progress towards these goals, strategic information planning increasingly requires patient centric monitoring3, and for public health decision making, establishing routine HIV case-based surveillance (CBS) is an essential tool to describe the dynamics of the epidemic. HIV CBS establishes a longitudinal data set to track key events of public health relevance along the continuum of care. The US President’s Emergency Plan for AIDS Relief (PEPFAR) is focusing its effort where the impact of resources is maximized by targeting high burden geographic areas and high volume service delivery settings4. PEPFAR has also supported implementation of electronic medical records (EMR) systems and improved information and communications technology (ICT) infrastructure. This work lays the foundation for leveraging EMR data in the design and implementation of an HIV CBS system5.

Methods
The organization of health services, including governance and policy, are all inputs in the design of the physical architecture and information flow of a national HIV CBS system. For HIV, privacy and security concerns are particularly critical. Based on guidelines mentioned, we describe key events in the care continuum and define the trigger conditions to transmit data from service delivery to the public health level. We construct a minimum data set for the corresponding case report message, and describe the process and content standards that promote data sharing and reuse in public health. Through data mapping, we assess an EMR system’s ability to generate the minimum dataset, which could help identify and address potential gaps in data quality before implementation. We define the role of a surveillance officer - an EMR user who reports to the public health level; and we discuss the role of ICT infrastructure as a primary enabler for electronic data exchange. Lastly, we define an evaluation criteria used to measure the HIV CBS system’s impact on public health decision making.

Results
We have defined a minimum dataset and trigger conditions for an HIV CBS system whose case reports are generated from an EMR, and documented how information flows from a health facility to a public health agency using a business process model.

Discussion
Governance and policy; standards and guidelines; workflow; and ICT infrastructure influence the design of a HIV case surveillance system. This approach leverages on EMR data and increases the value of patient data for public health decision making, and may improve program planning. A thorough documentation of this approach aims to inform a country-led process of defining a regulatory framework, which would enforce compliance to standards and guidelines for HIV case surveillance. A country that aims to implement an HIV CBS system will benefit from an evaluation design where informatics principles and practice as outlined in this work may contribute to the evidence base on how the information system impacts public health decision making.

Does Practice Follow Guidelines? Improving Accuracy for Comparison of Structured and Unstructured Text in Medical Records to Expectations
William J Murphy, MS, Academy of Nutrition and Dietetics, Chicago, IL; Martin M Yadrick, MBI, MS, Computrition, Inc., West Hills, CA; Rosa K Hand, MS, Academy of Nutrition and Dietetics, Chicago, IL

Background: Comparative effectiveness research on evidence-based practice guidelines must be able to distinguish whether care follows recommendations in order to attribute health outcomes to guidelines. Previously, we convened an expert panel to translate recommendations from one guideline into 6 connected steps of an expected care plan (ECPs) using a combination of the Nutrition Care Process and Terminology (NCPT) standardized language(1) and unstructured text. We created an R language(2) script to process data from Registered Dietitian Nutritionist visit documentation to determine the congruence of practiced care with ECPs. We reported previously(3) on a validation study using a blinded manual audit of a random subset of 124 standard comparisons and computed intra-class correlations (ICC, $1 - \beta = 0.8$ for an ICC of 0.6 v. 0.1). The results were acceptable overall (ICC = 0.60), but steps including natural language processing (NLP) performed poorly (ICC 0.0 – 0.38). This report describes our process of improving algorithm performance, including integration with the Unified Medical Language System (UMLS) SPECIALIST lexical tools (SLT) and Metathesaurus (MT) version “2016AA” including >100 ontologies (4).

Methodology: We created an R language interface to the SLT command line tools and the MT Web API. We considered care plan text to match an expectation if they shared ≥ 1 common result in MT queries. We used normalized strings, converted via the SLT Norm program, as MT queries. For documented care unstructured text, we also corrected spelling with SLT GSpellFind and tokenized into n-grams of length 1 – 4. We report on the "goal" step, i.e. specific behavior and health outcome targets, which is unstructured and started with an ICC of 0.00.

Results: All ECP standards for unstructured text matched to ≥ 1 MT concept, indicating relevant concepts were well represented. In sum, “goal” step ICC increased from 0.00 to 0.66 and overall ICC from 0.60 to 0.81. Stepwise improvements are listed in Table 1 to distinguish steps with generalizable NLP from study-specific audits. We recovered “goal” step records from 15 comparisons inadvertently excluded due to missing data. We refined some ECPs based on audit reviews by: excluding some broad concepts causing false positives (e.g. “percent energy intake”), expanding some narrow concepts causing false negatives (e.g. from “protein intake” to “protein”), and adding some near-synonymous standardized terms (e.g. “concentrated sweets intake” in addition to “sugar intake”).

</tr>
</tbody>
</table>

Table 1. ICC improvements with each additional algorithm refinement

Conclusion: Using a medical lexicon and tools greatly increased the accuracy of NLP comparisons between documented care and expectations. Audit results also facilitated the correction of data processing errors. There is a risk for over-fitting due to the repeated use of validation data, but this is limited as we did not use statistical learning or modelling. We now have a tool with acceptable accuracy for the automated comparison of large quantities of structured and unstructured clinical care documentation to guideline expectations.

Vaccine Code Set Management Service Pilot

Stuart Myerburg, JD¹; Regina A. Cox, MPH²
¹Centers for Disease Control and Prevention, Atlanta, GA; ²Deloitte Consulting, Atlanta, GA

Abstract:

CDC’s Immunization Information Systems Support Branch (IISSB) publishes the vaccine terminology code sets used for interoperability and reporting across vaccine delivery communities. Methods to manage and distribute these data sets have not kept pace with technology. The Vaccine Code Set Management Service (VCSMS) pilot has introduced automation and advanced practices to improve data quality, management, and distribution. Results will be demonstrated through feedback and testing, along with examples of data transformation and leading practices.

Introduction:

IISSB works with Immunization Information Systems (IIS), health information management vendors, standards development organizations, and other health organizations to assist with the development of standards and tools for the exchange of immunization data between healthcare providers and IIS. As part of this effort and in order to promote interoperability, IISSB has created a number of code sets to identify and map vaccines, vaccine manufacturers, vaccine groups, and Vaccine Information Statements (VIS). Electronic health records (EHR), drug databases, and public health organizations require these important data sets for recording and tracking vaccine events. The codes and maps are available for download on the CDC website. The data sets include:

<table>
<thead>
<tr>
<th>CDC Authored Standards</th>
<th>Externally Authored Standards (used in CDC maps)</th>
</tr>
</thead>
<tbody>
<tr>
<td>CVX – Vaccine identification codes</td>
<td>NDC – National Drug Codes (FDA)</td>
</tr>
<tr>
<td>MVX – Vaccine manufacturer identification codes</td>
<td>CPT® – Administration Codes (AMA)</td>
</tr>
<tr>
<td>VIS – Vaccine Information Statements, document IDs</td>
<td></td>
</tr>
</tbody>
</table>

The Vaccine Code Sets Management Service (VCSMS) pilot was established to explore new tools for management and delivery of these immunization code sets. The pilot tools and data foundations have been implemented, and pilot constituents will be engaged from March 2017 – August 2017. The effectiveness of the pilot to meet the requirements of the participants will be reviewed based on a pre-defined approach. Lessons learned will be captured and used to inform future discussion and decisions around this service. These findings will be communicated in August.

The main objectives of the pilot are:

- Improve data management and quality – Increase automation to improve efficiency and quality, establish consistently-applied data editorial policies, and improve sourcing of external reference data used for code set maintenance and mapping.
- Expand content structure – Deliver new content data files specifically designed to aid integration with electronic systems.
- Provide distribution alternatives – Provide new configurable options for direct delivery to end user organizations.

Results will include:

- Detailed review and documentation of content changes attributable to pilot automated approaches
- Highlights of new workflow and automation practices implemented for the pilot
- Pilot participant feedback and analysis
- Summary of lessons learned
Pilot study using wearable and mobile app data in patients with the sickle cell disease to describe and predict painful vaso-occlusive crisis.
Kalindi Narine, MD\textsuperscript{1}, Fan Yang\textsuperscript{2}, Tanvi Banerjee\textsuperscript{2}, Jude Jonassaint\textsuperscript{3}, Nirmish Shah, MD\textsuperscript{1}
\textsuperscript{1}Duke University, NC; \textsuperscript{2}Wright State University, OH; \textsuperscript{3}University of Pittsburgh, PA

Abstract: Sickle cell disease (SCD) is a red blood cell disorder complicated by lifelong issues with pain. We used a novel mobile app with wearable sensor to allow analysis using machine learning to better display changes in pain and interventions. We found important correlations between pain and physiologic measurements, therefore believe this technology will provide important insight into patients hospitalized for pain with the potential to predict pain.

Introduction: SCD is typically complicated by painful vaso-occlusion, the most common cause for hospitalization. Through an innovative and interdisciplinary approach involving both clinicians and computer scientists, we have utilized a novel mobile app combined with wearable technology to improve measurements of subjective (such as pain) and objective data (such as heart rate and activity). We now describe our novel TRU-Pain system (Technology Resources to better Understand Pain) that uses statistical analysis and machine learning to map the patients’ physiological information with their pain scores as a means to assist with documentation of pain, interventions, and overall general health. Ultimately, we aim to supplement subjective reports of pain with these objective measurements to better predict pain.

Methods: Patients recorded their symptoms including pain and general health using the TRU-Pain application while wearing the wearable device up to 7 days while hospitalized. The wearable sensor (Microsoft Band 2) measured data including heart rate (HR), activity (steps), galvanic skin response (GSR), and ambient light. Pain is being determined using nursing assessments of pain using visual analog pain scores (0-10; with 0 indicating no pain and 10 indicating the highest pain level) and vital signs (HR, temperature, systolic and diastolic blood pressure). We began our analysis of patient pain data and vital signs using statistical measures including multiple imputation and correlation, as well as machine learning techniques such as logistic regression and Bayesian networks. Wearable data was preprocessed using signal processing techniques such as signal magnitude area and interpolation.

Results: We enrolled and analyzed 11 patients, 40\% females, median age 17 (range 13 to 54) who were admitted for a median 5 days (range 2 to 8). Median data collected was 18,415 (range 352-39,294) points per day with a median of 7 hours (range 6 min to 15 hours) of wearable data. Variation and missing data was found due to removal of the device to charge or the device losing charge while patient was wearing it and not realizing. The need to charge the device frequently is due to the high frequency of measurements. We found a sampling rate reduction of 10 to be reliable for data recording i.e. wearable data entries of 1 per 10 seconds.

We utilized multinomial logistic regression (MLR), one of the most popular and simple machine learning techniques, and support vector machines (SVM), a more complex and nonlinear supervised machine learning technique. MLR proved to outperform the SVM for the SCD patient data. Using clinical records, we were successfully able to identify the patients’ pain score using HR, temperature, and blood pressure data. Using MLR, we obtained a median accuracy level of 0.618 and a weighted F1 score of 0.551. Specifically, we chose weighted F1 score as it is a more generalized metric of evaluation for imbalanced classes. At an individual level, for example, for Patient 3 we were able to achieve a prediction accuracy of 80\% with a logistic regression model to predict the pain scores using multiple imputation method for missing data handling. We chose to analyze the data with machine learning techniques due to it not being temporally challenged; depending more on the number of data samples generated rather than the duration of the data collection, as well as the technique used for evaluation (such as resubstitution, cross-validation, etc.).

Conclusion: Our TRU-Pain system shows strong potential in being able to describe and predict the subjective pain in SCD patients using physiological measures. Our next steps for integration into our pain prediction model include wearable objective data (such as heart rate and activity) and patient subjective reports via our TRU-Pain mobile app. Furthermore, we are decreasing the sampling rate to help battery life and continue to enroll patients admitted in pain.

The Pulse: An Interactive Web-based Application for Tracking Clinical Quality Measure Performance

Benjamin E. Nealy, BS; Raja A. Cholan, BS; Nicholas V. Colin, MA; Bhavaya Sachdeva, MPH; Kevin G. Loftis, BS; David A. Dorr, MD, MS
Oregon Health & Science University, Portland, Oregon, United States

Introduction. The EvidenceNOW initiative provides support to thousands of primary care practices nationally across seven regional cooperatives to improve patients’ cardiovascular health by increasing adherence to key clinical quality measures (CQMs). The regional cooperative in Oregon, Washington, and Idaho is known as “Healthy Hearts Northwest” (H2N). The Pulse is an R-Shiny application used to provide timely, performance-based feedback to 197 practices within the H2N cooperative. We sought to meet information needs of the clinics by creating and revising a display incorporating data validation, benchmarks, performance over time, and changes in population.

Methods. We collect data in quarterly intervals for four CQMs using REDCap surveys. Known as the “ABCS”, the CQMs are: Aspirin when appropriate (CMS164, NQF0068), Blood pressure control (CMS165, NQF0018), Cholesterol management (CMS347, NQF pending), and Smoking cessation (CMS138, NQF0028). Raw survey data is extracted from REDCap into a MySQL database with minor processing. The Pulse Shiny application pulls data from the database in a daily refresh. Additional features, such as tables displaying past submissions, were added based on user feedback. Design and interface improvements were made using Nielsen’s Usability Heuristics, along with feedback from semi-structured qualitative user interviews.

Results. A test page for the application can be viewed at the following URL: https://octri.ohsu.edu/healthyheartsnw/?clinic=TEST. Each participating practice is assigned a unique identifying tag, which serves as a URL parameter directing users to their specific page. The page displays practice-specific process control charts, numerator and denominator bar plots for each CQM, data summary tables, and data validation messages. With an actively refreshed connection to the database, information on The Pulse is kept up to date within 24 hours. Users can display any of the four ABCS measures individually, or view all four simultaneously, using navigation buttons at the top of the application. A set of tabs allows users to switch between the process control charts, numerator and denominator bar plots, both plots side-by-side, or a CQMs summary and definitions page. The first screenshot shows the general layout of the process control chart next to the numerator and denominator bar plot; the second displays sample data validation messages. Participating practices have expressed enthusiasm for The Pulse as a data review tool. Practices' use of The Pulse varies from detailed review of the practices' data to a display used in patient waiting areas. Many facilitators working with enrolled practices use the application to share the practice’s CQM progress at site visits. Others print pages and make annotations to track quality improvement changes and historical changes in performance.

Discussion. We successfully developed and launched The Pulse to fulfill H2N-enrolled practices' need for up-to-date progress tracking and data presentation. The use of both peer and global benchmarks, changes over time, data validation, changes in submitted populations, and variations in display have led to wide use and expressed satisfaction. The technical build can easily be replicated, and the code base used for the application and the REDCap survey is available as an open resource.
Experiences Implementing a User-Centered Design Process across a Large Patient Safety Learning Laboratory

Pamela M. Neri, MS1, Anuj K Dalal, MD2,3, Theresa E. Fuller2, Dominic J. Breuer, MS4, Awatef Ergai, PhD4, David W. Bates, MD, MSc1,2, James Benneyan, PhD4

1Partners Healthcare Information Systems, Boston MA
2Brigham and Women’s Hospital, Boston, MA, 3Harvard Medical School, Boston, MA
4Northeastern Healthcare Systems Engineering Institute, Boston, MA

Problem: User-centered design (UCD) is a critical component to ensuring health information technology is adopted in complex health settings. Yet, many healthcare IT projects struggle to follow a rigorous user-centered design process because they do not have access to resources and expertise. We describe our experience of implementing a centralized UCD process as part of a large AHRQ patient safety learning laboratory initiative to design, develop, and implement novel technology (acute care patient portal, safety reporting system, safety dashboard, safety screen-savers) with the goal of making acute care safer.

Description: We assembled a core team of interdisciplinary experts with the goal of providing centralized systems engineering, human factors, and data analytic expertise to each of three projects. With assistance from the core, individual project teams worked to develop and implement patient- and provider-facing tools designed to identify, assess, and mitigate safety threats. The core shared templates and examples of user research collection forms and usability test plans that were used by each of the projects. Patients and providers on the study units were invited to participate in these methods. Core members attended individual project meetings to guide and encourage a user-centered approach. We provided usability feedback on prototypes that was used for iterative refinement, and conducted workflow observations to evaluate use of these tools during pilot testing. We assisted with content analysis of feedback gathered from these activities. We used a 2-person consensus approach to identify lessons learned.

Lessons Learned: While there was some success in soliciting input from users on the usability and design of individual tools and using UCD methods for individual projects, we encountered several challenges integrating a centralized and rigorous UCD process across the entire learning laboratory as originally envisioned. Key lessons learned include the need for 1) upfront expectation setting and standardization of the UCD approach across individual projects; 2) focused UCD educational sessions and tutorials to ensure consistent and comprehensive methods for gathering user feedback; 3) centralization of the user requirements gathering phase to specifically include requirements for how individual technological components (safety icon on bedside screensaver for patients and clinicians; dashboard event indicators on safety dashboard for clinicians) could work together as a unified system to prevent specific harms (fall, CAUTI, CLABSI). A secondary goal was to ensure we addressed the needs of all user types. We learned that different user types varied considerably with regard to their needs, mental models, literacy, and experience using technology in general, including the technological components of our intervention. Particularly challenging in this setting was gathering user input from a vulnerable patient population. Lastly, another major challenge to incorporating user-centered design across the individual projects of our safety learning laboratory was navigating the technical and design constraints of a new vendor-based enterprise EHR.

Summary: The core team of interdisciplinary experts was able to provide some centralized guidance and expertise in user-centered design across the patient safety learning lab. We learned that we could have benefited from earlier and more rigorous planning, education and requirements gathering, including identification of and planning in regards to the specific challenges of conducting this work in the healthcare environment.
Impact of Predictive Analytics on Clinical Outcomes, Clinical Decision Making, and Healthcare Organization Performance: A Systematic Review

Neris M. Nieves-Robbins, MD1, Matthew Parry, DO1, Andrew J. Holdaway, MD1, Robert C. Marshall, MD1, Fredric Wolf, PhD2, Peter Tarczy-Hornoch, MD2
1Madigan US Army Medical Center, Tacoma, WA; 2University of Washington, Seattle, WA

Introduction

Adoption and focused use of predictive analytic capabilities have been proposed as effective strategies to improve clinical practice, patient health and the delivery of healthcare services. Despite the rapid growth of the healthcare analytics market, there is a lack of integrated evidence from the peer-reviewed literature to understand the impact of predictive analytics across the various healthcare industry domains.

Purpose

The purpose of this study was to systematically review the literature for evidence of predictive analytics’ impact on clinical outcomes, clinical decision-making and healthcare organization performance.

Methods

An electronic literature search of PubMed, CINAHL, Web of Science and Business Source Complete databases was conducted for articles published in English from January 1, 2010 to January 30, 2017, after consultation with a librarian. All searches included the keywords (predictive analytics) OR (machine learning). The Business Source Complete search also contained the term AND (healthcare) to exclude results from other industries. All studies that evaluated the impact of predictive analytic capabilities used by healthcare organizations or employees to optimize performance, patient outcomes or decision-making were considered. Studies that did not refer to predictive analytics or systems with predictive capabilities, did not pertain to healthcare, and/or did not refer to systems used in actual practice were excluded. Two reviewers independently screened the titles and abstracts to assess publication eligibility. Differences were resolved by consensus and as needed, in consultation with an experienced researcher. Information was extracted from the eligible publications in accordance with Preferred Reporting Items for Systematic Reviews and Meta-analyses Protocol 2015 (PRISMA-P). Standard tools were used to assess the methodological quality and the risk of bias of the eligible publications.

Results

Database searches returned a total of 42144 articles. A total of 41382 unique titles remained after 3679 duplicate publications were removed. The titles and/or abstracts of the 41382 articles were reviewed. A total of 257 articles required a detailed abstract review. Sixteen articles were categorized as potentially eligible based solely on detailed abstract review and were retrieved for full article review. After full article review, a total of 5 out of the 16 articles were categorized as eligible. The most common reasons for article exclusion were that the articles were limited to: the conceptual domain, a computerized test environment and expert opinion. The eligible articles focused on two major areas: high acuity service over-utilization and operations management optimization. Risk of bias and methodological quality assessments of the studies showed mixed results. The designs, participants, interventions, comparators and outcomes of the eligible studies were varied. The studies focusing on operations management showed mixed results. The studies focusing on high acuity services showed reduction in over-utilization, with the caveat that the studies were of variable quality and had varying risk of bias.

Conclusions:

Our results show that applied healthcare predictive analytics research is in its early stages. Our results also indicate that there is insufficient high-quality evidence to assert that predictive analytics has significantly impacted clinical outcomes, clinical decision-making and organizational performance. Additional evidence-based information may be needed to hasten broader adoption and effectively leverage this capability to enhance all healthcare domains.
**Data Management, Sharing, and Citation Strategies in The Cancer Imaging Archive (TCIA)**

Tracy S. Nolan, BE¹, Justin S. Kirby, BS², Fred W. Prior, Ph.D.¹

¹Biomedical Informatics, University of Arkansas for Medical Sciences, Little Rock, AR
²Frederick National Laboratory for Cancer Research, Leidos Biomedical Research, Inc., Frederick, MD

**Introduction:** Big Data are expensive to collect, and complex to share

Imaging is a key component of precision medicine research. Unlike genomics and proteomics it is non-invasive, capturing the whole tumor and its spatial environment. Cancer imaging is expensive to acquire in time, cost, specialized hardware, and patient population recruitment. Sharing such data is not easy due to government regulations regarding patient privacy. Retaining key scientific information for downstream research while removing protected health information is particularly challenging. So it is extremely valuable that The Cancer Imaging Archive (TCIA)¹ ² extends global sharing and re-use of such data for secondary research aims and reproducibility studies.

**Data Management: Biomedical data are heterogeneous**

Biomedical data that have been aggregated and curated on standardized criteria into public repositories produce the widest reuse potential. Each hospital department uses their own local terminology, scan protocols, and different vendor hardware. Heterogeneity in clinical and research data acquisition pose significant curation challenges to research data centralization, compatibility, searchability, security, quality, and ease of use up- and down-stream. TCIA addresses these problems and provides centralized access through a trusted, curated repository. For example, a research question needing slides, CT scans, and drug response from a dozen different clinical trial sites can be accomplished via a single download request through TCIA.

**Sharing: The Cancer Imaging Archive (TCIA) is an open data repository federated with others**

TCIA hosts mostly DICOM³ format imaging of human cancer, often with supporting data (linked out⁴ or attached via wiki) used to generate the results that the authors who share their research have published. TCIA shares “Primary Data” (e.g. original radiological scans, clinical and imaging protocols, segmentations, software), and encourages users to recombine data (to create, cite, share new data groupings) as “Analysis Results.” These Analysis Results, created with diverse commercial and open source tools, have myriad file formats too. TCIA and other open biomedical repositories (genomics, pathology) expend considerable effort to use common terminology and research identifiers across data types. Data sharing and fusion across modalities increase overall research data quality and guide policy; helping the community distribute, test, and converge upon standards as tools mature.

**Citation: The Digital Object Identifier (DOI) as a citation tool both upstream and downstream**

Granularity of data citation through persistent DOIs in TCIA can be variably tailored to refer to articles, datasets, feature sets, or a wiki page of project details. The data authors, PubMed, TCIA, or granting agencies can use DOI tracking analytics to show that data mining is ongoing by the primary investigator and others, proving the initial grant investment was good – or that data are not being used, so resources can be optimized.

**Conclusion**

Federated, curated, public open data archives like TCIA support increased hypothesis complexity, then also the validity and value of results. Original research resources are extended by new analyses. However, it is essential to quantify the quality and completeness of source data, which DOIs can help facilitate. Dataset publishers open doors for researchers, clinicians, and the public to stretch the available technologies, with academic credit to data and process sources, to address precision medicine responsibly.

The Depth of Historical Electronic Information Seeking by ICU Clinicians

Matthew E. Nolan, MD¹, Rodrigo Cartin-Ceba, MD, MSc², Pablo Moreno-Franco, MD³, Brian Pickering, MD¹, Vitaly Herasevich, MD, PhD¹
Mayo Clinic, Rochester, Minnesota; Mayo Clinic, Scottsdale, Arizona; Mayo Clinic, Jacksonville, Florida

Abstract
The electronic information-seeking behaviors of intensive care unit (ICU) clinicians are incompletely understood. We surveyed 234 ICU clinicians about the historical depth of their ‘electronic chart review’ when admitting new patients, receiving 155 responses (66% response rate). 2/3 of clinicians estimate reviewing data at least 3 years back, highlighting the need for thoughtful design and intelligent filtering techniques within critical care information systems to provide ready access to such large volumes of historical data.

Introduction
Electronic chart review (or “chart biopsy”) is a prevalent and important task performed by clinicians in order to build a patient narrative, but there are few studies evaluating this information-seeking behavior. Our research group is developing an electronic tool that can display longitudinal health data in a visual narrative for medical intensive care unit (ICU) patients, which requires an in-depth understanding of chart review habits.

Methods
We surveyed medical ICU clinicians at three Mayo Clinic sites, including rotating residents, fellows, attending physicians, and advanced practice providers. Among other questions, clinicians were asked to estimate how far back into the medical record they browse when admitting a new ICU patient.

Results
155/234 ICU clinicians responded (66% response rate). Sixty-six percent of clinicians reported reviewing data at least 3 years back, and over 1/3 of clinicians review data from 10 years or more (Figure: Estimated Depth of Historical Electronic Chart Review by ICU Clinicians Admitting New Patients)

Conclusion
Most ICU clinicians require ready access to the majority of the historical medical record for new patients, which emphasizes both the importance and simultaneous difficulty in providing and displaying this information succinctly. Critical care information systems require thoughtful design and intelligent filtering to address this information need.

The Relationship Between “Reason for Exam”, Radiologist’ Perceived Unexpected Effort, and the Time to Complete Interpretation

Daniel T. Nystrom, MS1, Heidi Kramer, PhD1, Marta E. Heilbrun, MD, MS2, and Charlene Weir, PhD, RN1

1Department of Biomedical Informatics, University of Utah, Salt Lake City, UT; 2Department of Radiology and Imaging Sciences, University of Utah, Salt Lake City, UT

Introduction
The reason for exam provides key clinical information to radiologists that support an accurate determination and efficient search through radiologic images. Despite the importance of the reason for exam, little research has been done to consider how aspects of the reason for exam impact radiologist workflow. The purpose of this pilot study is to assess the relationship between the clarity of the reason for exam, the amount of information, and the time to complete the exam, and radiologist’ interpretative effort.

Method
We observed 4 radiologists at a local academic health care system perform multiple image interpretations during 1-hour sessions and across 51 image interpretations (ranging from 8 – 22 interpretations). The amount of time to perform each interpretation was collected. In addition, radiologists were asked to make 3 judgements about each interpretation; 1) the clarity of the reason for exam using a 7-point Likert scale ranging from 1= “Poor” to 7= “Excellent.”; 2) the amount of unexpected effort they experienced while performing the exam ranging from 1= “None” to 7= “Exceptional.”; and 3) the amount of information available in the reason for exam from 1= “None” to 7= “Sufficient.” The correlation between clarity of the reason for exam, the amount of information available in the reason for exam, unexpected effort, and time to complete the exam was assessed.

Results
A weak negative correlation (r = -0.33) was observed between clarity of the reason for exam and perceived unexpected effort (Table 1). Unexpected effort was positively correlated to the amount of time spent on the exam (r = 0.52). No correlation between clarity of the reason for exam and time to complete the exam was observed (r = -0.03). The amount of information in the reason for exam was correlated to unexpected effort (r = -0.29) and the clarity of the reason for exam (r = 0.92), but not to time (r = 0.06).

Table 1. Mean ± (SD) and results of Pearson correlations for radiologist ratings and time to complete exam

<table>
<thead>
<tr>
<th>Variable</th>
<th>Mean ± (SD)</th>
<th>Variable Correlations</th>
<th>Pearson r</th>
</tr>

<tbody>
<tr>
<td>Clarity of reason for exam</td>
<td>4.10 ± (2.12)</td>
<td>Clarity X Effort</td>
<td>-0.33 (p&lt;.05)</td>
</tr>
<tr>
<td>Unexpected effort</td>
<td>2.00 ± (1.55)</td>
<td>Effort X Time</td>
<td>0.52 (p&lt;.001)</td>
</tr>
<tr>
<td>Time to complete exam (in seconds)</td>
<td>217.49 ± (244.94)</td>
<td>Clarity X Time</td>
<td>-0.03 (p&gt;0.05)</td>
</tr>
<tr>
<td>Amount of information</td>
<td>3.79 ± (2.30)</td>
<td>Amount of info X Effort</td>
<td>-0.29 (p&lt;0.05)</td>
</tr>
<tr>
<td></td>
<td></td>
<td>Amount of info X Time</td>
<td>0.06 (p&gt;0.05)</td>
</tr>
<tr>
<td></td>
<td></td>
<td>Amount of info X Clarity</td>
<td>0.92 (p&lt;0.01)</td>
</tr>
</tbody>
</table>

Conclusion
Results of this study indicate that as the clarity of the reason for exam and the amount of information in the exam decreases, the perceived effort to complete the exam increases. However, neither clarity of the reason for exam nor the amount of information in the exam was significantly correlated to the amount of time radiologists took to complete their interpretation. Based on these results, we are conducting further research to determine the strategies that radiologists use to regulate their workflow to compensate for poor reasons for exam.

Using Point of Care Systems to Deliver Patient-Centric Care: Lessons from an Australian Case Study

Louise O’Connor1, Peter Haddad 1, 2, Nilmini Wickramasinghe 1, 2

1Epworth HealthCare, Victoria, Australia, 2Faculty of Health, Deakin University, Melbourne, Victoria, Australia

Abstract
Ensuring a high level of patient-centric care is an integral consideration globally for healthcare delivery today. Evidence from the literature underscores the benefits of such an approach for enhancing the quality of care and reducing associated costs. This study investigates the use of a point of care system’s ability to deliver high value patient-centric care across a private not-for-profit tertiary healthcare group in Australia. The results show that the examined system supports patient-centric care by facilitating the fostering of good relationships between patients and their clinicians, as well as building a cultural shift towards patient-centric care as part of standard practice.

Introduction
Patient-centric care provides customised precision care to each patient’s individual needs and requirements [1]. The literature identifies several components of patient-centric care delivery, including: patient participation and involvement and the context where care is delivered [2]. This study focuses on the use of the OneView Point of Care system at an Australian not-for-profit tertiary healthcare group and its role in building a strong patient-centric healthcare system. This system is a bedside computerised information system whose terminals provide patients with a range of entertainment, education and information services, and clinicians with a range of integrated clinical applications including electronic prescribing and administration, patient results, and electronic nurse rounding. In addition, it serves non-clinical functions to cover the food and environmental needs for patients.

Methods
This exploratory multi-site, single case study [3] adopts a mixed methods approach. Data collection includes a series of 15 semi-structured interviews carried out across the various sites of the selected case over 12 months. The interviews targeted the users of the system, including clinicians (nurses and allied health), and other staff (food and environmental services). The interviews were transcribed and analysed using thematic analysis [4]. Data triangulation was achieved by site visits and hermeneutic analysis of documents, including annual reports and various case reports.

Results
The results highlight various aspects of how the system supports patient-centric care as a senior executive describes: “the point-of-care system is about creating an environment of patient-centric care, putting the staff and the doctors back where they want to be, which is in the patient's room”. In addition, as the system is at the bedside, it requires the nursing staff to visit their designated wards more often, which helps better monitoring of their patients and prevents incidents as another interviewee explains: “If staff are not in the patient's room, that's when bad things happen. That's when patients feel dissatisfied, that's when the doctor doesn't know what's going on, etc.” The system has also enabled a cultural shift so that being a patient-centric healthcare provider is now part of standard practice: “Culture is the most important thing in healthcare, because how you behave as a clinician and how you develop relationships with a patient - so your culture - is what drives your results as well”.

Conclusion
The OneView Point of Care system was found to clearly support the sustained delivery of patient-centric care. Critical aspects enabled and supported through the system include: patient participation and involvement, the relationship between the patient and the healthcare professional and the sharing of germane and pertinent information. In addition, a culture shift took place. Thus, the study is expected to highlight key aspects of enabling and supporting patient-centric care through technology implementation and adoption.

Validation of the Knowledge and Self-Management NOC Outcomes for Adults with Diabetes

Hyunkyoung Oh, PhD, RN1, Sue Moorhead, PhD, RN, FAAN2
1University of Wisconsin-Milwaukee, Milwaukee, WI; 2University of Iowa, Iowa City, IA

Introduction
Current health care focuses on preventive care to avoid the development of chronic diseases. Specifically, diabetes is one of the most significant chronic diseases due to its high prevalence and mortality. People with diabetes have to know how to self-manage their health conditions to promote, maintain, and restore their health. The Nursing Outcomes Classification (NOC) has been developed to evaluate and quantify the status of the patient and the effects of nursing interventions over time and across care settings1. NOC is one of recognized standardized nursing languages by American Nursing Association. The 5th edition of NOC has provided the two NOC outcomes for people with diabetes to evaluate their knowledge and self-management behaviors. First NOC outcome was Knowledge: Diabetes Management and its definition was “extent of understanding conveyed about diabetes, its treatment, and the prevention of complications”. This NOC outcome has the 36 indicators to evaluate knowledge status of patients. Second NOC outcome was Self-Management: Diabetes and its definition was “personal actions to manage diabetes, its treatment, and to prevent complications”. This NOC outcome has the 44 indicators to evaluate patients’ behaviors for self-management. However, these two NOC outcomes were not validated yet. Generally, validation of a measurement tool is required to provide trustworthy evidence2. As measurement tools, these two NOC outcomes need to be validated for accuracy, meaningfulness, and usefulness in clinical settings. The purpose of this study was to validate the knowledge and self-management NOC outcomes for adults with diabetes published in the fifth edition of NOC1.

Overview of methodology
A descriptive exploratory design using the Delphi technique was used to validate the two NOC outcomes and collect data. Two sets of experts were invited to participate in the review of the outcomes. The first expert group was related to standardized nursing languages and invited experts were members of the NANDA International or a fellow of the Center for Nursing Classification and Clinical Effectiveness. The second group was related to self-management and invited experts were members of Midwest Nursing Research Society. Descriptive statistics were used to determine the definition adequacy, clinical usefulness, and content similarity. The Outcome Content Validity (OCV) method was used to evaluate the content validity of each outcome and the indicators.

Results
A total of 16 nurse experts participated in this study. The mean experience in specialty of respondents was more than 20 years. Each definition adequacy of the two NOC outcomes was over 4.0 (perfect score is 5.0). This means that each definition was adequate to describe the outcomes. Clinical usefulness was also over 4.0. and this rating indicates that the measurement scales were easy to use in the clinical settings. The range of content validity of the two NOC outcomes was from 0.89 to 0.92 (perfect score is 1.0) using average OCV scores. According to OCV method3, over 0.80 means that this outcome is critical. The indicators of two NOC outcomes should evaluate consistent diabetic knowledge and behaviors. The invited experts reported that the content of this outcome pair was very similar each other (mean=4.0, SD=0.516).

Conclusion
The two NOC outcomes focused on knowledge and self-management for diabetic patients were validated, and the results provided strong validity. By using validated NOC outcomes, nurses who take care of patients with diabetes can evaluate patient outcomes effectively and determine the effect of nursing interventions accurately. Additionally, nursing students can understand and utilize the outcomes to specific populations based on linguistic accuracy of the validated outcomes. In order to obtain more accurate reliability and validity, these NOC outcomes should be revalidated after applying them to patients in the various clinical settings.

Parsing MetaMap Files in Hadoop

Amy L. Olex, M.S., Alberto Cano, PhD, Bridget McInnes, PhD
Virginia Commonwealth University, Richmond, Virginia, USA

1 Problem Description
Processing and interpreting text is natural to humans but extraordinarily difficult for machines. Much of how a person interprets texts is based on prior knowledge of concepts and associations between concepts. The UMLS::Association Perl package aids in interpreting biomedical texts by quantifying levels of association between UMLS (Unified Medical Language System) concepts. The UMLS Metathesaurus contains over 2.5 million names representing over 900,000 concepts identified by Concept Unique Identifiers (CUIs). MetaMap parses biomedical and clinical texts and links them to UMLS CUIs, and this output is processed by UMLS::Association to collect CUI bigram frequencies and quantify CUI associations. The collection of CUI bigram frequencies provides a background of knowledge from which to extract associations between biomedical concepts for further processing. However, parsing this information is time consuming, as there are hundreds of large (several gigabytes) MetaMap files for each processed text corpus.

UMLS::Association relies on the collection of CUI bigram frequencies identified by the CUICollector module, which parses the nested MetaMap structure one utterance at a time. As the CUI bigrams are parsed they are stored in a nested hash of hashes that is periodically dumped to a MySQL database. This serial implementation has several limitations: 1) Perl code is serial and not parallelizable due to Perl’s limitations in sharing nested hashes across threads for synchronization. 2) The bigram hash can become very large, very fast and fills up program memory, which forces the program to periodically write results to a MySQL database, introducing additional latency.

2 Purpose of Project
CUICollectorMapReduce takes advantage of the Hadoop MapReduce framework to overcome serial implementation limits. MapReduce algorithms are well suited to parsing text and counting occurrences. In addition, the Hadoop environment reads and writes all results directly to disk thereby resolving the memory issue. MapReduce was chosen over other distributed processing technologies (e.g. SPARK, Flink) due to system limitations in memory, a large data set size, and the batch nature of the problem that requires accessing the data only once. CUICollectorMapReduce has two modes: cui and article. In cui mode MetaMap output is parsed directly, one utterance at a time, and duplicates the results of the serial implementation. In article mode CUICollector concatenates utterances to allow the processing of an entire PubMed citation, which includes collection of CUI bigrams that cross utterances.

3 Results
Evaluation was conducted on the MetaMap 2015 MEDLINE Baseline, a 132GB compressed dataset of biomedical citations. The efficient implementation in Hadoop resulted in a 28x speedup in cui mode, reducing run time from 229 to 8 hours on a 4-core, single-node Hadoop system. Analysis of Hadoop output in comparison to that of the serial implementation revealed equivalent results. Required database operations in the serial implementation account for the majority of the serial running time. To more directly compare just the parsing speedup of Hadoop, all database operations were removed from the serial program, resulting in no program output. Hadoop still processed the data faster with a speedup of 2.8x when run on the full MetaMap 2015 MEDLINE Baseline compared to the modified serial implementation.

4 Contributions
The contributions of CUICollectorMapReduce are: 1) Parallel processing of MetaMap files with seamless scalability. 2) Eliminating the need to periodically write to a MySQL database by utilizing Hadoop’s framework where all intermediate and final results are written and read directly from disk. 3) Algorithm improvements allow for a full PubMed citation to be processed at once instead of one utterance at a time. In conclusion, implementing CUICollector in the Hadoop MapReduce environment provided significant speedup as well as additional flexibility in the type of data being processed. The Hadoop implementation also allows parsing of larger datasets that were not feasible using the serial module, thus, opening up additional avenues of research.
Medication Errors Following a Home-Grown Electronic Health Record Implementation: Identifying and Overcoming Unanticipated Challenges

Waldo Ortega, MD1, Carolina Ibañez, RN1, Marcelo Lopetegui, MD, MS1,2
1 Departamento de Informática Biomédica, Facultad de Medicina, Clínica Alemana Universidad del Desarrollo, Santiago, Chile
2 Centro de Innovación e Investigación en Informática Biomédica, Facultad de Medicina, Clínica Alemana Universidad del Desarrollo, Santiago, Chile

Introduction
Medication errors are one of the most important topics regarding patient care safety, reaching up to 1,000,000 serious medication errors per year in American hospitals, and producing 7,000 deaths annually. Although the introduction of computerized physician order entry (CPOE) has decreased medication errors, there is sparse evidence suggesting it could add new adverse events. Fifteen years after the publication of “To err is human”, The National Patient Safety Foundation (NPSF) reports that not significant changes have been made since.

In an attempt to improve patient safety and quality of care, our institution decided to replace its aging commercial electronic health record with a home-grown hospital information system, with modules specifically developed to support a safer medication process management. This study aims to identify and describe the impact of the implementation of this new system, and report the remaining gaps and opportunities to improve patient safety.

Methods
We analyzed a self-report registry of medication errors maintained by nurses at a large private hospital in Chile in order to identify existing errors, their source and moment of occurrence. Then, we assessed the perceived impact of the new hospital information system on medication errors by conducting semi-structured interviews with key stakeholders using the Reason Model. We performed content analysis of the interviews, focusing on errors solved and potential new errors introduced by the system. This information was contrasted between the different interviewees and with published evidence.

Results
The new EHR solved most of the problems identified at baseline. However, it introduced opportunities for new unexpected errors. Among newly introduced opportunity for errors, we identified two main categories: 1. Errors related to the use of the Chilean standardized pharmacological nomenclature, which differs from international standards; and 2. errors related to changes in clinical workflows. Most of them occurred during prescription or medication administration. The knowledge gathered is being used to develop updates to the involved modules and maintain a continuous patient safety assessment cycle.

Discussion
Medication errors evaluation in the era of EHRs requires a systematic approach. International guidelines and recommendations should be followed by all major EHR vendors as well as home-grown solutions in order to avoid repeating mistakes that have been already solved elsewhere. We recognize the value of adopting international instruments to conduct continuous internal assessments and benchmarking against similar healthcare institutions in Latin America, and reporting opportunities to clinicians. (Leapfrog evaluation, Medication Safety. http://www.leapfroggroup.org/).

Information and Communication Technologies Adoption by Healthcare Professionals in Brazil
Cristina Lucia F. Ortolani, PhD¹; Fabio Senne¹; Alexandre Barbosa, PhD²; Heimar F. Marin, PhD, FACMI³
¹ Universidade Federal de São Paulo, Brazil ² Universidade Paulista, São Paulo, Brazil, ³Regional Center for Studies on the Development of the Information Society – Cetic.br, São Paulo, Brazil.

Abstract
The range of possible applications of ICTs in the healthcare system is enormous. The technology has progressed significantly and ICT implementation is expected to result in higher quality and more efficient healthcare system. The main objective of this research is to share information about ICT adoption and use by health care professionals in Brazil according to OECD indicators, considering the current stage of technological infrastructure implementation, including the availability of ICT-based services in Brazilian healthcare facilities.

Introduction
Information and communication technologies (ICTs) are defined as digital and analogue technologies that facilitate the capturing, processing, storage and exchange of information via electronic communication¹. ICTs used in the health sector have well-known advantages as they have the potential to improve information management and access to health services. They are also effective for cost containment and promotion of education among patients and health professionals⁴. However, implementation of ICTs remains difficult and involves changes at different levels: patients, healthcare organizations and healthcare professionals. The aim of this study is to understand the stage of ICTs adoption in Brazilian healthcare facilities and their appropriation by healthcare professionals.

Methods
This descriptive study, in which the researcher interacted with the participants, was dedicated to collect the necessary information through surveys. The sample was comprised by 3,582 health facilities in 350 Brazilian cities selected by probability-proportional-to-size sampling, using the square root of the number of professionals in each facility. Data collection was performed through two structured questionnaires, one applied to administrative professionals (n=1,685), and another to healthcare professionals (n=1,484 physicians and n=2,696 nurses). The physicians and nurses answered questions about their own routines as healthcare professionals, their profiles, as well as ICT access, use and appropriation.

Results
Among those with computer access at the healthcare facilities, 59% of nurses used computers daily when seeing patients, a percentage that reached 70% among physicians. Regarding computer use in other work activities, meaning those that do not involve direct contact with the patients, percentages were higher: 84% of physicians and 75% of nurses with computer access used them daily. The main problem with the use of electronic information by professionals when accessing the patient electronic clinical data was the lack of availability at the facilities.

Conclusion
Health professionals referred to registered data and used system functionalities when those were available at the facilities. This corroborates the idea that professionals’ compliance to the use of technological solutions is not a hindrance to implementation. Instead, the unavailability of technological applications and functionalities in facilities is still one of main challenges to adopting ICT-based solutions.

Sepsis Risk Stratification among the CMS Oncology Care Payment Model Population

Benjamin E Orwoll, MD1, Konrad Dobbertin, MPH1, Michael Savin, MD1, David A. Dorr, MD1, Peter Graven, PhD1
1Oregon Health & Science University, Portland, Oregon, USA

Introduction

In 2016 the Centers for Medicare and Medicaid Services (CMS) initiated the Oncology Care Model (OCM), an alternative payment model for chemotherapy care. Participating practices are incentivized to provide more efficient, high quality coordinated care at reduced cost, with shared financial risk. Incentives are based on patient outcomes and in overall Medicare costs during each 6-month episode. Historical claims data provided by CMS on patients from our institution's practice identified sepsis admissions, both at our institution and outside facilities, as a major source of potentially avoidable cost. Early identification and monitoring of patients at high risk for this condition could lead to better patient health and lower care costs. Community acquired sepsis risk scores exist, but may not represent this high-risk population. We sought to develop a predictive model to identify OCM patients at high risk for sepsis hospitalizations.

Methods

Patients were identified by CMS as those who would have been assigned to our institution between 1/2012-6/2015. We used Medicare claims data from that period provided by CMS to identify sepsis hospitalizations at any hospital based on MS-DRG and ICD-9 codes for sepsis, septicemia, and septic shock. Data from the local EHR including demographics, problem lists, medical history, labs, and medication orders were evaluated for inclusion in the predictive model, based on literature and clinical plausibility. We used survival-time models with Weibull distribution and stepwise elimination (threshold \( p \geq 0.05 \)) to calculate the sepsis hospitalization risk (SHR).

Results

1501 patients had care episodes during the study period. Characteristics are shown in Table 1. There were 123 sepsis hospitalizations (8%), with only 41% of those occurring at our institution. Mortality was 41% for the entire sample, but 74% of patients with sepsis died by the end of the study period. We identified 12 significant factors (Table 2) that formed the risk prediction model; while some of these were static, such as cancer type, others were time varying. For prediction of sepsis within 30 days our model had an area under the receiver-operating-characteristic curve of 0.73 (95% CI 0.70-0.76)

Conclusions

We developed a risk prediction model for SHR among high risk chemotherapy patients in the OCM. Our model uses data that is available up to date within the local EHR to predict events at all locations. We plan to validate the model using future CMS claims data, which are only available retrospectively. The model could potentially be used to identify high risk subgroups who might benefit from more intensive monitoring and care coordination, and a 30 day outlook provides a manageable time frame and cohort size. The contribution of both static and time-varying predictors suggests that monitoring and decision support programs may need both initial and ongoing evaluations for those at highest risk.

Implementing a Real-Time Location System (RTLS) at an Ambulatory Oncology Surgical Center

Aaron Ostrovsky, MPH, Alex Stevens, MA, ED, Justin McManus, Marcia Levine, MSN, RN, NE-BC, Brett Simon, MD, PhD, Peter Stetson, MD, MA, Daniel Stein, MD, PhD
Division of Health Informatics, Department of Nursing, Josie Robertson Surgery Center; Memorial Sloan Kettering, New York, NY

Introduction

Real-Time Location System (RTLS) technology, which involves the automated, collection of location-based data from a tagged entity, has been used in healthcare for a variety of use cases, such as: asset tracking, patient safety, workflow optimization, and environmental monitoring. Asset tracking has offered the greatest return on investment; however, recently the desire to focus on patient flow and workflow optimization has increased. This has been reported in the outpatient setting for monitoring room allocation or improving the efficiency of patient and staff flow. Here we present a novel use case of using RTLS to optimize care coordination and patient flow at a new ambulatory oncology surgical center, the Josie Robertson Surgery Center (JRSC).

Methods

The system implemented at the JRSC was Versus RTLS (Versus Technology, Inc., Traverse, MI). This implementation involved the installation and deployment of 768 wired-infrared (IR) sensors, 677 staff badges and 244 asset tags. The staff, patient and caregiver badges utilize both IR and radio frequency (RF) whereas the asset tags use IR and Wi-Fi locating. Interfaces with several other systems were built, including two EHRs, the nurse call system, and our in-house patient engagement system. The RTLS client was installed on 450 clinical and non-clinical workstations. Displays with live facility maps were mounted throughout the facility, so clinicians and staff could determine location of patients and care team members and monitor the status of operating and patient rooms.

Results

Since the opening of JRSC in January, 2016, we had an average of 360 unique RTLS users per month. Of that user population, 15% were perianesthesia nurses, 10% were nurse anesthetists; and the remaining 75% were other clinical and non-clinical groups. There were 7,677 patients who received an RTLS badge. Implementation of the RTLS system has resulted in reduction of error-prone documentation through the automation of clinical time stamps and has augmented communication through location-based awareness and presence-based nurse call cancellation. Bed management was enhanced by using the RTLS system for Pre-op and Post-op bed assignment. For patients and their caregivers, RTLS offered care team awareness through real-time staff and role identification, a novel patient metric for ambulation post surgery, and a family waiting view that provided updates and visual cues to family members.

Discussion

RTLS in this setting has the capability to save clinicians time, improve accuracy of data, enable care team awareness, solve unmet workflow needs, and provide new data to clinicians and patients that could impact care decisions and overall quality of the surgical experience. However, there are technology and process limitations such as badge-wearing compliance, high implementation costs, and the lack of robust native analytical tools. Future work and recommendations include integration with staff communication systems, studies to formally evaluate clinician and patient experience with RTLS, and a retrospective analysis to optimize efficiency within the perioperative space.

Innovative Approaches in Informatics Education

Bunyamin Ozaydin, PhD\textsuperscript{1}, Sue Feldman, RN, MEd, PhD\textsuperscript{1}, Laura J McNeill, MS\textsuperscript{1}, Amanda Dorsey, MSHI\textsuperscript{1}, Meg Bruck, MSHI\textsuperscript{1}, Eta S. Berner, EdD\textsuperscript{1}

\textsuperscript{1}University of Alabama at Birmingham, Birmingham, AL, USA

\section*{Introduction}

After revising University of Alabama at Birmingham’s (UAB) online Master of Science in Health Informatics (MSHI) curriculum to a core/track model in 2014\textsuperscript{1}, a decision was made to take relevant portions of it to offer as an online graduate-level credit certificate in clinical informatics. Because the proposed certificate courses are drawn from the existing core courses in the MSHI program, they, like the UAB AMIA 10x10 program\textsuperscript{2}, can be applied to the full master’s degree in Health Informatics. This poster describes both how the different programs interrelate as well as the innovative instructional methods that have been employed. Live demonstrations of the innovative methods will be shown.

\section*{Methods}

Development of the Graduate Programs in Health Informatics at UAB has taken an approach in which all other programs are built upon the solid foundation of our MSHI core program. The four courses in the certificate program, which include one course that is also part of the AMIA 10 x 10 program, provide basic information for someone wanting to learn about health informatics, but who may not be degree-seeking. It is important to note that while the content of the same course offered in different programs contains the same content, the delivery modality was modified to accommodate the type of student enrolling in the AMIA 10x10 program or Clinical Informatics Certificate. The courses that are included in the certificate program have been redesigned to contain a set of self-paced online modules, 2-4 units/weeks long, within specified module release and end dates. Students can apply the single AMIA 10 x10 course to the certificate or directly to the MSHI program, and all certificate courses can be used to exempt courses in the MSHI program.

For the new certificate program, we added enhancements that can be used across all programs. These enhancements include video recording of lectures using a variety of engaging technologies, and designing the videos so they can be used for other online courses. This approach consists of: (a) short videos each containing material related to a single topic, (b) avoidance of references to the specific course, module, or unit, and (c) separate content-specific introductory and/or summary videos for the specific unit to put the modular videos and the units within them in context. By converting longer lecture videos into this shorter format, we envision a modular video repository, whereby each video has a description and a set of keywords to allow instructors to reuse them in other courses where that specific content may be needed.

In order to foster more engagement than a typical video lecture, we utilized interactive strategies for online presentation of the material. For example, to provide more of an in-class instruction feeling, we used the Smart Podium technology for the instructor to interact with the content by drawing diagrams and charts and/or pointing to certain portions on them, instead of talking over a static slide. We also developed online orientation material where students answer a series of multiple-choice questions and receive personalized audio feedback for their response choice.

\section*{Results and Evaluation}

Evaluation of the content and format of the course (60\% response rate) showed that students were generally satisfied with course content and teaching methods. One of the courses used text instead of video module introductions and students indicated that they liked the video introductions better than the text. Analysis of number of plays and average duration of the videos on a technical course revealed that students accessed more often and for a longer duration videos that included hands on practice of the concepts and that were more relevant to case study assignments.

Portable Precision Phenotype Algorithm for Chronic Rhinosinusitis

Jennifer A. Pacheco\textsuperscript{1}, Agnes S. Sundaresan, MD, MPH\textsuperscript{2}, Kenneth M. Borthwick\textsuperscript{2}, Sergio E. Chiarella, MD\textsuperscript{1}, David T. Coleman, MD\textsuperscript{1}, Andy Y. Wu\textsuperscript{1}, Abel N. Kho, MS, MD\textsuperscript{1} M. Geoffrey Hayes, PhD\textsuperscript{1}, Marc S. Williams, MD\textsuperscript{2} \\
\textsuperscript{1}Northwestern University, Chicago, IL; \textsuperscript{2}Geisinger Health System, Danville, PA

Introduction

Extracting patient phenotypes from the Electronic Health Record (EHR) has become very popular; however, it is difficult to extract more complex phenotypes, and more precise sub-phenotypes, especially in a format that is portable and executable across sites. Yet, it is important to be able to do so for precision medicine, as treatment can differ depending on the sub-phenotype. This is true for sub-phenotypes of chronic rhinosinusitis (CRS), with and without nasal polyps (NP), CRSwNP and CRSsNP, which are even more precise than chronic versus acute rhinosinusitis.

Methods

Previously Northwestern University (NU) published an algorithm for extracting CRS cases and controls from the EHR\textsuperscript{1}. For the electronic Medical Records and Genomics (eMERGE, gwas.org) project, we modified that algorithm to be portable and executable across sites, and more precise, by: adding International Classification of Diseases (ICD)-10 diagnosis codes, differentiating between CRSwNP and CRSsSNP, and to have more stringent controls (Figure 1). Another eMERGE site, Geisinger Health System (GHS), created a portable executable version of the phenotype algorithm, using Konstanz Information Miner Analytics Platform (knime.org), which NU was then able to easily modify to complete the new algorithm and execute. These 2 sites conducted blinded chart reviews of patients selected by the new algorithm, and a third eMERGE site is doing the same, to assess the specificity of our new algorithm.

Results and Discussion and Future Work

The new algorithm found 226 cases, 78 with NPs, and 1,485 controls at NU, out of 6,172 eMERGE subjects; plus 214 cases, 78 with NPs, and 2,057 controls at GHS, out of 12,295 eMERGE subjects. Compared to our previous algorithm, the positive predictive value (PPV) based on chart review remained relatively high overall for cases and controls, with a combined PPV of 0.87 for all cases (0.9 at NU for 200 cases reviewed, and 0.77 at GHS for 53 cases reviewed), and combined PPVs of 0.66 and 0.81 for CRSwNP and CRSsNP (both 0.7 at NU, and 0.62 and 0.85 at Geisinger), which should be sufficient to conduct a genome-wide association study of our sub-phenotypes with all eMERGE sites. However, to be more thorough, the difference in case PPVs between the 2 sites is being examined and a third eMERGE site is conducting reviews. For controls, PPV was 1.0 at NU, and 0.97 at GHS (out of 100 and 29 controls reviewed).

Conclusion

Our initial results show that it is possible to detect and automatically extract patients with precise phenotypes from the EHR, across multiple sites with different EHRs, even though it is not perfect nor simple.

Towards Spatial Analysis of Opioid Abuse Using Twitter

Sheetal Pandrekar, MS, Manish Valakonda, MS, Xin Chen, MS, Fusheng Wang, PhD
Stony Brook University, Stony Brook, NY

Introduction
From 2000 to 2014, the deaths from opioid overdose in United States, has seen a 200% increase in the rate. Combating opioid epidemic has become a high priority for both the U.S. government and local governments. The social networking site, Twitter, is being increasingly explored as a source for understanding the changing attitudes towards use of opioids. One advantage of Twitter over traditional surveys is the immediate accessibility of data. Analyzing opioid-related tweets has the potential to reveal patterns of opioid abuse at a large scale, and provide insight to support prevention, treatment, recovery and enforcement. In our study, we first identify keywords related to opioids by employing a 3-step procedure in order to carefully select the keywords to alleviate noise. We perform unsupervised Topic Modeling to discover the topics of discussion in the tweets. We also perform a statewide spatial analysis of opioid-related tweets in the United States.

Methods
For the 3-step procedure to select relevant keywords, we use seed keywords from the previous work. For each of the seed keywords, we perform the following steps: Step 1- Collect all slang terms for the keyword from UrbanDictionary.com; Step 2- Individually search each slang term on Twitter; and Step 3- If more than 50% of the top 20 results are relevant to opioid, include the keyword to the final list. We have finalized a list of 20 keywords. Our current dataset has a total of 19872 tweets collected with Twitter’s Streaming API, which provides access to a random sample of 1% of tweets. Initially, we manually analyze 764 tweets and classify them as relevant or irrelevant to opioids. From the complete dataset, we identify the topics using unsupervised Latent Dirichlet Allocation (LDA).

Results

LDA provides the top ten words for each identified topic. The popular topics of discussion in our dataset identified with LDA are crisis, pain, Pharma, constipation, Obamacare, Trump, treatment and bill. We map the tweets using the locations and normalize the total count by the per state population. The top 10 states identified are Oregon, Washington, Massachusetts, Ohio, New York, Pennsylvania, Maryland, Tennessee, Vermont, Rhode Island.

Conclusion
We describe a 3-step procedure for generating keywords related to opioids abuse. Our initial results demonstrated that the new keywords are able to fetch tweets with less noise. Oregon and Washington ranks No. 1 and No. 2 on the number of opioid-related tweets, which could be due to their legal use of Marijuana. Ohio ranks No. 4, and it has second highest number of drug overdose deaths. Our future work includes collecting more tweets and identifying the types of users (e.g. Personal, Organization, etc.) in the Twitter dataset for more insightful analysis.

Building Better Timeline Interactions for Patient Chart Reviews

Heekyong Park, Ph.D.1,2, Taowei David Wang, Ph.D.1,2,3, Vivian Gainer, M.S.3, Victor M. Castro, M.S.3, Shawn Murphy, M.D., Ph.D.1,2,3

1 Massachusetts General Hospital, Boston, MA, USA; 2 Harvard Medical School, Boston, MA, USA; 3 Partners HealthCare, Somerville, MA, USA

Introduction

Reviewing a patient’s medical history is at the heart of many medical informatics problems. Because the temporality of patient data is important, timeline visualizations are often used to help reviewers. However, naïve implementations of timelines can result in many interaction problems, undoing some of its benefits. We systematically examine our own implementation, generalize common problems, and present our solutions.

Methods

i2b21 has been a platform for developing new informatics workflows. Its Timeline plugin, based on LifeLines2, visualizes a patient’s medical observations. They are displayed as ticks, and details of observations are available with mouse hovers. However, feedback from chart reviewers suggests the following limitations:

1. Using classic zoom and pan to navigate is not ideal. First, they are slow. Secondly, they tend to lose context for the users. For example, after a sequence of zooms and pans, users lose their original place.
2. Ticks can partially or completely occlude others in the visualization. This impedes mapping of the right data, which might result in misinterpretation. In addition, users are forced to use the problematic zoom and pan interactions to get around this issue.
3. There are no visual cues to help keep track of which of the hundreds of observations are viewed or noteworthy.

We developed a visual-semantic layer that sits between mouse clicks and the display of information. The layer receives mouse position and dynamically detect occluded ticks. A list is then presented to display data of these ticks and allows users to traversal to nearby ticks. The occlusion detection and alternative navigational method enable overlapped ticks to be fully interrogated without zoom or pan while keeping users’ temporal context intact. Furthermore, we added a coloring system so that all the already-read observations are colored ‘gray.’ Users can mark interesting observations as ‘yellow.’ The indicators obviate the need to remember which ticks are read, unread, or noteworthy (Figure 1).

Discussion and Conclusion

Unlike many information visualization tasks, chart reviews require constant reading of details while maintaining context. Without specific support, timelines can be cumbersome to use. We present three problems of naïve implementations and propose our solutions. By no means these are the only solutions. Recent advances use a variety of techniques such as a mini timeline for overview to maintain context. We aim to explore these and other solutions and compare them with ours in the future.

Identifying Health Interests of the General Public using Reddit
Albert Park, PhD1, Mike Conway, PhD1
1Department of Biomedical Informatics, University of Utah, Salt Lake City, Utah

Introduction
The Health Interests of the General Public (HIGP) are constantly changing and accurately identifying the current HIGP can be a challenge. The general public, however, openly discusses their health interests in health focused communities like r/health, which is a discussion forum from a popular social media platform called Reddit. A popular platform like r/health has the potential to provide opportunities to improve public-health practice. In August 2016, r/health has been active for 8 years with 118,949 members. The members of this community discuss a wide variety of topics ranging from newly emerging topics like Zika to long-standing interests like HIV. In this pilot study, we use r/health as a proxy and aim to identify health topics that are most frequently discussed over the past 8 years.

Methods
1. Data Collection: we used the Reddit Application Programming Interface (API) to download 1,000 all time ‘top’ rated posts determined by members and their associated 48,544 comments made from October 2008 to August 2016.
2. Preprocessing: we preprocessed the dataset to remove common stop words, punctuations, and URLs as well as posts and comments with less than 5 words.
3. Identify Topics: we processed the content of these posts and comments and identified the main topics using a machine learning algorithm called LDA, a topic modelling algorithm. We considered each post and its associated comments as a single document. We extracted and included nouns from each document and then employed the Gensim implementation of LDA1 to identify 25 main topics from this community.
4. Visualization: we created a word cloud visualization to visually represent the importance of topics and their top 25 associated terms, using the weights that are determined by the LDA.
5. Validation: we manually identified main topics from the 100 ‘top’ rated posts and then compared the results against the automatically recognized topics.

The study was exempted from review by the University of Utah’s Institutional Review Board [IRB 00076188].

Results
According to the LDA and the visualization, the members of r/health discussed topics related to nutrition (e.g., food, diet, calorie), medicine (e.g., doctor, healthcare, cancer), money (e.g., insurance, money, claim), and scientific facts or news (e.g., studies, science, research) as shown in Figure 1. Using the manual method, we identified 14 topics (frequency): news (58), personal medical experience (7), expensive medical care (5), vaccine conspiracy (5), addiction (5), medical marijuana (4), public health (3), medical information (3), insurance (2), sex education (2), nutrition (2), advancement in medicine (2), obesity (1), and dental care (1). While the specific topics are similar to automatically identified topics, a majority of the 100 ‘top’ rated posts were started by sharing news concerning medicine or health (e.g., “Drug Goes From $13.50 a Tablet to $750, Overnight - The New York Times”), which shows the potential for using social media for identifying the current HIGP.

Conclusions
We have presented preliminary findings on developing an automated method to identify the current HIGP. Our initial results suggest that, on the basis of our analysis of r/health, we may be able to identify health and medicine related news that is of most interest to the general public. We also provide several interesting directions to future work to accurately track HIGP. Analysis of additional platforms, Facebook and Twitter for example, could bolster our findings.

Explorative Analyses on Indexing OMOP based Clinical Datasets with DATS

Ethan Park; Diana Guijarro, BA; Imho Jang; Stephen Trac, BS; Nansu Zong, PhD; Elizabeth Bell, MPH; Hyeoneui Kim, RN, MPH, PhD

Department of Biomedical Informatics, University of California, San Diego, La Jolla, CA

Introduction and Background

bioCADDIE (biomedical and healthCare Data Discovery and Indexing Ecosystem, http://biocaddie.org) aims to index biomedical data to help researchers find them for large scale data analyses. Data Tag Suite (DATS) is the standardized metadata specification of bioCADDIE developed by incorporating existing metadata standards in biomedical research and high priority data search use cases (http://biorxiv.org/content/early/2017/01/25/103143). Although some of the use cases reflect the clinical and/or healthcare domains to some extent, they are relatively underrepresented in DATS compared to the content from omics research. Healthcare related content areas appearing in many use cases are mostly limited to the phenotypes represented by disease names, laboratory test results, medication names, and sample demographics. It is unclear whether these limited content areas will sufficiently support dataset search needs for various types of healthcare research. With the launch of the Precision Medicine Initiative (PMI), a need for indexing datasets that represent diverse content areas such as clinical, behavioral, and environmental information became a reality. To ensure the robustness of DATS in representing these content areas, we first evaluated how effectively DATS supports searching clinical datasets structured by the Observational Medical Outcome Partnership (OMOP) Common Data Model (CDM) and 100 dataset search scenarios. We selected the OMOP CDM since it is one of the most widely adopted methods of standardizing healthcare datasets.

Methods

We first conducted mapping between OMOP CDM and DATS at the property level. We also selected 100 non-omics observational and/or experimental studies published in clinical journals for the past 2 years and extracted dataset search use cases by asking ourselves “How would we search for a dataset to replicate this published study?” We then identified the information types required for dataset searches and how these types of key information would be stored in the OMOP CDM based structure. Finally, we evaluated the efficacy of DATS in supporting the 100 dataset search use cases by reviewing to what extent the CDM fields holding key information are mapped to the core DATS items (meaning, this information is always indexed and thus available for search).

Results

The majority of OMOP CDM’s components were mapped to Dimension of DATS. Dimension is defined as “a feature of an entity, i.e., an individual measurable property of the entity being observed,” and takes Entity-Attribute-Value format. For example, patient’s race information “Asian” is indexed to Dimension with its attributes Name and Value that take values of “race” and “Asian” respectively. Pertinent clinical information relevant to the standardized clinical data tables of the OMOP CDM was mostly mapped to Dimension. The topic areas covered by the 100 studies were effectiveness of a treatment/procedure (N=53), comparative effectiveness of treatments/procedures (N=29), diagnostic accuracy (N=5), and others (N=5, e.g., observation on clinical manifestation, workflow analysis, etc.). The information deemed most frequently used for dataset search is medical diagnosis (N=76) followed by the demographic information of patient populations (N=51), which were the clinical content areas already considered for DATS. Twenty-five use cases required rather complex data searches combining more than demographics and diagnosis. The full mapping and the use cases are available at https://tinyurl.com/zuwuz4b.

Discussion

We were able to map the tables and attributes of the OMOP CDM to DATS. However, we found potential challenges to searching healthcare datasets structured with OMOP CDM using the indexing DATS offers because searching for the key information frequently used for healthcare datasets requires searching through the massive information held in Dimension of DATS. More importantly, the dataset search requires evaluating the value of the attributes (e.g., age, gender, diagnosis name, etc.), which is set as optional information in DATS. We are currently discussing these challenges with the DATS developer team. This explorative analysis was done with the use cases that do not fully represent the diverse topic areas of healthcare research; we plan to continue the analysis with the dataset search use cases that represent additional topic areas.

Lessons Learned from the Conversion of MIMIC3 to the OHDSI Common Data Model

Joongheum Park MD¹, Liana Tascau MD², and Adler Perotte MD, MA²
¹Englewood Hospital and Medical Center, Englewood, New Jersey; ²Columbia University Medical Center, New York

Introduction

The format and schema of observational health databases can be quite variable, which makes the systematic analysis of disparate databases difficult. The Observational Health Data Science and Informatics (OHDSI) collaborative provides a Common Data Model (CDM) and standard vocabulary. These tools allow for the systematic analysis of disparate observational databases given that they have all been transformed to conform to the OHDSI CDM. MIMIC3 is the newest version of a popular critical care database that is freely available and quite comprehensive in terms of EHR recordings in ICU settings. Although the data model for MIMIC3 is comprehensive, it is not an easily understood analytic database using a well-controlled vocabulary. This work aims to create a standardized version of MIMIC data so that computational methods can be developed and compared based on an easily understood data model and this dataset could be explored with the tools developed by the OHDSI community. More specifically, our goal is to develop a PostgreSQL-based extract, transform, and load (ETL) program that generates a CDM v5-compatible database from MIMIC3.

Materials and Methods

MIMIC3 is the latest iteration of a relational database of critical care patients from Beth Israel Deaconess Medical Center¹. It is comprised of de-identified health data for over 58,000 hospital admissions for 38,645 adults and 7,875 neonates. Entities mapped to the OHDSI CDM were coded using concepts from the standard vocabulary. For example, condition occurrences were mapped to standard concepts from the SNOMED-CT vocabulary and medications were mapped to the RxNorm vocabulary (see http://www.ohdsi.org/web/athena/). PostgreSQL was chosen as the database of choice for this ETL such it could be performed with strictly open-source resources that are compatible with the existing tools for the OHDSI CDM.

Results

We mapped 11 tables from the MIMIC3 database to OHDSI CDM v5 tables. We were able to successfully map demographic, diagnostic, procedural and medication data to the OHDSI CDM. Important issues encountered during the translation include: (i) Representation of temporal granularity. Given that MIMIC3 encodes data from the critical care setting, data elements have precise timestamps and patients evolve on an intraday timescale. However, certain tables in the OHDSI CDM were only capable of representing time at the granularity of days. We modified the data model slightly to accommodate granular timestamps. (ii) Certain data element types in MIMIC3 are not represented with a controlled vocabulary. Therefore, their concept identifiers were assigned by the researchers manually (e.g. SOFA scoring, spontaneous tidal volume). When data elements were represented with a controlled vocabulary, the ETL procedure leveraged the mappings available in the OHDSI standard vocabulary for identifying the appropriate standard concept (e.g. mapping a Read code to a SNOMED-CT code for a condition occurrence). The CDM standardized health system tables and health economics data tables were not populated as relevant data was not available in MIMIC3. Unmapped MIMIC3 tables includes clinical notes except for discharge summaries, culture sensitivity data, procedural data with CPT codes, data regarding caregivers and discharge planning information.

Conclusion

Although there are challenges in converting a database such as MIMIC3 to the OHDSI CDM, it is possible with slight modifications. Our work with the OHDSI collaborative has led to consensus-driven incorporation of timestamps with higher temporal granularity in the OHDSI CDM. Future work will involve further refining this ETL through collaboration with the OHDSI community.

Assessment of Laboratory System-Assigned LOINC Codes for Common Tests

Sharidan K. Parr, MD, MSCI\textsuperscript{1,2}, Shuanghui Luo, MS, PhD\textsuperscript{2}, Sina Madani, MD, PhD\textsuperscript{2}, S. Trent Rosenbloom, MD, MPH\textsuperscript{2}

\textsuperscript{1}Veterans Affairs Tennessee Valley Healthcare System, Nashville, TN; \textsuperscript{2}Vanderbilt University Medical Center, Nashville, TN

Introduction
To represent clinical data accurately and consistently across different healthcare institutions, any site-specific information must be represented by and mapped to a standardized terminology, such as The Logical Observation Identifiers Names and Codes (LOINC\textsuperscript{®}). However, mapping can be hindered by idiosyncratic, ambiguous local data representations. We hypothesized that by evaluating the relationships between local laboratory system-generated LOINC mappings and corresponding internal electronic health record data, we would be able to systematically identify examples of LOINC mapping inaccuracy amenable to remediation.

Methods
This project was conducted at Vanderbilt University Medical Center (VUMC). Laboratory results for a subset of 52 common blood chemistry, hematologic, and urine tests were collected from 2012 through 2016. Data was obtained from the Research Derivative, a research-ready data replica derived from VUMC’s clinical enterprise. In our initial assessment of LOINC accuracy, we examined aggregate laboratory results using reference range; median, minimum, and maximum result; and units of measurement. For each locally-defined laboratory test (e.g. hemoglobin), we assessed LOINC code accuracy using the Component, Property, Time Aspect, System, and Scale attributes of the assigned LOINC code. The LOINC Component identifies what is being measured; Property refers to the type of quantity measurement (e.g. mass concentration); Time Aspect distinguishes specimens collected at a moment in time or over a specified time interval; System refers to the sample from which a specimen was obtained (e.g. blood versus urine); and Scale specifies the unit of measurement (e.g. quantitative or ordinal).

We defined LOINC codes of uncertain validity as those having a local test name inconsistent with the LOINC Component; units of measurement inconsistent with the Property, Time Aspect, Units, or Scale of the associated LOINC code; and/or locally-reported specimen type differing from that of the assigned LOINC System. The LOINC codes of uncertain validity were further examined using manual chart review. For each locally-defined test, we also quantified the number of different LOINC codes assigned within each laboratory test, and the number of specimen types assigned within each laboratory test. We identified a subset of laboratory tests associated with multiple LOINC codes and/or multiple specimen types. For these records, we collected patient-level data for manual chart review. We also examined the relationship between the laboratory-generated specimen type and its relationship with the resulting LOINC code.

Results
We examined over 13 million laboratory results from the 52 selected tests. Forty-three tests were associated with a single, correct LOINC code, and one correct specimen type. One test was associated with multiple LOINC codes and multiple specimen types, resulting in one incorrect LOINC code due to an erroneous local specimen type. Two tests each mapped to two LOINC codes and one specimen type, and were associated with accurate LOINC codes. Intra-test LOINC code heterogeneity occurred when laboratory instruments with different LOINC mappings were used to analyze the same local test (e.g. ‘Glucose Urine’). Six tests mapped to a single LOINC code with multiple specimen types, due to mapping schema ambiguity. Within this group, two LOINC codes were inaccurate, resulting from incomplete local concept coverage.

Conclusion
We present a generalizable, systematic approach to evaluating LOINC code accuracy. Using this approach, we detected errors at both the mapping schema level and at the individual test coding level. At the mapping level, errors were either due to ambiguity/heterogeneity in the mapping schema, or incomplete coverage. We found no temporal trend. Optimizing LOINC code accuracy at our institution will require harmonizing the laboratory mapping schema with the locally-defined laboratory tests. This process will require reducing redundancy in the laboratory mapping schema, further examining the role of the technician and the laboratory device in generating mapping features, and improving concept coverage.
Validating Vector Representations of ICD Diagnoses Using Readmission Prediction and Dissimilarity Testing: A Pilot Study

Matthew Parry, DO, Neris M. Nieves-Robbins, MD, Keith Solveson, BS, MS, Eric A. Shry, MD

1Neurology Service and 2Clinical Informatics Division, Madigan US Army Medical Center, Tacoma, WA

Introduction

Advanced analytics including natural language processing (NLP) have been promoted as an effective strategy to reduce hospital readmissions. These tools may not fully exploit the rich categorical data found in patients’ past medical histories (PMH) to forecast risk, due to the format of the data. Readmission risk prediction tools powered by novel NLP techniques that produce exploitable representations of PMH data such as Doc2Vec may be a suitable alternative, but there may be insufficient evidence to support this.

Objective

The purpose of this study is to validate Doc2Vec for analysis of International Classification of Diseases (ICD) codes by showing prediction of all-cause readmission risk and concurrence with physicians’ interpretation of diagnoses.

Methods

An open-source implementation of Doc2Vec was used to analyze 3.5 years of de-identified electronic medical records data from a single tertiary care hospital to establish relationships between 30-60-90 day readmissions and ICD codes. The resultant vectors were used to predict readmission risk using cross-validated logistic regression. An “odd one out of four” dissimilarity test, analogous to the semantic and syntactic reasoning tests used to validate NLP algorithms, compared the model’s ranking of similarity to answers from 33 licensed, blinded physicians.

Results

Readmission prediction accuracy at 30, 60 and 90 days was 91.3% (+/- 0.81%), 95.2% (+/- 0.47%), and 96.6% (+/- 0.33%), respectively. In the dissimilarity test, physicians had significant concordance of 38.3% with the model on the generated questions compared to a random chance of 25% over 660 example (chi-squared p<0.0001).

Conclusions

The results from this small database study may over-estimate the effectiveness of the model, given the limited, homogenous sample used. Further evaluation using larger datasets and data from other facilities may provide a more accurate assessment of the model’s efficacy. To the best of our knowledge, this is the first application of Doc2Vec for analysis of medical diagnoses, as opposed to its standard application of single word analyses outside of healthcare. Results from this study may help promote a greater understanding of the use of diagnoses and vector representations in clinical practice.
The Adolescent Patient Portal: Are we meeting the needs of our most connected patients?

Chase R. Parsons, DO1, Jonathan D. Hron, MD1, Fabienne C. Bourgois, MD MPH1
1Boston Children’s Hospital, Boston, Massachusetts, United States of America

Introduction

With the rise of Electronic Health Record (EHR) adoption in the United States, healthcare organizations have implemented patient portal functionality to fulfill government regulations and promote the “meaningful use” of EHRs1. In pediatrics, research has demonstrated increased patient engagement in both the inpatient and outpatient setting with use of a patient portal2, 3. Despite strong recommendations from The Society for Adolescent Health and Medicine (SAHM) to implement patient portals with confidentiality standards, including differential access for parents and adolescents4, it is suspected that pediatric institutions have heterogeneous policies surrounding adolescent access to the patient portal, with most institutions significantly restricting access. This study aims to evaluate the current state of pediatric patient portals, focusing on differential access policies for the adolescent population.

Methods

Our team, consisting of Clinical Informaticists at an academic children’s hospital, developed a 50-item web-based survey to delineate policies and features of pediatric and adolescent patient portals. The survey covers general user-access policies, patient data and documentation viewing, secure messaging, and medical results access for both the adolescents and their parents/guardians. It also explores whether the adopted policies were guided by institutional decisions, EHR vendor limitations, and/or specific state regulations. We identified our participants using the Children’s Hospital Association (CHA) member directory and electronically delivered our survey to the chief medical informatics officer (CMIO) (or nearest equivalent staff member) of the 226 CHA U.S. children’s hospitals. We compared characteristics of responding hospitals (size, region, freestanding children’s hospital status, number of portal accounts, and EHR implementation year) with survey results. Early data was analyzed using descriptive statistics.

Results

This survey has now been deployed and early results are available. One week after survey deployment, 10 of 226 CHA hospitals responded (4.4%). Responding hospitals were heterogeneous and characteristics were consistent with the overall composition of general acute care hospitals in the U.S. The number of total institutional portal accounts amongst respondents ranged from 3,167 to 1.1 million. Sixty percent of responding institutions enable separate adolescent and parent accounts at the onset of adolescence (12 – 14 years old) and 50% of those require patient assent for full parental access, while 30% of respondents disable both adolescent and parental portal access at this time. The remaining 10% report the capability for only one account which is either used by the parent, patient, or shared. Narrative comments from responding institutions varied, but multiple centers report that the adolescent patient portal is both a “struggle” and a “challenge.” Respondents report that institutional portal policy is limited by both state law and EHR vendor offerings. Larger freestanding children’s hospitals were associated with more granular user access policies aligning with SAHM’s recommendations.

Conclusion

This study, to our knowledge, provides the first evaluation of common practices in adolescent patient portals. Preliminary data demonstrates significant variability in pediatric hospitals’ policies regarding adolescent patient privacy and access in the patient portal. Further data will be collected and analyzed. These results will help inform efforts toward standardizing policies and procedures regarding adolescent patient portal access across pediatric centers and help identify gaps in current vendor-provided portal solutions.

America Walks - A Cross-platform Mobile ResearchKit Study of Walking Behavior Based on Passive Step Tracking

Chintan Patel PhD, Nickolas Whiting, Aamir Bhat, Mir Suhail, Priya Menon, Shweta Mishra, Sharib Khan MD MA MPH
Applied Informatics Inc., New York, NY

Background
Nearly two-thirds of Americans own a smartphone and routinely use them to actively seek or manage health and wellness information. The release of ResearchKit, an open source framework and software development kit (SDK), has enabled the creation of study apps with e-consent, surveys, phone sensor recorded tasks and wearables data. However, apps created using ResearchKit are only available to Apple device users, which excludes a large population of potential participants that use other platform smartphones (primarily Android), thereby introducing the likelihood of sampling bias. This paper describes our effort to address this limitation by conducting the America Walks study (https://clinicaltrials.gov/ct2/show/NCT02792439) to track walking behavior using phone step count sensors, using an app for both iOS and Android users.

Methods
To develop a study app that could run on both Apple iOS and Android phones, we first developed ResearchDroid, an Android port of ResearchKit. ResearchDroid deeply integrates with the Android platform and is designed from the ground up to meet the requirements of capturing participant consent, surveys, extracting sensor data and meeting the security considerations for IRB approval. Though ResearchDroid contains similar capabilities to ResearchKit, operating system differences between Android and iOS, such as explicit back button use in Android phones, necessitated some differences in UI implementation. Moreover, whereas iOS provides a standard interface to access sensor and health data (HealthKit), Android phones come with a variety of sensors from different manufacturers, so several connectors were written to obtain sensor data from Android phones.

We next developed the America Walks Study app using ResearchKit for iOS and ResearchDroid for Android users. The entire study was app-enabled; participants pre-screened themselves using a two-question survey and completed the entire informed consent within the app. Upon enrollment, they answered a demographic survey and provided permission for the app to access their step counts data from Apple’s HealthKit or Android step count sensors. Step counts were tracked automatically for 30 days from enrollment. A real-time study dashboard provided participants the ability to view their step counts and compare that to counts of other participants combined. Participants could opt out anytime or extend participation after the 30 day period. The primary objective was to determine walking activity as measured by daily step counts and to compare this across demographic categories.

Results
The study enrolled 210 participants, (114 females, 96 males) of which, 41 used Android phones and 169 used iOS devices. Recruitment was done via social media marketing and listing on ClinicalTrials.gov. Participants spanned across 35 states and 130 cities. A total of 22,219,847 steps were tracked over 300 days (out of the 305 days the study was live) of which 19,619,679 (88.2%) steps were recorded by iOS and 2,600,168 (11.7%) steps were recorded by Android devices. The average daily step count of an iPhone user was 9,868 steps, compared to 3,042 daily steps for an Android user. Maximum step count activity was recorded at noon and 6pm. 63% of participants were active over the 30 day study period, indicating sustained engagement.

Discussion
We successfully demonstrated the possibility of creating a study app that can run on both iOS and Android phones. Though significant programming work was needed to build ResearchDroid, subsequent app development was much faster. Android development using ResearchDroid required equivalent effort as compared to iOS development with ResearchKit. The existence of numerous manufacturers of Android phones causes variability in screen sizes and sensor implementations, which do add debugging and screen rendering complexities. We are currently working on three studies that will be launched as cross-platform apps.

For the Common Good: Sharing Data Extracted from Text

Olga V Patterson, PhD\textsuperscript{1,2}, Scott L DuVall, PhD\textsuperscript{1,2}

\textsuperscript{1}VA Salt Lake City Health Care System; \textsuperscript{2}University of Utah, Salt Lake City, UT

Abstract

The Department of Veterans Affairs (VA) Informatics and Computing Infrastructure (VINCI) resource center mission includes the goal of improving the quality of research with services and innovations supporting acquisition and analysis of healthcare data. VINCI is engaged in a number of projects to meet this mission. This poster reports on a new approach to supporting the research community it serves by applying natural language processing (NLP) on all VA notes and reports and making the output available as a new data source.

Methods

VINCI sponsored development of a high-performance scalable rule-based extraction system for identifying quantitative values for left ventricular ejection fraction (LVEF) in clinical notes. LVEF is an important measure that reflects heart health and any study that evaluates heart disease requires this variable, which is why it is commonly requested.

The system is based on the Leo framework\textsuperscript{1} that extends the Apache Unstructured Information Management Architecture Asynchronous Scaleout (UIMA AS)\textsuperscript{2}. The extraction system is light-weight because it utilizes a highly targeted custom lexicon and a specific rule set. For system validation, we evaluated documents from three sources within the medical record – echocardiograms, radiology reports, and clinical notes – which combined have more than 3 billion text documents. Therefore, we created a comprehensive but targeted set by filtering all documents based on the presence of at least one of the following highly sensitive and specific keywords: “ef”, “lvef”, “eje*”, “function”, “fraction”, “dysfunction”. We randomly selected 200 documents from each source. The documents were manually annotated with the values for LVEF and compared against the values found by the NLP tool. Precision of the extracted LVEF values ranged 0.981-0.993 across the three sets with average of 0.986. Recall ranged 0.887-0.935 with average of 0.925. F-score ranged 0.932-0.960 with average of 0.955. A failure analysis revealed that the main source of error is mistaken LVEF values for the normal range that is often included in documents as a reference.

The NLP tool was applied to all records with the first run completed in September 2015 and three additional incremental runs were completed in May 2016, November 2016, and June 2017. After the raw NLP dataset was created, additional data cleaning steps were performed to normalize values and discard values above 100\%. The combined set contains 35 million LVEF values for 3.4 million patients, supplementing the original structured Echo dataset, which contains only 429 thousand values for 277 thousand patients. The current plan is to continue with periodical incremental updates to this dataset.

Conclusion

Since the dataset has been created, over a dozen of studies have already benefitted from having this dataset – without having to rerun the NLP tool each time. The novelty of the approach required development of a new procedure on how to ensure regulatory compliance when a data request is processed. Initially, each data request was reviewed individually, but with the acceptance of a new regulatory procedure, the requests will be processed routinely and access to the new dataset is available to any VA-affiliated researcher.

Providing structured datasets that result from NLP processing enriches available data, which saves time for all other researchers and makes it possible to ask new research questions. VINCI has plans to continue with this approach and provide additional values extracted from text: vital signs, smoking status, ankle brachial index, and others.

Distance learning as a strategy for the education of health informatics professionals: possibilities and challenges
Andréa P. S. Pelogi¹, Alissa P. Penteado¹, Ivan T. Pisa¹, Claudia G. Novoa¹
¹ Department of Health Informatics -Unifesp, São Paulo, Brazil

Introduction
Health informatics is a discipline that involves several areas of knowledge and has been considered of extreme importance(¹). There is a paradigm shift in higher education such as the result of technological advances, the introduction of e-Learning and a greater participation of higher education professors in the area of distance education (DE). It is necessary to explore which is the best way to use scarce resources in order to cause a great impact on the training of such professionals so that they can make the best use of the available technologies to support the provision of health services (²-³). New technologies can help the affective process between professors and learners, who will be mediated by the interaction that technological resources provide, generating relationships which involve respect, trust and cooperation(⁴).

Methods
In total, 682 students were separated into 15 groups. The pedagogical project of the course was designed so that its content was divided into disciplines. Each discipline was developed in 4 axes: 1 - Concept: didactic material; 2 - Collaboration: collaborative activity; 3 - Reflection goal: description of learning; and 4 - Assessment: collaborative tasks. In all moments throughout the course, content-specific tutors clarified doubts, followed-up the attendance and improvement of participants. Professors developed the pedagogical content with the help of a team of instructional designers using the teaching resources available in the LMS that best served the purpose. The course emphasized collaborative tasks from the perspective that the graduate student learns with both professor and peers.

Results
The result obtained showed that 374 (54.83%) of the students passed, 53 (7.77%) failed, and the registered withdrawal was 255 (37.39%). During the course the students participated in self-assessments about their work in collaborative format. The questionnaire consisted of 10 questions. Students' responses demonstrated if they were prepared for the collaborative work: 0.46% never prepared; 2.75% rarely; 24.71%, sometimes; 41.88% many times and 30.21% always.

Discussion
Distance Education uses communication and information technologies to promote both professional and human development. Therefore, this teaching approach makes that student learns without moving him away from his daily activities. Its characteristics enable the elaboration of an online course based on the proposal of intercommunicative teaching, promoting autonomy and the exchange of experiences (²). However, even with the support of machines and virtual learning environments (LMS), the DE requires motivated professionals, reliable technical structure and suitable monitoring. It is necessary to think over on the conceptions of collaborative learning in this teaching modality, and also evaluate the strategies used and the role of the teacher when collaboration occurs in LMSs(³). These are some obstacles to the full use of DE resources: difficulty to access information and communication technologies, difficulty to use tools, lack of time to develop activities, difficulty to communicate with tutors and to manage personal life. Nevertheless, it is well known that DE with collaborative bias represents an interesting possibility for lifelong education considering the challenges faced by professionals in the area of health informatics in the scope of access to continuing education.

Conclusion
The course provided students both individual and collective learning experiences in order to prepare them to work in hospitals and health services where there are information systems and other resources based on the use of information and communication technologies. The obtained results showed that the variety of presentation structures of the conceptual domain favored motivation. This could be verified through the participation in several collaborative learning activities and by the learners' self-assessment questionnaires. Distance Education based on a collaborative method seems to be an efficient, practical pedagogical strategy faced with the need to qualify the health professionals.

RxNav 2.0 – A web-based, mobile-responsive RxNorm browser

Lee Peters, M.S. and Olivier Bodenreider, M.D., PhD
U.S. National Library of Medicine, National Institutes of Health, Bethesda, Maryland, USA
Contact information: RXNAVINFO@LIST.NIH.GOV

Motivation
RxNav is a browser for several drug information sources, including RxNorm, RxTerms and NDF-RT. Since its release in 2004, many features have been added over the years, including pill images and drug-drug interaction information. However, the Java Web Start framework originally used was not adaptable to an environment where web resources are increasingly used on mobile devices. In 2016 RxNav was redesigned to conform to modern web application development principles, with the goal of simplifying the user experience and supporting mobile devices.

Features and look of RxNav 2.0
Startup. The redesigned RxNav 2.0 is a web application which can be run by selecting the RxNav button from the RxNav website (https://rxnav.nlm.nih.gov). Based on Java Script, it only requires a browser such as Chrome or Firefox, whereas the original version of RxNav required users to have java installed on their system in order to run the application. RxNav 2.0 has a faster startup time than the original application, as well as faster search times.

Responsive Design. Based responsive design techniques, RxNav 2.0 can be displayed appropriately on workstations, tablets and mobile devices. The original application was limited to devices running java and required a large display area. Figure 1 (left) shows a screenshot of RxNav 2.0 on a mobile phone.

Functionality. Our goal in developing RxNav 2.0 was to keep the functionality of the original application and provide additional features. These new features include:

- **Ubiquitous searching.** Searching can be done while visiting any tab in RxNav 2.0.
- **NDC properties.** The NDC tab displays properties from DailyMed for each NDC.
- **NDC History.** The NDC tab contains a history feature that displays all past and present NDCs for the RxNorm concept.
- **Links to RxClass.** The nodes in the graphs in the Class View tab are linked to RxClass and clicking on a class in RxNav 2.0 opens RxClass for that class.
- **Search history.** A search history allows the user to conveniently revisit previous searches.

Appearance. RxNav 2.0 keeps the basic tab structure of the original application, but the tab views have been modified in some cases to provide better navigation and enhanced look and feel. In particular, RxNav 2.0 offers a simplified graph view limited to ingredients, brand names and drug products (Fig. 1, right).

Acknowledgments: This work was supported by the Intramural Research Program of the NIH, National Library of Medicine.

Assessing Inter-Hospital Clinical Processes Variability with Process Mining

Marius Petruc, MD MS¹, Mihail Popescu, PhD²
¹MU Informatics Institute, ²Department of Health Management and Informatics, University of Missouri, Columbia, MO

Introduction

The last decade has brought an increasing awareness that current, unsustainable healthcare cost levels need to be lowered, that the patient experience of care could be much improved and that the health of the population should be advanced. Outcomes and costs depend, among other factors, on the way care and care-related activities are organized and performed so that best practices are followed and variability reduced. As part of a process improvement project at our multi-hospital system, we have started inventorying clinical processes and measuring their variability across hospitals. Time-motion studies have proved successful previously, but they are costly and do not scale easily. Data science methods, especially process mining, are promising to address these limitations. In this poster we describe our experience assessing the feasibility of using process mining techniques to gather process variability and performance data related to the interpretation of ER CT examinations in two hospitals at an academic medical center.

Methods

Process mining leverages data already generated by information systems for other purposes (HIPAA compliance, debugging, etc). For our study, we collected log data generated from January 1st, 2015 to December 31st, 2015 (one year of data) by the radiology information system (RadNet, Cerner Corporation). The initial dataset consisted of 268,361 records representing event traces for all imaging examinations performed across our multi-hospital system. This dataset was imported in RStudio Version 0.99.486 for pre-processing, which consisted of removing duplicate records, transforming the date/time information to a consistent format, and filtering out all traces for events that were not related to Emergency Room CT examinations. In the end we extracted 17,408 ER CT cases, which were further split in two groups based on the location where they were performed: the adult hospital (15,660 cases) and the children’s hospital (1,748 cases). Data analysis was performed using the Disco (Fluxicon Process Laboratories) process mining application using the fuzzy miner algorithm.

Results and conclusions:

Figure 1 shows the two causative workflow nets (Adult-ER-CT and Peds-ER-CT) mined by the fuzzy miner algorithm in the Disco application. The blue boxes represent steps in the process. They are connected to each other by arrows to form paths, the most frequent of which are highlighted by darker arrows. The numbers shown in the boxes and next to the arrows are the actual counts of events. The arrows also show the average number of minutes between each step in the process. Examining the two diagrams shows that there is little variability between the two hospitals in terms of process flow, which is to be expected. However, there are differences in the time it takes to perform specific steps: the peds ER-CT studies seem to be dictated and finalized faster than the adult ones, while the exams themselves appear to be performed faster at the adult hospital.

Developing a Framework for Evaluating Influencers of Frailty in Aging

Andrew B. Phillips, PhD, RN1,2, Margarita Sordo, MSc, PhD3,4,5, Ruth Palan Lopez PhD, GNP-BC1,3, Jacqueline A. Merrill, PhD, MPH, RN6
1MGH Institute of Health Professions, School of Nursing, Boston, MA; 2Massachusetts General Hospital, Boston, MA; 3Clinical Informatics, Partners eCare, Partners Healthcare, Boston, MA; 4Department of Medicine, Brigham and Women’s Hospital, 5Harvard Medical School, Boston, MA; 6Columbia University, Nursing and Biomedical Informatics, New York, NY

Introduction
Frailty, a decrease in physiological reserve, is a serious threat for older adults that significantly increases their risk of chronic illness, institutionalization, poor quality of life, and death. Early intervention during the pre-frail state may reduce poor outcomes associated with frailty. As there is little consensus on how to measure frailty, there is wide variation in both estimates of frailty prevalence and poor understanding of interactions among known factors that contribute to frailty. There is a need for a dynamic adaptive agent model (AAM) of frailty to gain insight into interactions between individual preconditions and other factors to guide and support decisions on pre-frailty interventions.

Methods
AAMs are a “bottom-up” probabilistic computational strategy for simulating complex systems. In such models, unique agents are assigned micro-level attributes, (i.e. at the individual and environmental level) and a set of computational (if/then) rules to govern agent actions within a system. By running multiple simulations of autonomous agent actions and interactions macro-level outcomes of the system emerge and can be evaluated. To develop parameters for a prototype AAM to test against known frailty prevalence outcomes, we utilized a single instrument, the Survey of Health, Ageing and Retirement in Europe—Frailty Index (SHARE-FI), that incorporates five well accepted criteria for assessing frailty. We used expert opinion to cross map the measures to selected variables in the National Survey of Midlife Development in the US (MIDUS). SHARE-FI measures constitute initial agent attributes and longitudinal distributions from MIDUS are the basis for action rules in our initial model. The results below present example criteria, SHARE-FI measure and operationalization based on MIDUS variable.

</tr>
</tbody>
</table>

Discussion
The results will provide initial data on the relative influence of each of the five criteria on frailty prevalence. The ability to successfully demonstrate predictive capabilities using a small prototype AAM, provides a foundation for increasingly complex models of frailty risk. The inclusion of social, economic, and other environmental factors within the MIDUS dataset will allow such an expansion. Future work will be guided by domain experts, using existing data, and scientific evidence to iteratively incorporate a greater number of data points and interactions.

A Simple and Efficient Method for Private Exact Matching

Le Trieu Phong, PhD¹, Xiaqian Jiang, PhD², Shuang Wang, PhD³
¹National Institute of Information and Communications Technology, Tokyo, Japan
²University of California San Diego, La Jolla, CA, USA;

Introduction
Genomic data are playing an ever-important role in medical research and clinical studies but the size of the raw data is very big (e.g., ~500GB for the whole genomes of an individual), which is cost-ineffective to host and analyse them locally in hospitals. A straightforward way is to utilize the cloud computing to store and analyze them on demand. But a major concern is that genomic data are highly sensitive and depositing raw data in a public cloud processes large privacy risks of data owners. In 2016, iDASH privacy workshop called for novel solutions to address this challenge and several teams demonstrated innovative approaches¹. But current solutions still have big overheads, limiting their practicability in applications with time constraints. We propose a simple and efficient solution with a slightly relaxed security assumption in this work.

Methods
As shown in Figure 1, given a genome database, Data Owner first encrypts this database using PRF before sending it to the Cloud Service. At a later time, Data Owner generates a plain query, which she encrypts and sends to Cloud Service. Cloud Service responds with an encryption that Data Owner can use to obtain the boolean result of match or non-match. It is required that Cloud Service should not learn anything about the query and the data. Our protocol is as follows. For a Database = {D₁, ..., Dₙ} of N records, the upload phase at Data Owner does the following steps:
1. Takes a PRF FK and generates a corresponding secret key K.
2. Computes and sends FK(D₁), ..., FK(Dₙ) to Cloud Service.

For the matching phase, Data Owner gets a query Q, computes and sends FK(Q) to Cloud Service who does the following steps:
3. Looks up FK(Q) in the set of FK(D₁), ..., FK(Dₙ).
4. If there is an index i such that FK(Q) = FK(Dᵢ) then return match; else return non-match.

Security can be argued as follows: the function FK is pseudo-random function with a secret key K known only to the data owner, thus, Cloud Service obtains no information from FK(D₁), ..., FK(Dₙ) in the upload phase and FK(Q) in the query phase. Therefore, information on the database and the query is kept secret from Cloud Service. In step (4), secure channel such as TLS/SSL can be used to securely transmit the result of match/non-match. In addition, revealing match/non-match to Cloud Service may be harmless or harmful depending on the structure of the database, the latter case can be addressed via adding dummy records in the database and asking dummy queries.

Results
Our experiment was conducted with a dataset from the iDASH 2016 genome privacy protection competition¹, which contains 100K records at the size of 5.3 MB. We used HMAC-SHA256 as the PRF². Table 1 shows that the proposed method is more efficient than the solution using homomorphic encryption in iDASH 2016 competition.

Limitation
To allow fair performance comparison, the proposed algorithm was only evaluated on a small scale dataset with 100K records in VCF files provided by the iDASH 2016 genome privacy protection competition. In our future work, we will evaluate the performance over a large dataset. The proposed method mainly focuses on the secure outsourcing protocol for a single site, which means the proposed algorithm does not support data and queries that need to be encrypted from different sites. The proposed method only support exact comparison in a secure manner, which justified the further investigation to support secure fuzzy matching efficiently.

A Usability Study to Evaluate the Impact of a Novel Automated Brain Tumor Assessment Application

Edgar A. Rios Piedra MSc, Iren Orosz MD, Mary Zide PhD, Suzie El-Saden MD, Ricky K. Taira PhD, Alex A.T. Bui PhD, William Hsu PhD

Medical Imaging Informatics Group, Radiological Sciences, David Geffen School of Medicine, University of California Los Angeles, USA.
Bioengineering, University of California Los Angeles, USA.

Introduction. Efficient and accurate evaluation of brain tumor imaging studies is an important facet of managing neuro-oncology patients but is a particularly challenging task due to heterogeneity in tumor appearance and the time required to perform a comprehensive evaluation. We have developed a novel image analysis application that automatically delineates tumor components and visualizes how tumor volume changes over time. In this project, we conducted a usability study among neuroradiologists to evaluate whether our computer aided system for automated image analysis can alleviate the challenges of image interpretation in this patient population.

Methods. On this exploratory study, eight experienced neuroradiologists evaluated the automated tumor segmentation application [1] on a set of six different patients with multiple follow ups (Figure 1), and afterwards answered a usability survey developed by the authors and consisting of ten questions. The questionnaire includes an evaluation of the user interface (intuitiveness of single and multiple data points), display (data display and arrangement), understanding of data (understanding probability maps and graphs, results have informative value), and program usability (performance, work facilitation). Results were gauged using a Likert-type scale ranging from 0 (no agreement) to 5 (complete agreement) (Figure 2) and found high agreement (4.62 ± 0.51) regarding the user interface being helpful to better evaluate data while a smaller proportion indicated it would improve their diagnostic workflow (4.12 ± .99). Additionally, visual aids that can display error-range in tumor measurements (e.g., timeline) were identified by the users (six out of eight) to be significantly helpful during the decision-making process.

Conclusion. With this exploratory usability study, we demonstrated that computer-aided approaches have a positive effect on the data understanding and effective work of neuroradiologists. Future work includes improving the application based on the feedback received on the surveys and expanding the evaluation sample size.

Presentation of Clinical Pathways for Improved Provider-Patient Shared Decision Making

Jose Pineda, PhD(s)1, Lina Bouayad, PhD1,2, Min Chen, PhD1
‘Florida International University, Miami, FL, ‘James A. Haley Veterans’ Hospital, Tampa, FL

Introduction

The study of clinical pathways to guide the diagnosis and treatment of patients has been shown to improve their prognosis. However, prior researchers have limited their studies to analyzing the usefulness of these pathways for the physicians performing the diagnoses, while paying little attention to how the patients could learn from this data themselves. Yet, these pathways offer major potential for informing patients about their conditions and treatments.

In the past couple of decades, a major move towards patients and physicians making decisions together has taken place1. Despite intentions to expand on this practice, researchers have identified barriers for patients to participate with the most significant being inadequate provisions of information2. By collecting the knowledge found in clinical pathways, matching it to the patients based on their characteristics and prior diagnosis as found on their personal health records (PHR), and presenting the results to patients in the form of decision aids, we argue that it will be possible to improve the patients’ understanding about their conditions as diagnosed by their physicians, so that the physician and the patient can have more meaningful discussion about the possible treatments options available.

To our knowledge, this would be the first study to use analytics to analyze clinical pathways and match them to the patient’s data in order to improve the patient’s knowledge. If successful, this approach could be used to improve interactions between physicians and their patients leading to more effective shared decision making.

Methods

In this study, we aim at extracting and presenting sets of possible treatment options to the patients. The data used in this study is extracted from 135,962 electronic discharge records of 285 hospitals in the state of Florida. For every patient admitted, 192 different variables are used to describe different diagnoses, procedures performed, and relative dates of admission. A unique patient identifier allows us to track patient admissions across hospitals and over time. We start by focusing on Congestive Heart Failure (CHF) patients, who have some of the highest readmission rates (23%-26%) of any type of patient.

First, patients’ matching is made by using patient characteristics and set of diagnoses. Next, we create clinical pathways using process mining techniques on 3 data elements: 1) a case identifier, 2) an activity identifier, and 3) a calculated time stamp based on the relative dates of admission and diagnoses. In order to make our dataset more human readable, we then convert all extracted clinical pathways from ICD9 and CPT code to matching description using data dictionaries published by the Agency for Healthcare Research and Quality (AHRQ). Sets of treatment options are then evaluated based on different criteria, namely 1) outcome – combination of efficacy and side effects represented by the status at discharge, and 2) procedure cost.

Results

Results including the sets of diagnoses and matching treatment options to be presented to patients will be presented at the conference.

Conclusion

In the present study we extract and present a set of treatment options to patients. Results from this study can help empower patients and drive their engagement.

Introduction
Medicaid finances 45% of U.S. births totaling $27.6 billion dollars annually\(^1\). While attempts to identify high risk maternity patients, in advance to improve outcomes and lower costs, the models are not used in daily practice because there are questions about availability of timely data, model validity, and accuracy\(^2\). Medicaid enrollment changes and churn exacerbates these issues because many predictive models rely on robust data sets, which may not be readily available. In addition, members may have survey data, pharmacy data, lab, and claims data all pointing to the same condition or severity within a condition. The objective was to develop an algorithm capable of integrating disparate data to assess the risk of pre-term, respiratory distress, or neonatal abstinence by the 20th week of pregnancy.

Methods
We identified 3539 births, between 2015 and 2016 in a large Medicaid plan in KY, that had at least 9 months of continuous eligibility for the mother, and could be linked to a live birth through ID or address match algorithm. We coded any birth pre-term, respiratory distress, or neonatal abstinence as 1 and the rest as 0 to create a binary outcome. Next we pulled medical, pharmacy, labs, and health assessment data, when available, for the members for the past two years prior to 20th week of gestation by normalizing for gestational age at birth. Because of data sparsity and reoccurring signals, we developed data munging process to combine similar information from different data sources. Our example for Periodontal Disease highlights our feature engineering process (See Figure 1):

Features included Diabetes, smoking, Substance Abuse (SA), Periodontal Disease (PD) in addition to demographic features such as Age. We employed a LASSO Logistic Regression classification framework using R’s Glmnet package with 5-fold cross validation.

Table 1: Selected Sample Dataset Descriptive Statistics

<table>
<thead>
<tr>
<th>Avg Age</th>
<th>% Diabetes</th>
<th>% smoking</th>
<th>% SA</th>
<th>% PD</th>
</tr>

<tbody>
<tr>
<td>26.01</td>
<td>14.91%</td>
<td>37.37%</td>
<td>11.24%</td>
<td>6.47%</td>
</tr>
</tbody>
</table>

Results
Our model had a validation c-statistic of .7. Significant features included: age, history of preterm, Diabetes, Substance Abuse, number of opioids.

Discussion
The model has a 10 percent higher c-statistic performance than other models built using comparable data sources\(^3\). It is possible model is does not generalize outside the dataset. Exploration is needed to test the validity of the model. We need to assess whether these predictions are useful to practitioners in the field. Three measures of interest include whether the predictions are valid, timely, and can effect change in patients.

A comprehensive Variant Analysis System for Molecular Pathology

A. Pozhikov PhD, S. Bolisetty MTech, MS, F. Martinez BS MBA, K. Honnavali MCA, T. Kirkpatrick MS, M. Guirgus, R. Rout, A. Shah, PhD MBA, R. Pillai MD
Beckman Research Institute and City of Hope National Medical Center, Duarte, CA

Introduction

Molecular analysis of tumor biopsies (molecular pathology) is critical for determining the course of patient’s treatment. Genomic sequencing of the biopsy specimen reveals the SNPs, fusions, CNVs and other genetic rearrangements occurring in oncogenes and oncosuppressors. Depending on the gene involved, either a targeted therapy or chemotherapy/radiation/surgery may be prescribed. Variant information handling, interpretation, and reporting of the results are the biggest bottlenecks in the tail-end workflow of the NGS-based testing. Several software applications, open source, commercially licensed, and custom designed such as ANNOVAR, AnnTools, VARIANT, SnPEff, SeattleSeq, Annotate-It, Appistry, IonReporter, NextGENE etc are available for variant annotation and visualization. The common features shared by these applications are SNP and insertion and deletion identification, gene and variant annotation, in silico prediction score annotations, and variant filtering features. For a comprehensive overview of the existing tools see “Standards and Guidelines for the Interpretation and Reporting of Sequence Variants in Cancer” by Li, Marilyn M. et al. The Journal of Molecular Diagnostics, 19:4-23.

Our group (Research Informatics and Systems) developed a comprehensive information system for molecular pathology (HOPESEQ). Unlike the above-mentioned existing packages, the HOPESEQ offers the following features: (i) archiving variants determined by sequencing; (ii) maintaining a knowledge base (KB) of previously classified variants as pathogenic or benign; (iii) matching patients’ variants to public databases, i.e., COSMIC and ExAC; (iv) providing natural language based searching to interpret published literature and clinical trials and (v) visualizing the variants of the patients archived within HOPESEQ.

Methodology

Raw sequencing files are processed with an experimentally-verified pipeline, which maps the sequencing reads to the human genome (e.g., HG19) and detects variants. The detected variants are filtered to satisfy minimum sequencing depth criteria followed by calculation of allele frequency. The allele frequency is important for estimating the pathogenic potential of the variant, i.e., there is a different impact of zygocity on oncogenes vs. oncosuppressors. The filtered variants are submitted to HOPESEQ (see fig. above) by a technician.

A pathologist and a geneticist (or more than one geneticist) review the submitted variants using the above 5 key features of the HOPESEQ. The purpose of the review is to make a determination of whether a variant is pathogenic or not. Specifically, if the variant was previously saved into the KB, the determination of the variant’s pathogenicity is based on that record in the KB. If the variant has never been seen before, the pathologist and the geneticists can use HOPESEQ and consult against the external databases (COSMIC, ExAC).

HOPESEQ automatically matches the variant in question to the records in COSMIC and ExAC. Natural language processing (NLP) aids the pathologist to interpret the literature referred by the external databases. If no records are available in the external databases, HOPESEQ visually shows which part of the gene product (e.g., enzyme, transcription factor) is affected enabling the pathologist to at least provide a mechanistic estimate of the variant’s pathogenic potential. Additionally, HOPESEQ facilitates a discovery of appropriate clinical trials based on the inclusion criteria addressing the variants of the patient. Finally, a report is generated that includes selected pathogenic variants, appropriate drugs and potentially suitable clinical trials.

Current status of HOPESEQ

The HOPESEQ platform is currently being used by the Pathology Department at the City of Hope. To our knowledge, no other existing software offers a cohesive interplay between the variant pathogenicity prediction and expert reviewing, whereby the prediction is aided by NLP and protein structure consideration.
Mobile system to gather patient-generated data in Parkinson’s Disease treatment.

Marco Prenassi, MSc1, Pierluigi D’Antrassi, MSc2, Sergio Barbieri, MD2, Lorenzo Rossi, PhD3, Simona Mrakic-Sposta2, Sara Marceglia, PhD1,2
1University of Trieste, Trieste, Italy; 2Fondazione IRCCS Ca’ Granda Ospedale Maggiore Policlinico, Milano, Italy; 3Newronika S.r.l., Milano, Italy;

Introduction

Deep brain stimulation (DBS) implants require a stabilization period to benefit patients affected by Parkinson’s disease (PD). A correct and constant monitoring of this period is essential to regulate their therapies. In a homecare environment is necessary an easy-to-use, comfortable, affordable, and reliable system. The scope of this work is to test if a commercially available and affordable accelerometric sensor bracelet paired with a mobile device is capable of assessing motor symptoms without causing discomfort to the patient.

Methods

A dedicated Android App was developed to provide a clinical diary to be filled in by the patients at predefined times. It is paired with a Pebble Time smartwatch that acquires tri-axial accelerometric data from the wrist. An offline Matlab algorithm was implemented to evaluate PD bradykinesia. For this study we enrolled 4 patients undergoing DBS implant surgery. During an 8-hours session the patients were asked to fill in the diary and wear the smartwatch. A clinician assessed their condition compiling a Unified Parkinson’s Disease Rating Scale part III (UPDRSIII) form several times during these sessions. After the 8-hr trial, a clinician asked the patients if the smartwatch was uncomfortable during the day (options: “No” or “Yes”, if the answer was “Yes”, please explain why).

Results

At the end of the session, the data was collected and elaborated remotely with an optimized algorithm that finds the Bradykinesia Acceleration Scores (BAS) in data bins of 4 minutes (Figure 1A). The BAS algorithm was modified from the patent by Griffiths & Horne; BAS is lower when the patient is bradykinetic. The correlation between UPDRS III scores and the BAS for 5 different recording sessions, shown in Figure 1B, is -0.582 (P<0.009, Pearson). The bracelet was well tolerated (everyone answered “No” without further comments). Three of 4 diaries were correctly filled in by the patients. The correlation between UPDRS III scores and the diary scores were not significant.

Conclusions

The smartwatch was well tolerated and the mobile app was used by the majority of patients to fill in the diary, a cumbersome activity if done on paper. The mobile app was able to support data collection and the wearable device was reliable to monitor the motor symptoms of the patients without causing discomfort.

Promoting adherence to antiretroviral therapy in HIV-infected patients using mobile phone text messaging technology

Yuri QUINTANA PhD1,2, Eduardo Gonzalez MARTORELL MD4, Darren FAHY1

1Division of Clinical Informatics, Beth Israel Deaconess Medical Center, Boston, MA
2Harvard Medical School, Boston, MA

Abstract
We conducted a systematic review to determine whether mobile phone text-messaging or mobile apps are efficacious in enhancing adherence to ART in patients with HIV infection.

Introduction
An estimated1 36.7 million people were living with Human Immunodeficiency Virus infection worldwide in 2015. The impact of Human Immunodeficiency Virus/Acquired Immunodeficiency Syndrome (HIV/AIDS) has been particularly hard on countries with limited resources. Antiretroviral therapy (ART) can help people with HIV infection to live longer, healthier lives, but adherence to ART can be challenging. It is important to find better ways to help patients stay adherent to their ART regimens. Mobile phone text-messaging has the potential to help promote adherence in these patients.

Methods
We conducted a computerized literature searches with no date or language delimiter using the databases PubMed/MEDLINE (NCBI), Embase (Elsevier), Web of Science (Thomson Reuters), Cochrane Central (EBSCO), CINAHL (EBSCO). The literature search was completed on Date January 19, 2017. We included any intervention evaluated with a comparison group where the intervention was delivered digitally (not just voice alone) via mobile phone or smart phone. We excluded interventions that were not evaluated (no data collected for evaluation of the mhealth intervention), those interventions focused only on the health provider and not involving patients using the intervention, and papers that just reported on the feasibility of intervention. Adherence was measured with the following outcome metrics: adherence over time, EAMD cumulative adherence, missed dose past week, pharmacy adherence over time, self-reported adherence, self-reported adherence over time, viral load adherence.

Observations
We retrieved 1188 articles, and after removing duplicates, we had 555 articles. We found 489 were irrelevant and did not match our inclusion criteria. We reviewed 66 papers with full text and excluded 46, leaving 20 papers that matched our inclusion criteria. We reviewed these for bias using the Cochrane review methodology. Table 1 shows the types of bias we found in the study papers. We found that 7 of these described interventions with no improvement in medication adherence, and 13 had positive outcomes when compared to the control group.

MeSHgram: An Open Source Tool to Visually Browse Co-occurrence of MeSH Terms in PubMed

Satyajeet Raje, PhD¹, Ravi Teja Bhupatiraju, MBBS, PhD¹, Abdelrahman Hosny, MS², Ben Busby, PhD¹

¹U.S. National Library of Medicine, National Institutes of Health, Bethesda, MD, USA
²Center for Quantitative Medicine, UConn Health, Farmington, CT, USA

Introduction
We present MeSHgram as a tool for convenient, visual and interactive exploration of the co-occurrence of MeSH terms over the entire PubMed corpus. The tool can assist in the quantification of known research patterns as well as potentially aiding novel hypotheses generation.

Methods
We used the NLM PubMed corpus¹ as our data source. As of Jan 2017, the corpus contained approximately 24.5 million publications from 1809 to 2016². Publications indexed in PubMed have human curated Medical Subject Heading (MeSH) terms associated with them. We leveraged these MeSH terms in MeSHgram.

We parsed the entire PubMed corpus and extracted the ID, year of publication and MeSH terms associated with each document. We excluded duplicate items such as revision entries and those with no MeSH terms, resulting in approximately 23 million publications in our database (MongoDB). We use a Python web controller (CherryPy) and JavaScript widgets (nvd3, jqcloud) in the front-end for the implementation.

Features
The tool allows searching with multiple MeSH terms via an auto-complete search box. It displays article counts by year for the searched terms along with the number of co-occurrences. It also displays a word cloud for other MeSH terms that appear alongside the searched MeSH terms to provide contextual visualization of other associated MeSH terms. Visually selecting specific year ranges in the graph updates the graph and the word cloud.

Acknowledgements
This work is supported in part by an appointment to the NLM Research Participation Program administered by ORISE through an interagency agreement between the U.S Dept. of Energy and the NLM. MeSHgram was developed as part of a hackathon organized by NCBI in Jan 2017. MeSHgram is currently under development and available at www.meshgram.org. The source code is open and available on GitHub under MIT license.

Figure 1. Screenshot of MeSHgram displaying co-occurrences of MeSH terms "Rubella" and "Rubella Vaccine"

Reducing Uncoded Allergy Information in the Electronic Health Record

Harley Z. Ramelson, MD, MPH
1Brigham and Women’s Hospital, Boston, MA; 2Partners HealthCare, Wellesley, MA; 2Harvard Medical School, Boston, MA

Abstract
Through a series of user interface design modifications, the percentage of all uncoded allergies being entered by users was reduced from 18-23% to around 8%. The increased coded information allows drug-allergy checking to be performed thereby improving patient safety.

Introduction
The LMR is an in-house developed EHR that used across the Partners HealthCare enterprise. In order to address the high rate of uncoded allergies in the LMR, a series of user interface changes were initiated.

Methods
The following user interface changes were implemented across two releases.

1) Requiring users to go through the search process and review a listing of search results of allergens
2) On the search results page, the functionality allows a user to enter an allergen in the record that may not be present in the dictionary. This enhancement presented a message next to that allergen indicating that it is uncoded and will not be used for allergy alerts.
3) If the uncoded allergen was selected, a pop-up alert is presented to the user again emphasizing that the allergen is uncoded and will not be used in clinical decision support, reporting and performance measurements.
4) The allergy views were enhanced to include the label “uncoded” next to the allergen. This would prompt the user to be able to codify the allergen and remove it from the uncoded category.

Results
Prior to the changes being made, the percentage of allergens that were uncoded in the LMR ranged from 18% to 23%. Following the first set of changes, this was reduced to around 15%. Following the second set of changes, the percentage was further reduced to around 8%.

Conclusion
Modifications in the user interface in an electronic health record can reduce the percentage of uncoded allergies in an Electronic Health Record, thereby improving quality of the clinical data and increasing the effectiveness of clinical decision support allergy alerting.
Setting the Stage for Implementing an EHR-Integrated Social Knowledge Networking (SKN) System on Medication Reconciliation: Phase 1 Results
Pavani Rangachari, PhD
Augusta University, Augusta, GA

Background: Despite the policy impetus towards meaningful use of EHR Medication Reconciliation (MedRec) Technology (to prevent medication errors during transitions of care), hospital adherence has lagged for one chief reason—low physician engagement, stemming from lack of consensus about which physician is responsible for managing a patient’s medication list. In October 2016, Augusta University received a two-year grant from AHRQ, to implement a Social Knowledge Networking (SKN) system for enabling its health system, AU Health, to progress from “limited use” of EHR MedRec technology, to “meaningful use.” The hypothesis is that an SKN system would bring together a diverse group of practitioners across settings of care, to facilitate the exchange of tacit (practice-based) knowledge on issues related to EHR MedRec, which in turn, is expected to increase practitioners’ engagement in addressing those issues, to enable learning and meaningful use of EHR. The goal of PHASE 1 of the project (completed in April 2017), was to identify a consensus-set of issues related to EHR MedRec across multiple subgroups of practitioners involved in the MedRec process, i.e., physicians, nurses, and pharmacists. A two-round Delphi process (interviews and survey) was used to achieve this goal. This process in turn, facilitated the development of a Reporting Tool on Issues Related to EHR MedRec, which, along with an existing SKN tool (Microsoft Yammer); was integrated into the EHR at AU Health, at the end of PHASE 1. PHASE 2 (launched in May 2017), involves conducting a 52-week pilot test of the EHR-integrated SKN system in outpatient & inpatient units at AU Health. The purpose of this paper is to describe the results of PHASE 1.

Methods: Phase 1 included 15 individual semi-structured interviews with physicians, nurses, and pharmacists at AU Health, to identify issues related to EHR MedRec. Thematic Analysis helped identify 56 issue-items grouped under 9 issue categories. These results in turn, were used to conduct a survey a larger group of physician, nurses, and pharmacists at AU Health. The survey sought practitioners’ importance-rating of all issue-items identified from interviews, on a 7-point Likert Scale. A total of 140 responses were received (out of 225 recipients), for a 62% response rate. Data were subjected to 1) Descriptive Analysis of importance-ratings of issue-items; 2) Factor Analysis to validate issue categories and generate indices, and 3) Index T-test Analysis to assess differences in rating of issue-items by professional affiliation and by unit affiliation.

Results: Factor analysis served to validate the first 8 of the following 9 issue categories identified from Thematic Analysis of the interviews. On average, the issue items under each of the 9 issue categories were rated as “Important” or “Extremely Important” by 70%-90% of all survey respondents: 1) Care-Coordination Issues (89%); 2) Patient Education Issues (84%); 3) Workflow Issues (83%); 4) Resource Issues (82%); 5) Ownership & Accountability Issues (81%); 6) Process of Care Issues (81%); 7) Workforce Training Issues (79%); 8) IT-Related Issues (78%); and 9) Documentation Issues (74%). The Index T-test Analysis revealed no statistically significant differences (at the 5% significance level) in the importance-rating of issues by professional affiliation or unit affiliation, indicating a consensus on issues related to EHR MedRec. A central theme that emerged from findings was an absence of a shared understanding of 1) the responsibilities of the various practitioner groups involved in the EHR MedRec process; and of 2) the importance of EHR MedRec as a tool for preventing errors during care transitions. This central issue in turn contributed to an overall sense of skepticism regarding the value of EHR MedRec, leading to system workarounds, and “limited use” of the EHR MedRec functionality.

Conclusions: Results suggest that successful implementation of EHR MedRec would first and foremost, require a shared understanding of the process for MedRec among multiple stakeholder groups. Importantly, results indicate considerable potential for an EHR-integrated SKN system to enable knowledge exchange among practitioners across care settings, to address aforementioned issues, and enable engagement, learning, and EHR meaningful use. If the hypothesis holds, federal EHR vendors could be encouraged to incorporate SKN features into EHR systems.

Use of the popHealth Open-Source Quality Measure Engine to Support Cardiovascular Care at Small- and Medium-Sized Practices

Luke V. Rasmussen¹, Andy Schriever², Pauline Kenly¹, Dejan Jovanov³, Stephen D. Persell¹, Theresa L. Walunas¹, Abel N. Kho¹

¹Northwestern University Feinberg School of Medicine, Chicago, IL; ²Park Street Solutions, Naperville, IL; ³Illinois Department of Public Health, Chicago, IL

Overview: The prevalence of electronic health records (EHRs) has grown since the advent of the Health Information Technology for Economic and Clinical Health (HITECH) Act of 2009¹, which incentivized adoption of EHRs through the Meaningful Use (MU) program. One aspect of MU has been recording and reporting of electronic clinical quality measures (eCQMs). As part of the AHRQ-funded EvidenceNOW network, the Healthy Hearts in the Heartland (H3) study has pursued the centralized calculation of cardiovascular health eCQMs from small- and medium-sized practices in Illinois, Wisconsin and Indiana. The use of a centralized calculation engine facilitated transparency and consistency in the calculation process across practices and vendors. Here we describe the use of the open-source popHealth software (https://github.com/OSEHRA/popHealth) as a means to that goal.

Methods: Four eCQM measures were implemented for the study: Aspirin, Blood Pressure, Cholesterol and Smoking (ABCS), using the HL7 Health Quality Measure Format (HQMF) definitions. This included the use of a draft Cholesterol measure accessible from the Measure Authoring Tool (MAT). Data were extracted from commercial EHR systems using a variety of methods (CCDA exports, integrated reporting workbench, or direct database access) and sent to a central study server for processing using software licensed from Park Street Solutions. The resulting data extracts were formatted as JSON documents in the format used internally by popHealth. Additional automation was built on top of the existing popHealth code base to streamline the management of quarterly data refreshes. An overview of the data flow and system components involved is shown in Figure 1.

Results: We established data feeds from 77 practices (representing seven different commercial EHR vendors) between June 2015 and February 2017, representing over 250,000 patient records. Currently 11 practice facilitators involved with the study and two practice office managers access popHealth to assess clinical quality scores.

Discussion: We experienced challenges obtaining sufficiently detailed patient data from some of the EHRs, including 1) a lack of batch export capabilities, 2) insufficient detail in CCDA and reporting exports (e.g., missing dates), and 3) a lack of historical data (e.g., exporting only the most recent blood pressure reading). Despite these limitations, we were able to demonstrate the popHealth platform to be a useful centralized eCQM calculation engine. The platform has been shown to be scalable, and has allowed aggregate eCQM calculations across health care networks and geographical regions. Ongoing work includes a formal validation of popHealth calculations against manual chart reviews. Since popHealth is capable of ingesting HQMF documents for measure logic, this solution may be easily expanded beyond the initial ABCS four measures with minimal effort. If the identified limitations can be overcome, popHealth may become a useful way for small and medium-sized practice groups to apply and report eCQMs and might eventually be used to support their participation in value-based payment or public reporting programs.

Exploring Barriers to the use of Electronic Health Records in the Trauma Room Using a Cognitive Work Analysis

Ryan J. Rasmussen MS, FNP-C, Doctoral Candidate1, Jane M. Carrington PhD, RN2
1 University of Arizona, Tucson, Arizona; 2 University of Arizona, Tucson, Arizona

Background. Trauma is one of the leading causes of death for individuals under 45 years old1 accounting for 192,000 deaths/year in the US in 20142. When both healthcare costs and lost productivity are calculated the total cost of trauma is more than 489 billion dollars annually in the United States alone3. When working in a multidisciplinary team of this size effective communication of critical information is often difficult to accomplish and information is delayed in reaching the intended target. The purpose of this presentation is to describe a planned research project where Cognitive Work Analysis (CWA) will be used to explore inter-trauma team communication to inform EHR design and adoption and increase patient outcomes.

Description of Problem. The trauma room is unique area of the hospital that employs complex communication patterns within and among trauma team members. Despite its promise to increase effective communication, the current electronic health record (EHR) has yet to meet the needs of the trauma team to support inter-team communication. Because of this most trauma rooms have not fully implemented or adopted the “real-time” use of an EHR during the care of trauma patients. The Effective Nurse-to-Nurse Communication framework describes nurse-to-nurse communication of a clinical event4 and provides a better understanding of how nurses communicate with each other and other parts of the medical team. This and Information Theory guide this research5. The objective of this study will be to understand the barriers to the use of electronic health records in the trauma room by increasing our understanding of intra-trauma communication.

Method. A CWA is a method of research designed to analyze a workplace and guide the use of technology within that workplace5. CWA has the unique ability to look at a current system, analyze the system, and suggest recommendations for future implementations and designs. CWA has great potential for contributing to the improvement of inter-team communication and facilitate the effective use of an EHR within the trauma room. Consistent with CWA described by Jenkins et al5, interviews and observations will be used to inform current inter-team communication. Interviews with trauma team members will be digitally recorded and transcribed for analysis. Observations will be documented using video recordings. The trauma room will be equipped with both video and audio recording devices that will be activated when the trauma patient arrives. These recordings will be analyzed for actual patterns of communication and documentation. Interviews will be analyzed for perceived patterns and barriers to communication and documentation. Data will then be analyzed according to the five domains of CWA: work domain analysis, control task analysis, strategies analysis, social-organizational and cooperation analysis, and worker competencies analysis6.

Impact. The findings of this study will increase our understanding of inter-team communication in the trauma room and result in suggested improvements to increase patient outcomes. This study will also inform design of the EHR that supports inter-team communication during trauma.

Conclusion. Increasing our understanding of intra-team communication during trauma can lead towards successful implementation and adoption of the EHR in the emergency department trauma room and contribute to increased patient safety.

Introduction
The United States Critical Illness and Injury Trials Group Program for Emergency Preparedness (USCIITG-PREP) has been coordinating multi-site exploratory studies to identify and overcome challenges associated with prospective data collection during public health emergencies. Efficient data collection is essential in this context, particularly if new medical countermeasures are being evaluated. An approach being considered is the population of clinical case report forms (CRFs) directly from Electronic Health Record systems (EHRs) in order to expedite real-time data collection while minimizing additional burden upon clinical providers. Eighty-three percent of sites from our 2016 Influenza Study reported transcription of up to 98.5% of CRF fields directly from an EHR. Integrating research data collection workflows within existing EHR clinical workflows has the potential to significantly decrease time and effort requirements for all providers involved with a given study. The overall aim of this project is to integrate research CRFs with EHRs, including reuse of data previously collected for clinical care.

Methods
USCIITG-PREP has initiated a new feasibility study in November 2016, focused on the treatment of severe cases of Influenza requiring Intensive Care Unit (ICU) admission. A new CRF has been created and implemented using an open-source and stand-alone electronic data capture tool. The new study provides the opportunity to evaluate the integration of the same CRF with a commercially available EHR system. This evaluation includes four steps: 1) selection of relevant EHR data and EHR data collection tool(s), taking into account typical ICU clinical workflows; 2) identification of CRF fields that map to structured clinical data elements (SCDEs) within the EHR; 3) validation of identified fields with clinical domain experts; and 4) implementation of prototype CRF integrated with the EHR, aligned with existing clinical workflows and including opportunities for data reuse. Once the prototype is implemented, we will explore options to de-identify and aggregate data from different sites, and also describe the process to disseminate the CRF to sites using the same EHR system. Throughout the evaluation, detailed documentation about available alternatives and challenges will be created, as well as records outlining resources and effort to implement the prototype.

Results
The Influenza Study CRF has 82 fields total, including details about laboratory confirmation, disease severity, treatment, and outcomes. The CRF includes 29 boolean, 18 single-select, 5 multi-select, and 30 free text fields. When identifying relevant EHR fields, special consideration must be taken to confirm data is being retrieved from the correct encounter and with the appropriate format. For example, dates might need to be converted to time periods relative to the first ICU admission. In the Influenza Study eCRF eight single-select fields represent relative dates. We have started steps 1 and 2 and plan to complete the prototype implementation by May 2017. The current data entry tools being considered include structured forms and flowsheets within the EHR. Preliminary results reveal challenges in translating dates to relative date fields, as well as calculating number of treatment days and obtaining details assessed during admission.

Conclusion
Data entry burden on clinical providers is a prominent barrier to multi-site and large-scale clinical research studies. This barrier is even more pertinent to prospective studies during public health emergencies, when real-time data collection is essential. USCIITG-PREP’s effort to evaluate EHR data collection tools is key to decreasing data entry time and improving the ability for rapid dissemination during emergent events. A CRF integrated with an EHR can support reuse of existing EHR data and decrease the need for manual data collection and transcription to a stand-alone data capture tool. If integration with a single EHR is successful, future evaluation will be necessary to understand how easily the EHR-based CRF can be disseminated to sites using disparate EHR systems.

Examining Nurses’ Use of Electronic Health Records to Document Symptoms in Acute Care Settings

Blaine Reeder¹, Mustafa Ozkaynak¹, Mary Beth Flynn Makic¹, Karen H. Sousa¹
¹University of Colorado College of Nursing, Aurora, CO

Introduction
A person’s perception of their own symptoms is a prominent factor in the decision to seek acute-care admission. Nurses perform symptom assessment and management as a core part of their practice and these activities longitudinally influence patient symptoms. Knowledge of how nurses’ use electronic health record (EHR) systems to document patient symptoms is incomplete, though clinical experiences of our research team members indicate that nurses often document symptom data in narrative notes. Our recent systematic review identified the need to improve symptom assessment documentation and design of systems that support this activity in acute care settings [1]. Accepted wisdom is that nurses document symptoms using the EHR but the extent to which this happens is unknown. Therefore, the motivation and aim of this qualitative descriptive study is to examine how nurses use the EHR system to document patient symptom assessment and management in acute care settings.

Methods
We conducted semi-structured interviews with nurses (n=14) who work at inpatient units of an academic hospital in the Mountain West region of the United States. Interview questions related to patient care responsibilities, patient assessment, symptom management, work experience, education and training, and use of information technologies to support patient care. The first and second authors conducted all interviews. A codebook for data analysis was iteratively developed with input from all authors. A data-driven, inductive coding approach was employed with first and second authors independently coding transcripts and then meeting to reconcile differences. After three transcripts, the first author coded the remaining transcripts with periodic checks by the second author for code drift.

Results
Participants generally had a positive view of the EHR as tool to support the patient care they provide, noting that symptom documentation and overall patient care was important. A common response was: “If it wasn’t charted, it wasn’t done” (Participant 8). Beyond patient care, a primary motivation for documenting patient care was for legal reasons.

With regard to general patterns of use, nurses reviewed other nurses’ documentation going back only 24 hours. Not surprisingly, symptom documentation varied by unit due to patient conditions. Symptoms reported as important are: pain, numbness, nausea, vomiting, numbness, tingling, alteration in cognition, dizziness, shortness of breath, dry mouth, cough, weight loss, constipation, mouth sores (oncology). As noted by one participant: “Pain is a huge symptom that is a problem in all patient populations” (Participant 7).

One identified challenge is that nurses are instructed to “chart by exception” though some participants disagreed with this practice due to loss of individual information about each patient. Another identified challenge is that increased patient care needs (workload) decreases quality of documentation (e.g.: timeliness and completeness). In these circumstances, nurses prioritize patient care over documentation. Other common barriers to system use are: system downtime, freezing or hanging; checklists that do not portray the patient; having to search where to document; charting the same thing in multiple places; and finding where other nurses have documented patient information. Some nurses identified the practice of copy/paste as contributing to poor documentation.

Conclusion
Our findings indicate opportunities to better support nursing practice by redesigning EHR interfaces and providing longitudinal reports of patient symptom status from nursing documentation. Full results and design recommendations from this study will be presented at the AMIA Annual Symposium 2017 in Washington, DC.

Natural Language Data Sampling: Principles & Strategies in Corpus Selection

INTRODUCTION: Designing a model of study phenomena allows hypothesis generation, testing and evaluation of the model’s validity against real-world data. But drawing inferences from the model are unlikely to prove valid outside the model unless its design incorporates methods of representing variation within the population under consideration. To achieve adequate representativeness of the data available, researchers sample some portion of it. Sampling from a patient cohort will involve considerations of the characteristics of the clinical model to determine suitable data types to represent variations across the population and how to stratify, for example, demographic data or diagnostic categories versus how to weight study variables such as lab, medication or behavioral values. While clinical models are often built with multiple data streams and require complex analytical methods to achieve integration into the model, it is important to distinguish a stream of raw data from a data stream which is itself the output of a model. Sampling patients by age group uses raw data (number of years since birth), while sampling patients whose clinical notes contain references to dehydration makes use of a language model. Building a natural language (NL) model for use in providing information from NL data sources differs in significant ways from building a model of clinical outcomes or clinical risks. Clinical models making use of information extracted from NL text need to intersect with the NL model associated with the clinical phenomena, but a successful NL model requires independent sampling methodology. METHODS: We reviewed the document sampling methods in 4 Natural Language Processing (NLP) projects aimed at extracting specific concepts for downstream analytics, each with differing corpora and targeted clinical concepts, all using narratives documents within the VA medical record system. The cohort selection for each project was performed prior to the document sampling, using structured data pertinent to each project (e.g., ICD codes, drug orders, lab values). Our corpora were derived from these cohorts and included the following four data sets: CCC: Cardiac Catheterization Clinical Note Corpus (starting corpus of 9,007,164 narrative notes); CRR: Cirrhosis Risk Radiology Report Corpus (starting corpus of 91,881,399 radiology reports); OIC: Opioid Induced Constipation Clinical Note Corpus (starting corpus of 1,158,681,416 narrative notes); PTSD: PTSD Treatment Mental Health Corpus (starting corpus of 4,090,310 narrative notes). Rather than risking possible over-fitting by pre-mining documents for instances of targeted concepts, we used available meta-data to construct each project corpus. The possible document features used in filter and categorize the documents were (1) document title, (2) provider type of document author, (3) clinic type producing the document, (4) document distribution across clinical workflow of targeted cohort (for example, ER, admission, procedure, inpatient progress, discharge, outpatient progress), (5) document distribution across cohort-specific determinates (e.g., over-sampling by age, gender, etc.). We were interested in finding strategies producing corpora with a high yield of targeted clinical concepts. We determined the proportion of the corpora that yielded documents with no targeted clinical concepts, as a (negative) measure of sampling success by assessing the annotated (tagged) sub-samples of each corpus for documents yielding zero annotations. RESULTS: Table 1 illustrates the feature sets used to generate each corpus, and the rate at which each produced zero concept documents. The feature set used to form the CCC performed the best (2% rate), using all 5 features; the worst being the OIC (40%) rate, using feature sets 1,2 and 5.

DISCUSSION: Successful document sampling resulted from filtering out irrelevant note types and balancing distribution across document features. The ability to filter and categorize by document feature depends to a large extent on the quality of the information in the feature set. For example, document titles among nursing notes tend to be highly underspecified. The sampling strategist can often rely on combining feature sets to produce better results. The corpus with the worst performance, the OIC had a very high rate of zero annotation documents, due to the inclusion of nursing notes authored from mental health services, most of which were not germane to the concepts (opioid use, constipation, constipation treatment, constipation procedures). Filtering nursing notes by clinic type (in essence, applying feature 3) would have reduced the zero-annotation documents to a rate of 14%. Creating a Corpus Resource for Text Simplification R & D

Debra Revere, MLIS, MA¹, Partha Mukherjee, PhD², David Kauchak, PhD³, Gondy Leroy, PhD²

¹Univ of WA, Seattle, WA; ²Univ of AZ, Tucson, AZ; ³Pomona College, Claremont, CA

Introduction

Text simplification (TS) involves rewriting complex text into simpler language that is easier to understand while retaining meaning. An important TS resource is text in which the difficulty of the text is known. Previous corpora have either relied on the text source (e.g., blogs vs. medical articles) or human perception to judge difficulty. These assessments have some value, but are subjective. To better quantify text difficulty, we have created a collection of texts and questions (Qs) which test knowledge (As) within those texts in order to systematically quantify text difficulty. Our Q/A process combines auto-generated and human-annotated methods to create a training corpus from texts of varying difficulty within the medical domain. To minimize factors that might influence performance other than text difficulty, we standardized the process using Heilman's (2011) framework which parses each sentence and then uses a rule-based approach to generate Qs based on syntactic structure¹.

Text Simplification Corpus Creation

Following auto Q/A generation, annotators received one Q/A file for 60 medical conditions that contained: 1) auto-generated Qs in Wh- (i.e., What, When, etc.) and True/False formats; 2) the A embedded in its complete original text; 3) the A; and 4) a score which indicated viability of the text to answer the Q. Files with scores lower than 2.5; illegible characters (e.g., HajduGČôCheney syndrome); or non-medical topics were eliminated—leaving a total of 8,637 Q/A item sets across 56 articles. Human annotators randomly selected 36 articles on common (e.g., dyslexia) and uncommon (e.g., Spondylocostal dysostosis) topics to ensure a wide variety of language and complexity. Annotators corrected grammatical errors and conducted up to 3 manual simplifications per Q/A item set to create a Q/A set that was simpler but retained lexical structure—syntactically reducing complexity by splitting sentences, eliminating non-standard abbreviations, or rephrasing strings containing double negatives. Table 1 provides annotation examples.

Table 1. Auto-generated Q/A item set input and human annotated Q/A item set output examples.

Results

The final training corpus contains 1264 questions: 670 Wh-Qs with 4 annotated multiple-choice As (1 correct, 3 incorrect) and 594 True/False-Qs with YES, NO, Sometimes and Not enough information As.

Conclusion

This corpus is the foundation for future TS work in which we will create smaller text fragments with matching Qs at different difficulty levels and generate comprehension data for readers with varying levels of literacy.

Family Data Linkage Methods Using EHR Data

Pedro Rivera, MS¹, Megan Hoopes, MPH¹, Stuart Cowburn, MS, MPH¹, Jon E. Puro, MPA¹
¹OCHIN, Inc., Portland, OR

Abstract

Although many EHRs have functionality for documenting family relationships among patients, explicit linkage between the health records of family members is still lacking in many systems. Such linkage is important for research on pregnancy, birth, health policy, childhood outcomes¹, and the study of conditions with genetic links. We present a generic methodology to impute reliable family linkages using EHR data commonly shared among family members, focusing on maternal-child relationships. A gold-standard dataset of explicit family relationships was utilized for validation.

Introduction

This study describes methods used to link family member data in electronic health records. To accomplish this linkage, we identified a variety of ‘target’ data elements, commonly captured in EHR systems that could potentially be used to establish family linkages. We then conducted a series of experiments to identify potential family linkages. Each experiment utilized a different combination of target data elements to predict family linkages. The results of each experiment were compared to a gold-standard dataset of explicit family linkages to determine the sensitivity and precision of each experimental approach. We focused on mother-child links for two reasons: (1) we felt we could more reliably identify these from available EHR fields than paternal relationships, and (2) areas of research interest requiring these linked data focus on reproductive health and early childhood outcomes, in which maternal factors are of greatest direct interest.

Evaluation Results

We identified 382K patient-mother links in a dataset of 2.1 million patients who had one or more face-to-face visits in the last 5 years. Only 44.5% of these linkages were explicitly documented in the EHR. The number of links was considerably higher for younger patients (link rate for patients ≤ age 18=55%).

Our gold-standard consisted of 25.5K patient-mother links explicitly documented in the Epic EHR both as an emergency contact and as a family relationship in the billing guarantor account(s). The use of home phone numbers as the common data element to group patients into potential household units resulted in the highest number of imputed links (sensitivity 0.8, precision 0.99), followed by Oregon Medicaid case number (sensitivity 0.34, precision 0.98) and geocoded last known address (sensitivity 0.18, precision 0.94).

Conclusion

These data lay the groundwork for future studies requiring data of family members be linked, particularly mothers and their children. This study shows that it is possible to impute such family linkages using standardized methods and available EHR data. A limitation of the current work is the focus on linking maternal-child relationships; future work would benefit from extending this method to paternal relationships and broader family units. Such methods would be important to the study of neighborhood-level factors (i.e., the social determinants of health) and conditions with a genetic component.

Sub-Phenotyping of Crohn’s Disease Using a Large Electronic Record Cohort

Jamie R. Robinson, M.D., Lisa Bastarache, B.S., Robert J. Carroll, Ph.D., Elizabeth A. Scoville, M.D., David A. Schwartz, M.D., Joshua C. Denny, M.D., M.S.
Vanderbilt University Medical Center, Nashville, TN

Introduction
Crohn’s disease (CD) is a chronic inflammatory disease of the gastrointestinal tract with increasing prevalence worldwide. The phenotype of CD is marked by variable clinical features and disease course, with the etiology thought be multi-factorial. Previous studies have suggested a genetic basis for the clinical heterogeneity of this disease. We sought to study the influence of known CD genetic risk loci on clinical heterogeneity via case-only phenome-wide association studies (PheWAS).

Methods
A retrospective, cross-sectional study was performed using the Vanderbilt University Medical Center (VUMC) Synthetic Derivative (SD), a de-identified version of the electronic health record linked to the VUMC biorepository, BioVU. A validated phenotyping algorithm was used to identify individuals with CD. Individuals genotyped on the Illumina HumanExome array platform with principle-component analysis indicating European ancestry were analyzed using a case-only PheWAS for each genetic risk loci, with pairwise comparisons conducted using logistic regression, adjusted for age and sex. Essentially, for each PheWAS, cases and controls were drawn only from among CD cases.

Results
360 individuals with CD meeting selection criteria were identified with extant genetic data. 38 single nucleotide polymorphisms (SNPs) associated with CD were reproduced in this cohort. In a case-only PheWAS, rs6596075 within IBD5 was associated with coagulation defects (OR 3.35, p=1.2x10^-5), acute post-hemorrhagic anemia (OR 2.94, p=7.2x10^-5), and pulmonary insufficiency after trauma (OR 4.38, p=2.7x10^-5) (Figure 1A-B).

Conclusion
This study shows the ability for case-only PheWAS to identify disease comorbidities. The polymorphism with greatest association with Crohn’s disease, nucleotide-binding oligomerization domain 2 (NOD2), showed no association with Crohn’s disease subtypes, suggesting less prevalent polymorphisms, as seen within IBD5, may contribute more significantly to disease heterogeneity. Larger studies are needed to fully characterize these effects.

Critical Factors for Developing a Personalized Warfarin Dosing Protocol: A Scoping Review Analysis

Jacee Robison1, MS, RN & Jia-Wen Guo2, PhD, RN
13M Healthcare Information Systems, Murray, Utah, U.S.A.
2University of Utah College of Nursing, Salt Lake City, Utah, U.S.A.

Abstract
Currently there is a lack of dosing protocols for Warfarin which encompass all the essential information for personalizing dosing. A scoping review was performed in this study to extract factors relevant to the use of Warfarin from existing literature and clinical documents. We identified factors vital in personalizing Warfarin dosing and grouped them into four components as genomic, demographic, health behaviors and clinical. This result can be used to develop a protocol for personalizing warfarin dosing.

Introduction
Warfarin is associated with a high incidence of serious adverse drug events due to its narrow therapeutic range. Patients metabolize warfarin differently, therefore making it important for individualized warfarin dosing to be more commonplace. Using a personalized approach would allow patients more accurate treatment and prevention strategies. However, there are some patient populations understudied and important patient factors left out in current dosing protocols. The research question for this study was: what essential factors are needed in order to develop a protocol for personalizing warfarin dosing?

Purpose
The purpose was to identify the critical factors that need to be considered when developing a protocol for personalizing warfarin dosing from existing literature and clinical guidelines.

Methods
A scoping review study was performed to identify factors which are important in determining the Warfarin dosage from existing literature and clinical guidelines. Following Arksey and O’Malley’s framework for scoping reviews, we started from conducting literature search based on the proposed research question, screening and selecting the relevant publications, extracting data by using narrative review, to summarize and report the results. We searched PubMed with the terms including Warfarin, protocol, prescription, dose, pharmacogenomics, personalized medicine, and precision medicine from January 2007 to February 2017. Google Scholar was also used to retrieve grey literature. Thirty-two articles and documents were relevant and included in the review process. Two reviewers independently extracted data from the retrieved articles.

Results
Inter-reviewer agreement regarding the four critical factors was assessed and the results were 99.91% in agreement, with a Cohen’s Kappa score of 0.93. The critical factors needed to develop a protocol for personalizing warfarin dosing were divided into four domains: genomic factors, demographic factors, health behaviors and clinical factors. Genetic variations play a significant role in warfarin metabolism. For example, CYP2C9, one common polymorphism, results in slowing down the body metabolism of Warfarin; VKORC1 causes the dose-anticoagulant effect of Warfarin. Demographic factors such as ethnicity, sex and age impacts Warfarin metabolism; age affects the ability to metabolize medications. Health behaviors including smoking status, diet and alcohol use also affect warfarin metabolism; alcohol use can lead to an increased risk for bleeding. Additionally, clinical factors such as drug interactions, co-morbidities and those receiving cancer treatment are important to consider when dosing; those taking amiodarone can experience a decrease in Warfarin metabolism requiring dosing adjustments.

Discussion
Further research needs to be conducted for those currently undergoing cancer treatment and those with kidney and liver diseases in order to better understand how these individuals process Warfarin. There is also a need for Clinical Decision Support development in order to make the complexity of the genomic data easier for clinicians. Comparative effectiveness research (CER) would be needed in order to accurately compare benefits and harms of alternate methods and protocols. This would assist patients, clinicians, policy-makers and purchasers to make informed decisions thereby improving healthcare in the individual and in the community.
Towards the Effective Management of EHR Configuration Integrity

Roberto Rocha MD, PhD,1,2,3 Priyaranjan Tokachichu MD, MS,1 Margarita Sordo PhD,1,2,3 Christopher Vitale, PharmD,1 David Dubois, MBA,1 Saverio Maviglia MD, MS1,2,3
1Clinical Informatics, Partners eCare, Partners Healthcare System, 2Brigham and Women’s Hospital, 3Harvard Medical School, Boston, MA

Introduction
An important maintenance challenge associated with electronic healthcare records (EHRs) is the need to detect and resolve broken configuration dependencies. For example, we recently updated diagnosis terms associated with ICD-10-CM to accommodate changes introduced with the FY 2017 release. Within our EHR system, terms were automatically remapped, but other system configuration items, such as ICD-based value sets, were not updated. As a result, problem list entries had the correct new codes, but other configuration items had to be manually updated to remove deprecated codes and/or include new ones. Likewise, patient data records that refer to deprecated codes continue to exist within the EHR, but subsequent use of these records requires mechanisms to recognize that new codes might supersede deprecated ones, while other codes are simply no longer valid. Similar configuration integrity challenges exist for many dictionaries and configuration artifacts used by EHR systems, but mechanisms to effectively detect and manage dependencies are not always available. At Partners, we are using a commercially available knowledge management system (KMS)[1] to represent and manage high priority configuration dependencies. Our focus is on configuration items typically associated with clinical decision support rules, and our goal is to use the KMS to identify and remediate broken dependencies proactively.

Methods
The KMS used at Partners allows the representation of any data or knowledge structure using configurable semantic models. A few dictionaries from our EHR system are represented in the KMS. For each dictionary, only high utility fields are considered. Each EHR dictionary becomes a semantic entity in the KMS, and each field is translated into either an attribute (e.g. numbers, dates, strings) or a relation (e.g. semantic-enabled links). Once created, relations provide the optimal mechanism to represent and track structural and semantic dependencies. Each dictionary record from the EHR becomes a valid instance of the corresponding semantic model in the KMS. The KMS includes robust mechanisms for versioning instances, and also enforces the integrity of each dependency (link) using a well-defined lifecycle. Lifecycle validation considers the state of each entity instance, with more restrictive rules as instances move from work-in-progress state to in-active-use state.

Results
We have implemented semantic models for two EHR dictionaries. The first dictionary represents diagnoses, and its model includes 33 EHR-specific properties (e.g. attributes and relations). The second dictionary represents value sets, and its model includes 45 properties. We are importing dictionary records extracted from the EHR, resulting in over 2 million diagnosis instances (multiple revisions), and over 3,500 value set instances. Many value set instances include links to diagnosis instances, enabling our team to track and manage dependencies as these dictionaries are updated and used within the EHR. Modeling each dictionary required 40-60 hours of an experienced informatician.

Conclusion
Effectively managing large number of dependencies (links) is an important challenge that requires well-defined processes and advanced tools. We are addressing this problem using a sophisticated KMS and expect to proactively identify and remediate broken configuration dependencies within our EHR, ideally before resulting in system malfunctions.[2] The KMS allows us to manage structural dependencies and also enables the use of semantic expressions to validate the meaning of the links. Efforts to manage link integrity within linked data initiatives offer promising methods that we plan to evaluate and compare against our current approach.

Automated Extraction of Pediatric Obese and Allergic Related
Asthma Phenotypes from the Electronic Health Record

Mindy K. Ross, MD¹, Javier Sanz¹, Douglas Bell MD PhD¹
¹University of California Los Angeles, Los Angeles, Ca USA

Introduction

Asthma is one of the most common chronic childhood illnesses, affecting over 6 million children in the United States. One challenge with asthma is its variability in underlying inflammation and treatment response. In order to understand this variation, different categories of asthma patients have been described that reflect underlying pathophysiology (i.e. allergic-asthma and obese-asthma).

These specific asthma phenotypes have been identified with data from protocolled clinical trials; however, they have not been extracted from the electronic health record (EHR) in an automated fashion. While some literature has reported on methods to identify asthma cases from the EHR, there are no widely used computable phenotype algorithms for general asthma, let alone specific categories of asthma. We feel that it is important to automatically extract patient cohorts from the EHR for applications such as clinical decision support and identifying patient cohorts for research.

Typically, reliance on ICD codes alone is not sufficient to accurately extract disease cases. We are in the early phase of the development of algorithms to extract pediatric asthma patients who meet strict criteria for allergic-not-obese (A⁺/O⁻), obese-not-allergic (A⁻/O⁺), allergic-and-obese (A⁺/O⁺), and neither-obese-nor-allergic (A⁻/O⁻). The aim is to define four separate groups for future application to decision support and predictive analytics.

Methods

For this IRB-approved study, our EHR (Epic Systems) Clarity data warehouse was queried from March 1, 2013 to present. There are approximately 66,000 adults and children with the diagnosis of asthma documented in their record. Algorithm rules were based on criteria described from previous studies of identifying cases of asthma, obesity, and allergic-related conditions. ¹,² Asthma: Our definition for an asthma patient included a) ICD-9 or ICD-10 codes of 493.*, J45* and b) ≥4 prescriptions for short-acting β-agonist rescue inhalers or ≥1 controller medication AND ≥1 short-acting β-agonist rescue inhaler based on the high-specificity algorithm by Paecheco, et al. The exclusion criteria were ICD-9 or ICD-10 diagnoses of any diagnoses that could lead to an inaccurate diagnosis of asthma or have pulmonary involvement as a complication of the underlying condition such as: chronic lung disease, pulmonary fibrosis, neuromuscular, cardiovascular, transplant, immunodeficiency, oncologic, metabolic, autoimmune disease, etc. Obesity: Based upon the PheKB algorithm for childhood obesity, we defined obese as a body mass index (BMI) >95 percentile. Allergy: We evaluated diagnosis based upon ICD-9 or ICD-10 codes (i.e. allergic rhinitis), laboratories (i.e. specific allergen IgE), and medications (i.e. ≥1 prescription over time of any combination of allergy medication).

Results

The number of pediatric patients with an ICD code of asthma was 7,746. After exclusion criteria were applied, 6,450 patients remained. When asthma medication was included, there were 3,606 patients that were labeled as asthma. We next evaluated allergic asthma patients based off of this cohort. Using allergy-related ICD codes, there were 1,924 patients identified. After allergy labs and medication criteria, 364 patients qualified as allergic-asthmatic. In regard to obese patients, we are currently working to develop a method to extract the pediatric body mass percentile from the data warehouse in an accurate manner, as it is not directly calculated in a manner similar to the BMI and is not stored in easily accessible locations. Limited sampling of our data appears to be accurate, but once we complete the identification of the obese-related cohorts, our next step is to more extensively manually review each category of phenotype for sensitivity (recall) and positive predictive value (precision) of the definition algorithm.

Discussion/Conclusion

Accurate identification of complex medical conditions from the EHR can be achieved with cautious definition of inclusion criteria. This is the groundwork to cohort identification for applications such as clinical decision support. In addition, this will be valuable for clinical trial cohort identification and application toward precision medicine.

Can Automated Retrieval of Data from Emergency Department Physician Notes Enhance Radiology Order Entry Process?

Justin F. Rousseau, MD, MMSc1,2, Ivan K. Ip, MD, MPH1, Ali S. Raja, MD, MBA, MPH1, Vladimir I. Valtchinov, PhD1, Jeremiah D. Schuur, MD, MHS1, Ramin Khorasani, MD, MPH1

1Brigham and Women’s Hospital, Harvard Medical School, Boston, MA; 2Dell Medical School at The University of Texas at Austin, Austin, TX

Abstract

Physician notes completed prior to image ordering were reviewed from 666 Emergency Department (ED) encounters with a chief complaint of headache and a completed head CT during the visit. We compared natural language processing-extracted concepts relevant to headaches from notes to image order requisitions. History of present illness was signed in 23% of encounters prior to image ordering. Significantly more concepts relevant to headache were extracted from notes than orders (median 3 vs. 1; p<0.0001).

Introduction

Clinicians are often required to enter redundant data in the electronic health record (EHR). For instance, in most commercial EHR implementations, clinical information is required both in the history of present illness (e.g., symptoms) in notes and in imaging order requisitions, often in structured form for quality and billing purposes, in the same EHR. Even when requisition forms are customized by imaging study, workflow limitations often lead clinicians to select the minimum number of indications required to order the imaging study. When a paucity of clinical information is communicated from ordering physicians to radiologists at the time of order entry, suboptimal imaging interpretations and patient care may result. We sought to evaluate clinical data documented in EHR notes prior to image ordering for ED patients presenting with headache. We hypothesized that data are present in the notes that could potentially be used to augment or prepopulate codified indications provided in the image order requisition.

Methods

In this Institutional Review Board-approved, retrospective observational study performed between 4/1/2013 and 9/30/2014 at an adult quaternary academic hospital, we evaluated data documented in EHR notes prior to image ordering for Emergency Department (ED) patients presenting with headache. We reviewed data from 666 consecutive ED encounters for patients with chief complaint of headaches with head CT performed during the visit. We compared the count of relevant Concept Unique Identifiers (CUIs) specific to headache in the ED notes, extracted via ontology-based natural language processing, to the count of indications in imaging order requisitions. We evaluated the percentage of head CTs graded by physician graders as appropriate based on extracted concepts compared to requisition indications.

Results

The history of present illness note section was completed prior to image order entry in 23% (154/666) of encounters. The number of CUIs specific to headache per note (median=3) was significantly greater than the number of indications per encounter identified in the imaging order requisition (median=1, the minimum required; Wilcoxon signed rank p<0.0001). Extracted concepts were unique from order requisition indications in 93% of cases. Extracted concepts added value in 23% of encounters when available by providing information to support the grading of the head CT as appropriate when the indications alone were not enough to grade the head CT as appropriate.

Conclusion

We identified unique, relevant clinical information present in unstructured physician notes in the EHR that were completed at the time of image ordering, with a significantly greater number of CUIs specific to headache extracted from these notes than the number of indications per encounter identified in the image order requisition. EHR clinical documentation provides a source of valuable information that, when available, could be used in a semi-automated fashion to augment communication between ordering physicians and radiologists. Future work is needed to evaluate whether automated retrieval of data from physician notes can inform clinical decision support and prepopulate imaging order requisitions to optimize efficient communication of clinically useful information in the ordering process.
Physician negation of nursing concepts in the electronic health record

Khawllah Roussi¹, Karen Dunn Lopez¹, Barbara Di Eugenio¹, Andrew D. Boyd¹
¹University of Illinois at Chicago, Chicago, IL;

Introduction

Electronic health records provide a shared understanding among health professions. Recently, nursing data has been shown to predict hospital readmissions.¹ Prior work has focused on the lack of common vocabulary between physicians and nurses (physicians only used 21% of nursing concepts).² Negation of a term means denying the existence of the concept and is patient dependent, (i.e. patient denies chest pain). In our prior study² negation was included in the use of concepts, but what the professional is trying to express are contrasting ideas. The study objective was to determine the frequency of term negation related to professions’ utilization of each others concepts.

Methods

Seven years of physician discharge summaries were processed by MedLEE (a medical information extraction program) to generate 53,423 physician² concepts: Unified Medical Language System (UMLS) concept unique identifiers (CUIs) and negation frequency. The discharge summaries were both free text and smart form summaries. A list of negated terms were generated and were then compared to the list of 1,011 NANDA (Nursing Diagnoses), NIC (Nursing Interventions Classification) and NOC (Nursing Outcomes Classification) terms which were gathered from the Hands-On Automated Nursing Data System (HANDS).³ For the overlapping terms (terms having identical CUI numbers), a comparison study of frequency of physician use and negation was performed.

Results

We discovered 19,737 physician concepts were negated at least once occurring 2,694,421 times. Out of the negated physician concepts, a total of 122 nursing terms were negated out of the 222 nursing terms physicians use. Of the 122 negated physician terms, 30 of the terms were also nursing concepts that were negated more than 10 times a year. The 33% of the most commonly negated nursing terms yielded an average frequency negation of 19.5%.

In 122 negated physician usage of nursing terms (55%), 62 NIC terms, 33 NOC terms, and 33 of the NANDA-I were included. The most frequently negated terms were Swallowing Problem, Bowel Incontinence, Neurological Status at 91.6%, 71.4% and 62.7% (respectively).

Discussion

Of the clinical concepts common to physicians and nurses, 55% of the terms were negated at least once. Of the entire list of physician terms, only 36.9% were ever negated. As reported before, very few nursing terms are used in physician language. The negation of Swallowing problems is likely due to review of systems, but is an important finding for both. The challenge of over half of nursing terms negated in physician utilization raises questions about meaning.² This highlights the little use of nursing data in physician language and how the utilization between the professions of the same concepts can differ, subsequently underscoring language differences between nurses and physicians.

Conclusion

The findings demonstrate even common terms between physician and nurses are used differently between the professions. When reading reports focused on concept it is easy to miss “not”, in standardized tests questions will capitalize NOT to ensure the correct meaning is portrayed. In collaboration, focusing on the context and how the concepts are written is just as important as the concept. A challenge is some nursing documentation practices does not allow negation of the concepts, creating a potential irreconcilable documentation difference between the professions.

Oncology Precision Network

Kerry Rowe, PhD, Lincoln Nadauld, MD
Intermountain Healthcare, Salt Lake City, Utah

Abstract
Cancer care is entering a new era of personalized treatment based on molecular profiles. Gathering evidence on molecularly-defined cohorts can inform treatment decisions for precision medicines. A multi-institutional genomics data consortium has been established to pool real-world data that provides large-scale, statistically powerful treatment insights. Clinical, molecular, treatment and outcome data is shared using methods that standardize and normalize data for comparisons across multiple health systems.

Description
Combining real-world evidence on molecularly-defined cohorts can inform treatment decisions for precision medicines. The use of molecular data to stratify populations leads to small sample sizes, limiting our ability to improve care. It is critical to pool real-world data across multiple institutions to draw large-scale, statistically powerful treatment insights.

A consortium led by founding members Stanford University, Intermountain Healthcare and Providence Health Systems has created a data-sharing network called the Oncology Precision Network (OPeN). OPeN combines data from electronic medical record systems, data warehouses, registries and other clinical systems at each institution. Using standard vocabularies such as RXNorm and LOINC, data is aggregated and linked with molecular profiles for patient. Using the services of the genomics software company, Syapse, a secure and trusted network is created where clinicians can review large sample sizes of patients grouped by cancer type and molecular profiles. Data is de-identified and stored in database hosted by Syapse. It is currently used for research but goal is to provide resource to assist in treatment decisions. A sample view of the data is shown here:

Work at Intermountain has focused on gathering data from all clinical sources where data exists for oncology patients. A number of queries and procedures have been created to extract data from our data warehouse and electronic medical record system. The clinical data is inserted into CDA documents that are securely transmitted to Syapse where it is combined with tumor sequencing data. This enables our data to be integrated with similar data from other institutions and removes the barriers associated with the use of different electronic medical record systems.
Development of an Automated Annual Cumulative Susceptibility Reporting Process

W. Cliff Rutter, PharmD, MS\(^1\), David S. Burgess, PharmD\(^1\)
University of Kentucky College of Pharmacy, Lexington, KY

**Background:**
The Clinical Laboratory Standards Institute (CLSI) recommends the use of cumulative susceptibility reports\(^1\), or antibiograms, to track the incidence of antimicrobial resistance. In addition to surveillance of resistance, clinicians consult the antibiogram to inform empiric antimicrobial therapy selection. Typically, antibiograms are developed manually by the clinical microbiology laboratory and require a significant time and personnel commitment. The purpose of this study was to develop a quick and reliable process to generate institutional antibiograms automatically.

**Methods:**
Antimicrobial susceptibility testing data from 1/1/2014 through 12/31/14 were obtained from the clinical microbiology laboratory for antibiogram creation. An algorithm was created to handle susceptibility data using open-source programs (RStudio v0.98 and R v3.1.2)\(^2,3\). Original raw data contain observations for multiple facilities, surveillance cultures, and multiple observations for individual isolates. Data were initially cleaned by selecting the locations of interest, eliminating surveillance cultures (i.e., axilla, groin, nares/perirectal swabs), and eliminating exact duplicate observations. Data were then transposed from narrow format into wide format with only one row for each observation. This “semi-clean” data still contains multiple observations per isolate, duplicate isolates, and many missing values generated by the transposition process. The final clean dataset is generated by combining multiple observations into one primary observation. This is accomplished by combining testing methods (Etest\(^\circledR\) and MIC), selecting the first isolate of the year, and removing duplicated isolates by selecting the more resistant biotype. CLSI breakpoints are applied to the current data and percent susceptible is calculated for each drug and organism to generate the antibiogram, which may undergo post-processing for optimal visual interpretation of antibiogram results. Between-method susceptibility results were compared with a chi-squared or Fisher’s exact test, as appropriate.

**Results:**
Antibiogram generation was significantly faster after development of the algorithm. Prior to algorithm development, the antibiogram was developed manually using Microsoft Excel\(^\circledR\) taking approximately 1 month of active work. The algorithm produces a completed antibiogram with CLSI interpretations of the MIC data in less than 60 minutes from raw data. The automated process produced similar results to the manually generated antibiogram with the same number of isolates. Results for non-beta-lactam antibiotics were nearly identical. The automated process produced higher percent susceptible for beta-lactams compared to the manually generated antibiogram, for example, *Klebsiella pneumoniae* was significantly less resistant to cefepime in the automatically generated antibiogram (98% vs. 92%, \(p=0.009\)). This suggests a practitioner bias towards beta-lactam resistant isolates instead of overall resistance profile.

**Conclusion:**
Antibiogram development can be significantly streamlined though the use of open-source data science technology. Automated antibiogram-generation functionality significantly reduces the time and resource commitment of previous antibiogram creation methods. This allows for more advanced analyses of the data available. Additionally, the automated process may be less susceptible to clinician bias in the isolate selection process.

MyHealthKeeper: Clinical Trial of Personal Health Record-Based Healthcare Management

Borim Ryu1,2, Nari Kim1, Eun-Young Heo1, Sooyoung Yoo1, Se Young Jung1, Yoojung Kim2, Joongsik Lee2, and Jeong-Whun Kim1

1Seoul National University Bundang Hospital, Seongnam-si, Gyeonggi-do, KOREA; 2Seoul National University, Seoul, KOREA

Abstract

Personal health record (PHR)-based care management systems can be expected to improve patient engagement and data-driven medical diagnosis in clinical settings. In this study, we conducted a clinical trial in patients with lifestyle-related diseases involving the collection of data on physical activity and diet using wearable devices and the delivery of care interventions over 4 weeks. The results of our study showed how patients and clinicians apply personal health data and mobile applications. We have successfully demonstrated a practical approach to implementing and monitoring a mobile-based health intervention for self-management in clinical settings.

Introduction

Widespread interest in using PHRs has been reported and their uptake has been increasing. Interactive self-management technology is reported to be suitable and useful in a variety of chronic health conditions. The use of PHR applications in improving health care is promising, but integration into routine clinical care and population health management has proven challenging. The purpose of this study was to demonstrate the design of a clinical trial to assess the effectiveness of a PHR-based mobile health application given the name MyHealthKeeper, which can help patients with obesity to manage their individual daily routine and improve lifestyle behaviors.

Methods and Results

We utilized an activity tracker (Misfit) to collect individual physical activity data and developed a smartphone application to record every meal and daily logs. We also monitored data collection in a web-based administration environment. For the trial, 80 persons were randomly assigned to a PHR feedback care group (intervention group, n=51) or a usual-care group (control group, n=29). All participants underwent a paper-based survey, laboratory test, physical examination, and interview on their opinions. Clinical workflow observations were also processed to monitor and evaluate the study design. During the 4-week intervention period, we collected health-related mobile data, and the PHR feedback group visited the clinic twice and received PHR-based clinical diagnoses and recommendations using their EMR. The mobile application developed for self-reporting was successful in collecting personalized daily health data. Additionally, clinicians were able to promote physical activity to their patients. A total of 68 participants (44 in the intervention group and 24 controls) completed the study. In the results, the PHR intervention group showed significant weight loss compared to control group participants (average –1.4 kg, 95% CI 0.9–1.9, p<.001) in the final week (week 4). In addition, other factors such as BMI (average –0.4 kg/m^2, 95% CI 0.3–0.6, p<.001) and TG (average –46.7 mg/dL, 95% CI 17.6–75.8, p<.05) also changed during the study period.

Conclusion

We have developed an innovative testing approach to integrate PHR data into the clinical workflow in order to support lifestyle interventions. The results of this study suggest that PHR-based intervention is successful in preventing weight gain with modest weight loss and improvement in lifestyle behaviors.

Innovative Method for Measuring Nursing Workload

Virginia K. Saba, EdD, RN, FACMI, FAAN\(^1\); Luann Whittenburg, PhD, RN, FNP, FHIMSS, PMP, FAAN\(^2\)

\(^1\)President and CEO, SabaCare, Inc. Arlington, VA; \(^2\)JP Systems, Alexandria, VA

**Keywords:** Clinical Informatics, Implementation, Care Plan, Clinical Care Classification, CCC, Nursing Workload, RVU

1. **Overview**
An innovative method for measuring nursing workload was developed by integrating a patient’s individualized plan of care (POC) in an electronic clinical system implemented with a standardized nursing terminology: the Clinical Care Classification (CCC) System, and CCC Information Model. The methodology uses POC nursing concepts with predetermined, valid Relative Value Units (RVUs) and CCC Base Value to determine workload.

2. **Methodology**
The CCC Terminology concepts provide the structure for the documentation of a coded patient POC following the six steps of the CCC Information Model. Once the POC has been implemented and tracked for a specific inpatient episode of illness, the four CCC Nurse Intervention Action Type Qualifiers in the POC’s for a given clinical/nursing condition are summarized and used to calculate nurse care with predetermined RVUs and which determine nursing workload (time). The CCC Information Model’s structure (six steps) is followed to track the patient’s POC; the four CCC Action Type Qualifiers (Monitor, Perform, Teach, or Manage). These are used to clarify and expand the focus of the CCC Nursing Interventions (core) and summarized; and their predetermined RVUs used to determine the nursing workload for the patient’s POC. The workload measurement is calculated using the time span of each Nursing Service Encounter Action and RVUs developed by RVS Inc.

3. **Example:** A CCC System Core Nursing Intervention Terminology Concept has been selected, such as CCC ‘Pulmonary Care’ to implement and track provider or nurse orders for inpatient care via the POC which is used to document the nursing care provided. The nurse during the patient’s hospitalization: a) ‘Monitors Pulmonary Care’ during evenings and nights, b) ‘Performs Pulmonary Care’ during the day shift, c) ‘Teaches Pulmonary Care’ to the patient and family, and d) ‘Manages Pulmonary Care’ by calling for new orders. In each nursing situation the Nursing Intervention Action Type Qualifier is documented and coded and on discharge aggregated.

This advanced analytic method was developed to integrate a standardized nursing terminology, the CCC System, into a patient’s clinical information system POC to provide reliable data on nursing workload based on predetermined RVUs, which reflect the value of nursing time (Table 1). This study extends a 2013 workload measurement study by coupling a Base Value of a disease condition with valid RVUs to determine the intensity of care required for the patient’s medical condition. The ability to accurately measure workload provides a care workload algorithm for use in determining future nursing workload predictions for the care of Pneumonia.

4. **Evaluation Results**
This innovative method of contextual workload analytics supports the design of a clinical information system for a nursing POC benefiting patient care coordination. The coding of nursing data advances the calculations of nursing workload (time). This method can correlate the Nursing Intervention Actions with the patient’s Nursing Diagnoses, and when combined with Nursing Interventions provide a protocol for the ‘Pulmonary Care’ POC.

5. **Conclusions**
This method integrates the CCC System’s standardized nursing terminology and CCC Information Model to demonstrate that a POC does provide reliable nurse workload calculations based on pre-determined valid RVUs, which reflect the workload value of nursing.
Remote Usability Testing Method for an EHR Platform

Inkeri Saiku, MSc1, Yalini Senathirajah, PhD2, Elizabeth M. Borycki, RN, PhD3, Andre W. Kushniruk, PhD3, Upasana Malik, MSc4, Jinglu Wang, MSc1
1Weill Cornell Medicine, New York, NY; 2Hofstra University, Long Island, NY; 3School of Health Information Science, University of Victoria, Victoria, Canada; 4SUNY Downstate Medical Center, Brooklyn, NY

Introduction
Scheduling suitable testing times with busy users is always a hurdle with any kind of usability testing, but when conducting a usability test for a clinical system with the participants being medical residents, being able to offer flexible test times and locations becomes imperative in order to recruit a fulsome sample of study participants. Remote usability testing can be a solution. In addition to being flexible in terms of testing times, remote usability testing can also allow for recruiting of participants from a larger geographic area. For these reasons a remote usability testing method was constructed for the needs of usability testing of a novel EHR platform, MedWISER. In this poster we describe our approach.

Method
To gain user insights and to test the usability of a novel EHR platform, MedWISER, remote usability testing in conjunction with think-aloud was employed. The prototype being tested can be accessed online and therefore it is especially suitable for remote testing. For a think-aloud usability test to be conducted remotely, both users’ actions on the screen as well as the audio of their thinking aloud needs to be recorded. Eight software applications for screen and audio recording were tested: Go-to meeting, TeamViewer, Validately, Loop11, TryMyUI, Morae, Inspectlet and Join.me. Criteria for selection were: 1) Ease of use for the participants. For example, downloading and installing the needed software should be as easy possible for the participants. In addition, participants might not have admin rights on the computer they are using, therefore downloading the software should not require admin rights. 2) Quality of audio and video recording. 3) Availability for different operating systems. Of the tested software, TeamViewer was selected.

The TeamViewer software was used as follows for the usability tests: the participant is asked to download the TeamViewer software before the scheduled test session. At the time of the test session and before establishing the TeamViewer connection, the moderator calls the participant by phone and asks the participant to remove all identifying or sensitive information anywhere on the participant’s screen e.g. participants name or patient data. Before connecting the moderator confirms in the call with the participant that there is no identifying or sensitive information anywhere on the participant’s screen e.g. participants name or patient data. To achieve this, the participant is asked to open a new (incognito) browser window and close all messaging programs, such as iMessage or What’sUp, that might bring up private messages on the screen during the recording. After the TeamViewer connection is established, the phone call is ended and verbal communication between participant and moderator continues via TeamViewer so that the audio is recorded along with the screen recording. Through the TeamViewer text chat option, the participant first receives links to demo videos of the think-aloud method and of the features of the EHR prototype followed by a link to the prototype. Within the MedWISE interface the participant is given tasks to solve clinical cases while thinking aloud. In a one hour session, the participant goes through 2-3 patient cases. After reviewing the cases the participant is asked to rate the ease of use and usefulness of the system, as well as comparing it to the systems they are currently using.

Results and Conclusion
The described method was considered successful for conducting remote think-aloud usability testing. The quality of screen capture and audio were suitable for recording and analyzing the use of the system being tested. Options for participating in the test either in the project premises or at participant’s own offices were also offered, but most participants (70%) chose the online method. Reasons participants mentioned for preferring the remote test were more flexible test hours and the convenience of participating from home. Ten test sessions have already been carried out and we will continue conducting more usability tests with this method.

Anticoagulation Safety Risk Assessment: Evaluating compliance with an anticoagulation protocol through secondary use of EHR data

Hojjat Salmasian, MD, MPH, PhD, Eric Venker, PharmD, MD, Emilia Hermann, MD, MPH, Iheanacho Obinnaya Emeruwa, MD, MBA, Daniel Farrell, MD, Jason Adelman, MD, MS

1The Value Institute, NewYork-Presbyterian Hospital, New York, NY; 2Columbia University, New York, NY

Introduction

The American Medical Informatics Association (AMIA) and the Office of the National Coordinator (ONC) are proponents of “secondary use of EHR data”, where electronic healthcare data are aggregated for purposes other than direct patient care. One important secondary use of EHR data is to support quality improvement and risk assessment initiatives. We aimed to use EHR data to evaluate compliance with the hospital protocol for intravenous heparin, an anticoagulant used to treat serious cardiovascular diseases such as atrial fibrillation, deep vein thrombosis and acute coronary syndrome. Intravenous heparin is considered a high-alert medication, as both under-treatment and over-treatment can lead to serious adverse outcomes; its dosing is adjusted based on the aPTT lab levels.

Methods

In this cross-sectional study, we analyzed all heparin orders placed in a one year period at two major hospitals in New York City. We excluded orders for ‘prophylactic’ use of heparin, or those for patients younger than 18 years of age, as the indications and dosing recommendations differ in these populations. In addition, we restricted the data to orders placed to treat deep venous thrombosis (DVT), pulmonary embolism (PE), Atrial Fibrillation (AFib), or Acute Coronary Syndrome (ACS). Our guidelines are based on best available evidence, and recommend a target value of 76 to 112 for aPTT in patients with these indications. Our guidelines recommend initiating heparin with a bolus dose of 2,000 to 10,000 units, followed by an infusion drip at the rate of 400 to 2,500 units/hr (based on weight and indication).

Results

Of 28,838 heparin orders included in the analysis, 14,224 were placed to treat DVT/PE, 10,012 to treat AFib, and 4,602 to treat ACS. Together, these orders were placed for 2,275 unique patients and in 2,450 unique admissions. An initial bolus dose was used only in 7.5%, 16.8% and 22.6% of patients with AFib, DVT/PE, and ACS, respectively. The first heparin drip order was also mostly at a lower than recommended dose (mean log expected-to-observed dose = -0.29, SD = 0.70). Overall, 55% of patients achieved target aPTT within 24 hours of heparin initiation. Target aPTT was more likely to be achieved whenever heparin therapy started with a bolus dose (p=0.039) and when the heparin drip was ordered at the recommended dose (OR = 1.18, p=0.013).

Conclusion

Secondary use of EHR data can play a significant role in designing quality improvement (QI) initiatives that are informed by the common practice behavior and target the most salient issues. Our analysis allowed us to identify two potential causes for suboptimal anticoagulation therapy at this institution: providers underused bolus heparin orders, and the initial infusion rate was often a lower rate than what is recommended for the patient’s weight and indication. These issues can be mitigated through the use of clinical decision support, whereby the guidelines would be incorporated into the order set and appropriate drip dose would be recommended at the point of care.

Detecting Adverse Drug Event Safety Signals from MEDLINE Reports: Challenges in Employing Cross-terminology Mapping of MeSH to MedDRA

Abhivyakti Sawarkar, MD, MMSc; Alfred Sorbello, DO, MPH; Anna Ripple, MLS; Olivier Bodenreider MD, PhD

1US Food and Drug Administration, Center for Drug Evaluation and Research, Silver Spring, MD, USA; 2Lister Hill National Center for Biomedical Communications, U.S. National Library of Medicine, Bethesda, MD, USA

Background: The Center for Drug Evaluation and Research/Office of Translational Sciences Data Mining Team at the US Food and Drug Administration (FDA) has recently developed a web-based prototype analytical software tool to automate detection of adverse drug event (ADE) safety signals from MEDLINE reports through quantitative data mining of Medical Subject Heading (MeSH) indexing terms. The prototype tool greatly enhances the FDA’s capacity to integrate outputs from MEDLINE with other data mining streams, such as the FDA Adverse Event Reporting System (FAERS), to support multimodal pharmacovigilance. The tool incorporates a system in which MeSH terms are leveraged to extract ADE associations from MEDLINE citations, and the ADE content of a MEDLINE report is conveyed through a single MeSH descriptor. A key element to facilitating interoperability of the data mining outputs from MEDLINE and FAERS is to standardize the representation of ADE content using the Medical Dictionary for Regulatory Activities (MedDRA). In this study, we assess the feasibility of rendering MeSH descriptors for ADEs to MedDRA leveraging the Unified Medical Language System (UMLS) to map MeSH descriptors to equivalent or finer-grained MedDRA preferred terms (PT).

Methods: We manually reviewed the cross-terminology mapping by assessing the completeness and quality of the one-to-one and one-to-many MeSH descriptor-to-MedDRA PT relationships in the context of an arbitrarily selected use case, ciprofloxacin. More specifically, we assessed how well the MedDRA PTs represented the clinical ADE content expressed by the MeSH descriptors in the source MEDLINE citations.

Results: We identified 219 unique drug-AE associations for ciprofloxacin in which the ADE content of the MEDLINE citations was conveyed by unique MeSH descriptors. There were 84 one-to-one MeSH-to-MedDRA PT mappings and 135 one-to-many MeSH-to-MedDRA PT mappings. Manual assessment of the one-to-one mappings confirmed that the linked terms conveyed similar meaning in translating the clinical ADE content of the source citations between the two terminologies. However, the one-to-many mappings included some MeSH descriptors mapped to a multitude of MedDRA PTs (e.g., ‘musculoskeletal diseases’ mapped to 276 unique MedDRA PTs) that required manual review to select the PT that most reasonably translated the clinical content between the terminologies. Overall, the major categories of cross-terminology challenges involved MEDLINE citations annotated with (1) general MeSH headings (e.g., ‘heart diseases’) that appeared broad and less distinct compared to the granular mapped MedDRA PTs and that may conflate multiple related major topics, and (2) pre-coordinated descriptors (e.g., ‘Drug Hypersensitivity Syndrome’) that are conceptually broad in scope and subsume distinct clinically important conditions (e.g., drug reaction with eosinophilia and systemic symptoms (DRESS syndrome)).

Conclusions: This study illustrates some of the challenges in cross-terminology mapping from MeSH to MedDRA and illustrates the limitations inherent in leveraging single MeSH descriptors to convey highly specific ADE content. While one-to-one MeSH descriptors mapped to single MedDRA PTs provide the best links to translate clinical ADE content between the terminologies, the accuracy of translating clinical content between MeSH and MedDRA in one-to-many mappings may be severely impacted by the granularity mismatch between MeSH and MedDRA. Future work will explore text mining of abstracts and full text citations with machine learning to resolve the translation of ADE content between MeSH and MedDRA and thereby support automation.

Development of a Conceptual Model for Clinical Deployment of e-Patient-Reported Outcomes

Courtney Segal, BA¹, Cynthia LeRouge, PhD¹, Elizabeth Kellogg, MPH¹, Elizabeth Austin, MPH¹, Danielle Lavallee, PharmD, PhD,¹
¹University of Washington School, Seattle, WA, USA

Introduction

Patient-reported outcomes (PRO) provide insight on patients’ experience and perspectives regarding treatment and outcomes. The growing availability of electronic PRO (ePRO) in clinical settings has the potential to improve the efficiency of data collection and analysis and to provide new opportunities to bring meaningful evidence to decision makers and patients in innovative ways. Despite the increasing pressure for using PRO measures (due to shifts towards patient-centered healthcare and payment reform initiatives), comprehensive models of clinical use do not exist. Literature reviews of PRO systems do not focus on the development and clinical use of e-PROs. The purpose of this research is to develop a conceptual framework that reflects a socio-technical systems perspective of ePROs in clinical use. The TURF (Task, User, Representation, and Function) EHR Usability Framework provides a system-level view that reflects both the social and technical aspects of an EHR system.¹ We use the TURF framework to systematically explore the constructs of clinical use of PRO systems.

Methods

The search parameters in EBSCO Host and PubMed were ((patient reported outcomes)) AND (implementation OR workflow OR usability OR adoption) NOT ((clinical trial)) among articles in English and academic journals published over the last five years, resulting in 268 articles. Investigators reviewed the 268 abstracts for inclusion and exclusion criteria (n=121). An additional 23 articles were excluded after reviewing the full text, resulting in 98 articles that were included for the detailed review. The TURF model served as a high-level coding schema that guided open coding within each TURF construct using Dedoose software. Resulting detail codes and supporting article text was reviewed by a team of appropriate experts (e.g., visualization and human-centered design experts for codes under Representations) at regular junctures to further refine the coding schema, validate propriety of the codes assigned to text, and, in the final stages, to identify cross-cutting themes.

Results

The literature review identified several emerging themes and common challenges for deploying ePROs in the clinical setting (summarized into design principles). FUNCTION - a PRO system can function to advance efficient care, care coordination, decision support, patient engagement, quality assurance and population health, . Patient-facing functions should support self-management of diseases and symptom tracking, and interactive functions (e.g., annotation of symptom charts). TASK - the length of the PRO measures selected should be optimized to reduce patient burden and improve data completeness; automated tasks support clinician workflow and improve data access and analysis; PRO/EMR integration is conducive to care coordination for patients and clinician/ staff communication and. REPRESENTATION – ePRO design should consider the use of color, reporting of MCID scores, raw scores versus incremental changes, and personalization of content.. USERS – PRO system design should consider non-English speaking, medically frail, and aged patients. Active motivation efforts (e.g., champion, case review, system-wide adoption, identified clinical value, peer support) are needed to promote clinician adoption.

Conclusion

We provide the first literature review of ePROs in clinical use and a resulting contextualized framework that reveals current approaches to ePRO design and practice and challenges to successful use. This framework can be used by developers, practices, and researchers to design and deploy PRO systems in clinical settings. We also demonstrate that the TURF EHR Usability Framework can be applied to the PRO context. The information gleaned from this effort will be synthesized with a larger ongoing project involving direct data collection resulting in ePRO design guidelines that reflect a systems, visualization, and workflow perspective.

Abstract: Clinical decision support (CDS) systems can provide clinicians with knowledge and patient-specific information to help guide their decision making. Balancing CDS with the risk for overexposure (e.g., alert fatigue) is needed. The objective of this study was to characterize and compare CDS override rates and appropriateness of these overrides in the inpatient and outpatient setting within our healthcare system.

Introduction: Medication-related clinical decision support (CDS) systems are a valuable tool for improving safety and quality of care by preventing medication errors. However, despite extensively modifying the CDS in our legacy electronic health record to improve user acceptance, we continue to observe a high level of overrides for many medication alert domains. In this study, we evaluated the overrides for drug-allergy interactions (DAI), drug-drug interactions (DDIs), duplicate therapy, geriatric, and renal medication substitution alerts in the inpatient and outpatient settings to determine if the overrides were appropriate or not.

Methods: Our primary outcome measure was whether a CDS medication alert was overridden appropriately. Data on these overrides were obtained over a period of four years (Jan 2009 to Dec 2012) for inpatients at Brigham and Women’s Hospital and outpatients within Partners HealthCare. The alert override reasons were collected and a sampling of each alert type override was evaluated for appropriateness by a trained multidisciplinary group.

Results: The most common reason given for overriding the DAI alerts in both settings was “patient had taken the drug previously without allergic reaction.” The most common reason for DDI overrides in both settings was “will monitor as recommended.” A chi-square test was used to compare inpatient vs. outpatient override appropriateness for each alert category. Details of the override rate and the appropriateness rate of the overrides for the inpatient and outpatient settings are detailed in Table 1.

<table>

<td>Duplicate</td>
</tr>
<tr>
<td>Renal</td>
</tr>
<tr>
<td>Geriatric</td>
</tr>
</tbody>
</table>

Appro = appropriate; Inpt = inpatient setting; Outpt = outpatient setting; OR = override; UTO = unable to obtain

Conclusion: The rate of medication-related CDS overrides continues to be high in both settings. DAI and duplicate therapy alerts were often appropriately overridden and should be refined to reduce the number of displayed alerts, in turn minimizing the risk for alert fatigue. Future research should focus on 1) the improvement of the clinical relevance of alerts to increase acceptance of DDI, geriatric, and renal alerts and thereby reduce inappropriate overrides and 2) seeing if adverse drug events are caused by these overrides in both settings.

This study was funded by grant #U19HS021094 from the Agency for Healthcare Research and Quality (AHRQ).
DeepSuggest: Query Expansion for Clinical Notes by Deep Learning

Emre Sezgin, PhD, Koushik Jinna, MS, Tran Bourgeois, MPH, Soheil Moosavinasab, MS, Yungui Huang, PhD, Simon Lin, MD, MBA
The Research Institute at Nationwide Children’s Hospital, Columbus, OH

Introduction

Today, more than 70% of the health information are stored in unstructured clinical notes, and healthcare providers (HCP) increasingly rely on the text search systems. However, these clinical notes may have spelling variations, typos, personal acronyms, and informal words. Although EPIC’s new search feature aims to help HCPs finding information quickly, it has limited capability in recognizing acronyms or suggesting spelling variations. To fill this gap, we propose an alternative search system (DeepSuggest) expanding queries by suggesting spelling variations, acronyms and other semantically relevant words through an unsupervised deep learning algorithm.

Methods and Data Retrieval

Our training corpus consists of over 50 million clinical notes (~69GB) documenting encounters at Nationwide Children’s Hospital between 2006 and 2016. After removing words with less than 30 occurrences, we created a vocabulary having 6.3 million unique 1-3 grams, representing 5.5 billion total words.

Word2Vec is an unsupervised learning approach that uses neural networks and word embedding to map the words into a vector space. In this process, the Continuous Bag-of-Words (CBOW) algorithm of Word2Vec (2 iterations and 400 dimensions) was used to create a statistical model of 1-3 gram word similarity across the corpus using word proximity in the notes (2 days 9 hrs of runtime). The nearest neighbor model was utilized to find the closest and semantically relevant N-Grams from the trained model. The model created by Word2Vec is indexed by Annoy (a library for nearest neighbors) and retrieved quickly and efficiently (<1sec). The model can be trained incrementally with more notes over time and run in a distributed environment to accommodate larger corpora.

Results and Evaluation

As an example result, DeepSuggest was able to suggest “tonsillectomy” (correction of “tonsilectomy”), “t&a” and “t/a” (alternative synonym for “tonsillectomy and adenoidectomy” procedure) or “tonsillectomy” or “adenoidectomy” (narrower concepts). In another test, a query for “worried about” (e.g. to identify patient concerns) led suggesting semantically related words, “afraid” and “fear”, and morphologically similar words, “worry about” and “worrying about”.

We will use Preferred Names in SNOMED as queries (count in corpus > 50), and use their synonyms to evaluate recall rate of DeepSuggest. We will also invite domain experts to evaluate suggestions that do not exist in SNOMED to calculate precision and NDCG. To understand the effectiveness and usefulness of DeepSuggest, a usability test was designed. The pilot study helped to build the study protocol and questions. 10 residents at NCH will be invited to join usability study and to test DeepSuggest in comparison to Epic search. We hypothesized that DeepSuggest is more effective and useful in assisting for clinical decision making than Epic search in clinical queries.

Conclusion

In the proof of concept stage, DeepSuggest proved its functionality after its implementation using our corpus, suggesting spelling variations, acronyms and semantically relevant words. The system is promising for a higher recall rate in EHR searches, and thus, increasing productivity in health care delivery.

Mapping CT Codes from a Health Information Exchange to LOINC

Jason S. Shapiro, MD¹, Anton O. Beitia, MD¹, Tina Lowry MS¹, Daniel J. Vreeman, PT, DPT, MSc², Bradley N. Delman, MD¹, George Loo, DrPH¹, Frederick Thum III, MD¹
¹Icahn School of Medicine at Mount Sinai, New York, NY; ²Regenstrief Institute, Indiana University School of Medicine, Indianapolis, IN

Introduction
As a prerequisite to building an alerting system to notify providers at the point of order entry of prior CT exams performed anywhere across a health information exchange (HIE), we are mapping proprietary CT names and codes from the Healthix HIE in the New York metropolitan area to LOINC®. We present preliminary results of LOINC’s coverage of the most frequently performed diagnostic CT exams at 26 sites within the Healthix HIE.

Methods
Healthix currently has 41 sites that transmit radiology data. In order to expedite mapping for a pilot prior CT alerting system, and using a data set of CTs performed between January 2013 and October 2015, we elected to first map up to the 200 most frequently performed diagnostic CT exams from each site to LOINC. If a site had fewer than 200 diagnostic codes, we mapped all diagnostic codes from that site. The rationale was that these CTs (as opposed to procedural/interventional or less frequently used diagnostic CTs) were the most likely to be repeated. At the time of this study, we had completed mapping 26 of the 41 sites. Sites were prioritized for mapping based on convenience and data availability. Mapping was performed manually by one of the authors (AOB), a radiologist and informatician with domain expertise, with the assistance of LOINC’s desktop mapping program RELMA®, to match local exam descriptions with LOINC names. We calculated the total number of CT codes for all sites and the absolute number and percentage of codes (concept-type coverage) for which we had an initial LOINC match, and the number and percent of codes for which there was no initial LOINC match. We also counted the number of codes with ambiguous descriptions which required additional investigation in order to disambiguate (e.g., a local site’s “CT Hematuria Protocol” required report review to ascertain that it was a “CT abdomen and pelvis +/- IV contrast”), because these codes are particularly time consuming to map. For exams without an initial LOINC match, we submitted requests to LOINC for the creation of new codes, assigned these exams temporary codes, and then tracked new LOINC codes that were created based on our requests. Because the requests were submitted to LOINC in batches over time, some are still pending a final decision. We recalculate concept type coverage for the 200 most frequently performed exams with the updated LOINC CT list.

</tbody>
</table>

Discussion/Conclusion
LOINC provided excellent coverage for the most frequently performed CT exams with concept coverage initially at 93% and improving to 95% with the addition of new codes. We are continually submitting requests for new codes to LOINC and expect concept type coverage to continually improve. Coverage will never be 100% because there are certain exam code types for which LOINC does not plan to create new codes, including nonspecific exam codes, such as “CT orbits, sella, ear, and/or posterior fossa”, in which the exam can cover any one or any combination of the areas specified. The benefit for LOINC to maintain specificity of anatomic location in the exam codes outweighs the loss of not having a code for such non-specific exams. As secondary use of HIE data becomes more commonplace, mapping to standard terminologies such as LOINC will be important. This study may help others gain a sense of effort involved and problems encountered in similar large mapping efforts for radiology codes.
Robust Lung Nodule Classification using 2.5D Convolutional Neural Network

Shiwen Shen¹,², Alex A.T. Bui² PhD, William Hsu² PhD
¹Department of Bioengineering, ²Medical Imaging Informatics (MII) Group, Department of Radiological Sciences; University of California, Los Angeles, CA, USA

Introduction

Discovering lung nodules in low-dose computed tomography (CT) is a difficult task. Moreover, it is challenging for conventional model-based lung nodule classifiers trained on one dataset to achieve comparable performance on a completely independent dataset. In this work, we develop a robust novel lung nodule classification model using a 2.5D deep convolutional neural network (CNN). The contributions of this work are: 1) a deep CNN architecture trained on axial, sagittal, and coronal views; and 2) improved model robustness with stacked small convolution (conv) filters (3×3) design enabling more layers, combined with dropout techniques and online training data augmentation scheme. We also present external evaluation results on a complete independent dataset.

Methods

The proposed deep CNN was trained and validated using 893 CT scans from the Lung Image Database Consortium (LIDC). Nodule annotations from four radiologists were used as positive subjects (lung nodules). The non-nodule objects were generated using adaptive multi-level thresholding and morphological operations. Figure 1 illustrates the overall 11 layer CNN architecture. For each candidate, a 3D cube of 40×40×40 mm is extracted, and then resized to 64×64×64 pixels (resolution of 0.625 mm/pixel). The center slices of this cube in the axial, sagittal, and coronal views are then aggregated as a 2.5D input (64×64×3). We used a conv module design comprising two 3×3 conv layers and one 2×2 max pooling layer (with stride of 2). Stacking two conv layers achieved an effective receptive field of 5×5, significantly reducing the number of model parameters while increasing the discriminative power. Three conv modules were used in total, consisting of 32, 64, and 128 kernels for each of their two conv layers, respectively. The output of the third conv module was linked to a fully-connected (FC) layer with 128 rectified linear units (ReLUs). Dropout and online data augmentation were implemented on to reduce training overfitting. We then performed an external validation using data from UCLA, consisting of 158 CT scans with annotated lung nodules.

Results

The scans in the LIDC dataset were randomly divided into five subsets of similar size. Three subsets were used for training, one for validation, and one for testing. This dataset contained a total of 6,776 nodules. The test subset contained 207 scans, with 1,262 nodules and 8,281 non-nodules. For the test set, our method obtained better results in all metrics compared to [1]: an area under the curve (AUC) of 0.991, sensitivity (SEN) of 95.6%, specificity (SPE) of 97.0%, and accuracy (ACC) of 96.8% (vs. AUC of 0.922, SEN of 91.9%, SPE of 94.7%, and ACC of 94.3%). The UCLA dataset, which included 158 nodules and 3,938 non-nodules, were used as an independent dataset to validate the model performance. The model achieved an AUC of 0.948, SEN of 88.6%, SPE of 88.7%, and ACC of 88.7%.

Conclusion

We present a novel robust lung nodule classification approach using a 2.5D deep convolutional neural network. We achieved significantly higher performance and robustness compared to previous work.

Accelerating Rare Disease Diagnosis with Collaborative Filtering

Feichen Shen, Ph.D., Sijia Liu, M.S., Yanshan Wang, Ph.D., Liwei Wang, Ph.D., Naveed, Afzal, Ph.D., Hongfang Liu, Ph.D.
Department of Health Sciences Research
Mayo Clinic, Rochester, MN, USA

Abstract

Patients with rare diseases are frequently misdiagnosed or undiagnosed due to the lack of knowledge and experience of care providers. We hypothesize that patients’ phenotypic information in electronic medical records can be leveraged to accelerate disease diagnosis. In this study, we proposed a collaborative filtering system enriched with natural language processing and semantic techniques to assist rare disease diagnosis based on phenotypic characterization. Results showed that our approach could stratify patients with similar rare diseases.

Introduction

The problem of diagnosing a patient with a rare disease based on patients’ phenotypic information is similar to recommending a product to a customer, and therefore it is natural to propose the use of collaborating filtering for rare disease diagnosis. In this study, we proposed a patient based collaborative filtering system, enriched with natural language processing (NLP) and semantic techniques, to assist rare disease diagnosis based on phenotypes extracted from free-text clinical notes.

Method

The system consists of two modules: i) a preprocessing module leveraging natural language processing and semantic processing techniques to identify patients with rare diseases and collect their phenotypes by building an annotation pipeline with Human Phenotype Ontology (Robinson PN et al., 2008) and MetaMap (Aronson AR, 2001); and ii) a user-based collaborative filtering model to recommend similar patients and possible disease recommendations. Four similarity measurements (Tanimoto (TANI: Jaccard, 1901), Overlap (OL: Szymkiewicz, 1934), Fager & McGowan (FMG: Fager et al., 1963), and Log likelihood ratio (LLRS: Dunning, 1993)) and two neighborhood algorithms (K Nearest Neighbor (KNN: Altman, 1992) and Threshold Patient Neighbor (TPN: Bellogin et al., 2014)) are applied.

Results

We used a subset of Mayo Clinic 2010-2015 clinical notes, including 24,000 patients with 437 rare diseases and 2,400 phenotypes. We applied a 10-fold cross validation to determine the optimal number of neighbor k and threshold t, and used three-level matching criteria to measure similarity between any two diseases: String matching, SNOMED-CT semantic matching (similar if shared the same ancestor within 3 generations), and GARD (Genetic and rare diseases information center) category matching (similar if in the same rare disease category). For patient recommendation, Table 1 gives the mean average precision (MAP) and precision-recall area under curve (PRAUC) for each experiment applied on all patients. For rare disease prediction, we applied TANI with KNN as an optimal algorithm. String, SNOMED-CT and GARD matching found 49.4%, 56.6%, and 92.1% correct predicted rare diseases, and weighted micro-average F measure for them are 0.4, 0.44, and 0.71.

An approach for preventive healthcare for elderly people in Japan using an information and communication technology-based system

Akiko Shibuya, RN, PHN, PhD\textsuperscript{1}, Tsuneo Yamada, MSc\textsuperscript{2}, Jimpei Misawa, PhD\textsuperscript{1}, Yukihiro Maeda\textsuperscript{1},
Rie Ichikawa, MD\textsuperscript{1,3}, Teruyoshi Hishiki, MD, PhD\textsuperscript{4}, Yoshiaki Kondo, MD, PhD\textsuperscript{1}
\textsuperscript{1}Department of Health Care Services Management, \textsuperscript{3}Department of Pediatrics and Child Health, Nihon University School of Medicine, Tokyo, Japan; \textsuperscript{2}The Medical Information System Development Center, Tokyo, Japan; \textsuperscript{4}Department of Information Sciences, Toho University, Chiba, Japan

Abstract
We developed a preventive health care system for elderly people using information and communication technologies (ICT). Users can record their health information (e.g., weight, physical condition, and mental health status) in the system via a password-protected portal at Amami city of Island, Japan, and can receive individually tailored advice, healthcare assessments, and messages from healthcare professionals via their computers and mobile phones. This system may have a significant impact on preventive healthcare for elderly people.

Introduction
With the dramatic aging of the population, a need exists to support preventive healthcare services for the elderly\textsuperscript{1}. Information and communication technologies (ICT), which include services such as communication, consultations, and monitoring, have a significant potential to be useful in enhancing quality of life and providing preventive healthcare for elderly people who live far away from or have limited access to healthcare systems\textsuperscript{2}. However, concerns still exist regarding barriers to ICT use by elderly people\textsuperscript{3}. In a previous study, lack of convenient access to the Internet and use of modern technologies, such as a personal computer, as well as difficulty in obtaining technical support, were considered important barriers to ICT for elderly people\textsuperscript{3}. We used ICT to develop a preventive healthcare system for elderly people.

Methods and results
Figure 1 shows the architecture of our ICT-based preventive healthcare system, which is accessible via a password-protected portal. With this system, elderly users can record their health information (such as body weight, exercise, physical condition, and mental health status) via a password-protected portal and can view their data in graphical forms or charts on their computers and mobile phones (Figure 2). Furthermore, both elderly users and healthcare professionals can access the information to obtain health data. Healthcare professionals can provide individually tailored advice and healthcare assessments, as well as send messages to patients regarding lifestyle factors such as physical exercise, mental health recommendations, and other important medical information regarding preventive healthcare. Family members who live far away (i.e., outside of the island) can be given access to sign-in names and passwords to monitor elderly people's information and communicate about and support the recommended preventive healthcare measures.

To verify the efficacy of the system, 18 elderly people (aged $\geq$65) in Amami City of Island, located 1,300 km southwest of Tokyo, participated in the trial. Participants first received lectures regarding the health site, after which they recorded their health status information and viewed the results in graphical form or charts on their computers. We then assessed their satisfaction and system usability using a questionnaire survey. Overall, 76% of subjects rated the usefulness of the system as excellent. And, 86% of subjects rated the operability of the system as excellent or good. This finding indicates that a preventive healthcare system using ICT was positively received, and it is believed that the system may be useful for providing preventive healthcare to elderly people.

Conclusion
The present study suggests that a preventive healthcare system using ICT may help meet various support needs of elderly people in terms of recommending preventive healthcare measures and enhancing quality of life.

Anesthesia Instrument Recognition System

Scott Siegel, Masters, Agyeiwaa Agyei, Anis Davoudi, Bachelors, Patrick Tighe, MD, Parisa Rashidi, PhD
University of Florida, Gainesville, Florida, USA

Abstract

Our goal is to develop a novel intraoperative anesthesia instrument detection and characterization system using deep region-based convolutional neural networks. This system will be designed to operate in real-time during surgical procedures and will provide surgical teams with the assurance that all anesthesia equipment required for a specific procedure is present without having to check manually.

Introduction

Surgical and anesthesia safety checklists are commonly used during surgical procedures and have reduced the rate of complications in the operating room (OR)\(^1\). Despite their success, there are still concerns about their time consumption and efficiency\(^2\). Preoperatively checking for the presence of anesthesia equipment is one example that can take a nurse anesthetist (NA) almost two minutes to complete if no items are missing\(^3\). An autonomous anesthesia instrument recognition system could perform a preoperative check for anesthesia equipment in less than a second. Our hypothesis is that a using a deep region-based convolutional neural network (R-CNN) for this task would reduce the time required to complete surgical safety checklists and improve efficiency in the OR.

We are utilizing the Faster R-CNN network to detect the presence of anesthesia equipment. This network utilizes Tensorflow as a backend and was trained end-to-end via backpropagation and stochastic gradient descent\(^4\). Images were extracted from videos of various anesthesia equipment were recorded as they were rotated and placed in different positions. A preliminary test was run on a training set that consisted of two objects (oxygen mask and syringe). The pretrained ImageNet VGG-16 network was used to initialize the fully convolutional portion of the network. A Mean Average Precision (MAP) of 90.6% for both objects was achieved. We are planning on testing other models in place of the VGG-16 network in the future and increasing the number of instruments to be detected.

![Oxygen Mask](image)

**Figure 1.** Example output of Faster R-CNN network.

Conclusion

This project utilizes recent advances in machine learning and object detection to eliminate the need for NAs to manually check for the presence of anesthesia equipment. Implementing this system preoperatively would reduce the time required to complete surgical safety checklists and give NAs more time to complete other tasks. Combining this system with other devices in the future could improve efficiency in the OR and reduce the rate of complications.

An Observational Study of Clinical Application Downtimes in an EHR

Rizwan Siwani, MBBS, Mohamed O. Seisa, MD, Vitaly Herasevich MD, PhD
Department of Anesthesiology and Perioperative Medicine, Multidisciplinary Epidemiology and Translational Research in Intensive Care (METRIC)

Mayo Clinic, Rochester, MN

Abstract

Health care delivery at our institution depends on our comprehensive electronic health record that is comprised of several applications. Any system is susceptible to downtime, which can negatively impact patient health outcomes. In this study we evaluated the incidence and causes of downtimes of applications critical to care delivery in a large academic tertiary care center.

Introduction

There has been an increase in uptake of EHR systems by hospitals in the United States. A data brief from the Office of National Coordinator of Health Information Technology reported that 96% of hospitals had a certified EHR in 2015. This increased use has exposed hospitals to the unintended consequence of vulnerability to system downtimes which can have a negative impact on care delivery and therefore, patient outcome.

Methods

We conducted a retrospective observational study of clinical application downtimes over a period of six years from January 2011 to March 2016. Six clinical applications used in the operating room setting were evaluated: the anesthesia information management system (AIMS), the picture archiving and communication system (PACS), an integrated clinical viewer that pulls in information from several sources into an easily navigable interface (ICV), computerized provider order entry system (CPOE), and the applications used to schedule surgeries (Surgical List Viewer) and to record information about all surgeries (Surgical Information Recording Systems). An institutional database was used to identify downtime incidents and data on the following characteristics was collected: application(s) affected, time and date, duration, cause, nature of disruption- impairment or outage and scheduled or unscheduled.

Results

There were 484 downtime incidents over 63 months; 25% scheduled and 75% unscheduled. 93% were characterized as impairments and 7% as outages. The median duration was 0.4 hours with an interquartile range of 0.02 to 1.39. The most commonly identified root cause was related to applications (58.7%), then systems software (33.5%). Human errors were minimal and there were no downtimes due to security violations.

Conclusion

Unplanned downtimes of applications in an electronic health record system occur and vary in severity. This study showed that individual applications within a comprehensive EHR are susceptible to application-specific failures. This information can be used to inform response strategies tailored to the application affected. Also, the clinical impact of downtimes is unclear. Accordingly, we are conducting a study to evaluate the effect of downtimes on patient outcomes.

Do They Talk About Risk? An exploratory study for developing tools to prevent delirium in older hospitalized patients

Stacey Slager MS,1, 2 Teresa Taft, BS1, 3 Daniel Nystrom, MS1, 3, Bryan Gibson, DPT, PhD1, 3, and Charlene Weir RN, PhD1, 3

1IDEAS 2.0, George E Whalen VA Medical Center, Salt Lake City, Utah; 2Division of Epidemiology, University Of Utah, Salt Lake City, Utah, 3Department of Biomedical Informatics, University Of Utah, Salt Lake City, Utah

Background: Delirium is sudden, cognitive dysfunction, which presents as confusion, a change in level of consciousness, and reduced ability to regulate attention. Delirium occurs in 11-42 % of hospitalized patients and is associated with longer hospital stays, increased admission to long-term care, increased mortality.1 Prior work has demonstrated that 30-40% of cases of delirium can be prevented, if risk factors can be identified.2 In this study we sought to determine the degree to which risk factors for delirium are documented in the electronic health record (EHR) (to address the feasibility of clinical decision support (CDS)) and/or discussed in handovers and rounds.

Methods: We conducted prospective observations of verbal communication between providers of patients aged 65-89 admitted to three VA medical Centers in the Western US between October 2015 and April 2016. These observations were recorded and transcribed. This poster reports on an initial analysis of 11 patients. To determine whether risk factors for delirium were documented in the EHR, we conducted chart reviews for each patient from the day of admit until either they were discharged or Day 4 of their stay, which we compared with observational data of nurse handoffs which were recorded across 2 shifts. We counted the prevalence of documented risk factors3 across observations and notes. To provide clinical context we also collected the terms used in reference to a patient’s mental status as well as risky medications mentioned.

Results: In preliminary analysis of the first 48 hours of 11 inpatients from the Salt Lake City VA, the data showed there were a median of 3 risk factors (0-8 instances of risk per patient) documented in the chart. In nurse handoffs and physician rounds there were a median of 6 risk factors (0-16 instances of risk per patient) mentioned. The agreement between these two methods for the same patient is very low. Figure 1 shows the difference.

Nurses and physician demonstrated clear differences in verbal and written communication regarding mental status. Nurses spend more time with patients and notice behavioral and mental status changes, whereas physicians pay closer attention to medications, infections, and labs. The poster will include the terms used in reference to a patient’s mental status as well as risky medications mentioned.

Conclusion: In this pilot work we have found that risk factors for delirium are commonly documented in the EHR but are much less frequently discussed by Nurses and Physicians in their handoffs and rounds. In addition, attribution of risk factors to delirium risk itself is rare. This finding suggests that computerized decision support to help clinicians prevent delirium based on data entered in the chart is feasible and may be necessary. Current work is addressing the design and implementation of such a decision support system that would aggregate risk-related data to alert providers to pay attention to acute mental status changes. The overarching goal is to create a decision support intervention that will facilitate early recognition of risk and appropriate intervention.

Health Care Providers’ Experiences of Moving from a Home-grown EHR System to a Commercial System

Sarah P Slight, MPH, PhD1,2, Diane L Seger, RPh1,3, Christine A. Rehr BA1,3, Sabrina A. Fowler3,4, Elizabeth R Silvers, BA1,3, Adrian Wong, PharmD1,5, Mary G Amato, PharmD, MPH1,5, Nivethietha Maniam1,3, Michael Swerdloff BS1,3, David W Bates, MD, MSc1

Introduction: Electronic health record (EHR) systems hold the promise of improving the quality and safety of patient care in hospitals. There has been widespread adoption of EHRs over the last few years, encouraged by the financial incentives offered through the US Meaningful Use Program. Different forms of EHR systems exist, and some hospitals have chosen to replace their existing systems with a fully-integrated clinical and administrative information systems. This study aimed to explore users’ experiences and views on using a home-grown EHR system, and after switching to a commercial system to explore their views on their current system.

Methods: After obtaining the necessary ethical and institutional approvals, a diverse range of outpatient and inpatient providers (including attending physicians, pharmacists, nurse practitioners, physician assistants and residents) were selected. These providers worked at a well-established, integrated delivery system in the northeastern U.S., which was undergoing a move from a home-grown EHR system to a commercial system. All interviews were digitally audio-recorded with each participant’s verbal consent and transcribed verbatim. We adopted an iterative approach to analysis, which enabled us to refine questions, and pursue emerging themes and concepts during subsequent data gathering. A workable list of main- and sub-themes was developed inductively and applied systematically to these data with the aid of the computerized qualitative data analysis software QSR N-Vivo V.11.

Results: Seventy semi-structured interviews were conducted between July 2013 and Jan 2016, each lasting from 10 to 74 minutes. Twenty-seven of these interviews occurred after the EHR transition had taken place, so providers were able to directly compare the move from one system to the other. Five key themes emerged that described important differences between the two systems: (1) how medications were displayed when ordering, (2) default drug doses and directions, (3) the location of pertinent patient information, (4) the timing of medication related alerts, and (5) the quantity of medication-related alerts and their navigation. Medications were displayed in a single drop-down list in the home-grown system, compared to three separate lists in the vendor system, causing some confusion around what the purpose and value of each of these lists were in the new system. Providers found some of the default medication doses suggested by the vendor system to be inappropriate. The vendor system replaced both discrete inpatient and outpatient versions of the home-grown system with a single integrated system, where all the patient’s notes were documented in one place. Although there were clear advantages to doing this, users believed it was now harder to find key information. All clinical decision support alerts were triggered at the time of ordering in the home-grown system; however, in the vendor system, they were presented at the time of signing and shown on one screen, which had advantages and disadvantages. Compared to the homegrown system, providers reported more alert fatigue using the vendor systems; they perceived this to be due to more complex system navigation and an increased quantity of alerts.

Conclusion: Improving the quality and safety of patient care through adoption of EHR systems is a priority area for governments and policy makers worldwide. The five key themes identified in this study provide some useful and potentially transferable insights into how potentially disruptive this change can be from a user’s perspective. This qualitative study was part of a larger project evaluating health care providers’ alert override behaviors, which may explain why the results focused mainly on medication-related elements. This study was funded by grant #U19HS021094 from the Agency for Healthcare Research and Quality (AHRQ).
HIPAA and eCR: Are You Sharing the ‘Minimum Necessary’?

Crystal L. Snare, DVM, MPH1, Julie Simon, MSPH1, Rita Altamore, MD, MPH2, Kim Peifer, MPH3

1Infectious Disease Assessment Unit, Washington State Department of Health, Olympia Washington; 2Office of the State Health Officer, Washington State Department of Health, Shoreline, Washington; 3Communicable Disease Epidemiology, Washington State Department of Health, Shoreline, Washington

Introduction

The Washington State Department of Health (DOH) is engaged in a CDC-funded project to promote electronic case reporting (eCR) of sexually transmitted infections (STIs) with a goal of improving completeness of reporting, when compared to paper reports. This pilot involves submission of reports for chlamydia, gonorrhea or syphilis-positive patients to DOH from a clinical partner using existing certified Electronic Health Record (EHR) and standards-based solutions. According to CFR 164.512(b)(1)(i), the Health Insurance Portability and Accountability Act (HIPAA), providers must share the minimum data needed to satisfy public health investigations, keeping in mind that other laws can be more restrictive about data relating to minors, addiction, genetics, domestic violence, mental health and HIV/AIDS. We summarize findings from the assessment of standard EHR generated records for the presence of contents that satisfy public health reporting requirements and contents which exceed the minimum data necessary.

Methods

DOH partnered with Planned Parenthood of the Great Northwest and Hawaiian Islands (PPGNHI), who uses a certified EHR (NextGen). CDA documents complying with the Continuity of Care Document (CCD) standard were generated by the EHR and securely transmitted to DOH. The data elements and values in these files were compared to those requested by the DOH STI public health reporting form. Data elements present in the CCDs, but not requested on the reporting form, were assessed in light of the HIPAA ‘minimum necessary’ rules.

Results

Sixty-two (62) CCDs were received, representing 17 patients; and included documents in both the EHR’s longitudinal and encounter-based styles. Extraneous or sensitive information was present for 59% (10/17) of patients when compared with information requested by paper case report forms. Examples include 18% (3/17 patients) whose CCD included mental health medications, 6% (1/17) with sensitive procedures, and 12% (2/17) with unneeded diagnoses included. HIV status is included if tested at any encounter reflected in the CCD.

Discussion

We found that unwanted sensitive information is present in unmodified CCD documents submitted as public health case reports, which would not be consistent with HIPAA’s ‘minimum necessary’ requirement. Additionally, some information needed by public health, such as partner treatment plan, is not present; previous work describes this mismatch. Information such as HIV status is present if a relevant test is performed in connection with one of the encounters included in the CCD. This information would be “unnecessary for public health” for reporting non-STI diseases (for example, pertussis or campylobacteriosis) -- but when present in an STI report the information is insufficient, since the date and results of any prior test were absent. Overall, public health case reporting needs were not fully met by data in unmodified CCD and in some cases data present exceeded the HIPAA mandate to share only the minimum data needed to accomplish appropriate public health action. Limitations include using files from a single instance of a single EHR and reliance on manual selection of positive cases. Next steps include exploration of triggering options, further gap analysis, and analysis of larger and more representative sets of records. While public health is committed to reducing burdens on reporters, case reporting implemented using unmodified CCDs produced by certified EHRs will present challenges, both in the necessary information that is absent, and in the unnecessary and unwanted information that is present.

References

Introduction and Background:
The internet has enabled the sharing and viewing of vast amounts of information, including biomedical datasets. However, unlike journal articles, there is no common site where datasets can all be found. Furthermore, due to the myriad of ways data can be developed and stored, finding one dataset does not mean the searcher will have access to datasets with further or related information on the subject.

The biomedical and healthcare data discovery index ecosystem, also known as bioCADDIE, is an effort between informaticians, biomedical researchers, administrators, and publishers to develop a Data Discovery Index (DDI) in order to enable the discovery of available biomedical and biological data in an efficient platform. The initiative is funded as part of the Big Data to Knowledge (BD2K) program by the National Institutes of Health. As part of this initiative, the DatA Tag Suite (DATS) developed in order to describe the metadata and structure a dataset requires to populate the DDI prototype known as DataMed. One of our teams at UCSD is focused on taking multiple data repositories that have data available to the public, ensuring that the necessary metadata to populate DataMed is available. So far there have been over 64 repositories that have been indexed in DataMed. In doing this, we have found there to be a large variety of ways that data repositories organize and represent their metadata, highlighting the need for standardization of datasets and metadata. In this abstract, we illustrate these inconsistencies with several example repositories to emphasize the multiple needs for a standardized platform such as DataMed.

Methods:
We first do an initial inspection to check if the repository is a good fit for DataMed, including checking to see if the datasets represented on the site, and their associated documentation, are available to the public. If a repository passes this initial inspection, it proceeds to the mapping stage. In this stage, we focus on linking the metadata available for the datasets in the repository to the relevant equivalent in DATS. Much of this work is done by downloading the datasets and associated documentation. We then manually find the metadata information of the dataset to the standardized metadata items of DATS. Once this is done the mapping is used to ingest the datasets of the repository into the DataMed pipeline.

Results:
The problem that we are currently encountering while doing the mapping is the heterogeneity in how metadata of datasets is defined and represented. For example, in DATS the entity-property used to identify the name of a dataset is “Dataset: Title”. In comparison, different repositories we have mapped represent this information in many different ways. The National Database for Autism Research (https://ndar.nih.gov) links this value to “General: Title”, while Nature Scientific (http://www.nature.com/srep) refers to this as “Assays: Study Assay File Name”. Many repositories don’t give titles for their datasets, but instead have what we call “Dataset: Identifier”, referring to a unique and primary identifier for a dataset, typically a combination of numbers and letters. In the Human Microbiome project (HMP, http://hmpdacc.org) alone, they host three different types of datasets, all of which refer to the primary identifier in different ways. In the HMP NCBI dataset, the value is referred to as “Submission: Primary_ID”, while in the HMP Metagenomic Samples dataset it is referred to as “SequencingProject: Sequence Read Archive ID”, and in the HMP Reference Genomes dataset it is referred to simply as “Project: HMP ID”. This continues through multiple metadata properties, ranging from information about grants and funding, to software used in data analysis. More examples can be found at https://drive.google.com/file/d/0BxvVDngaYh6vc0NTZ3pjBVkxZVE/view.

Conclusion:
The creation of a platform to allow access to datasets requires the standardization of the data presented, much like what PubMed has done for journal articles. Though at the moment much of this standardization must be manually curated before indexing, we hope that the introduction DataMed and DATs will eventually bring about a level of conformity to data production and organization so as to improve biomedical data ease of access.

Bayesian Prediction of Asthma Exacerbation in Children

Sunghwan Sohn, PhD1, Young J. Juhn, MD2, Sungrim Moon, PhD1, Chung-Il Wi, MD2, Katherine S. King1, Euijung Ryu, PhD1, Hongfang Liu, PhD1

1Division of Biomedical Statistics and Informatics, Mayo Clinic, Rochester, MN; 2Department of Pediatric and Adolescent Medicine, Mayo Clinic, Rochester, MN

Introduction

Asthma exacerbation is an acute or subacute episode of progressive worsening of symptoms of asthma, including shortness of breath, wheezing, cough, and chest tightness which is not responded to rescue or controller medications, so requiring systemic corticosteroids or visit to urgent care. It is a key cause of major morbidity related to asthma and a long-term decline of lung function. Thus, it is crucially important to have a tool for predicting asthma exacerbation enabling a potential preemptive intervention. In this study, we examined various predictors of asthma exacerbation and employed a Bayesian network (BN) to investigate the collective predictive capability of the predictors for future asthma exacerbation within a year. The predictive performance of the BN was also compared with logistic regression (LR), which is commonly used in the clinical domain.

Materials and Methods

The study cohort consists of 590 children who participated in an ongoing asthma intervention study at Mayo Clinic, Rochester MN. We used patient demographics and medical histories over the past three years (June-1-2012 to May-31-2015) to predict asthma exacerbation within post one year (June-1-2015 to May-31-2016). Of these 590 subjects, 300 subjects (35 exacerbation cases) were set aside as the training set, and 290 subjects (48 exacerbation cases) were set aside as the test set. We investigated various predictors of asthma exacerbation (selected through discussion with clinicians) in electronic medical records (28 total variables, Table 1) that were retrieved from structured data and were also extracted from unstructured data (i.e., clinical notes) using natural language processing techniques. Information gain was applied to rank variables. The prediction performance of a BN and multivariate LR has been investigated using all variables versus top five variables (bold in Table 1). We also examined a resampling technique to balance class distribution (i.e., oversampling).

Results

Table 2 contains the receiver operating characteristic (ROC) area under the curve (AUC) of predictive models with different settings. A BN performed better than LR when using all 28 variables, but they were similar under the five selected variables. Figure 1 demonstrates the ROC curves of a BN and LR using all variables. A resampling technique increased predictive performance with the exception of LR using all variables.

Discussion

Patient past histories relevant to previous asthma conditions and management (top five variables) appeared to be important predictors of future asthma exacerbation. The predictive models on five selected variables demonstrated predictive capabilities comparable to the model using all variables without significant loss of performance (BN) or with even better performance (LR). This suggests that we may use as few predictive variables as possible with adequate performance with less burden of variable extraction, realizing a parsimonious model to be implemented in clinical settings. Our predictive models of asthma exacerbation demonstrate the potential to identify high-risk asthma exacerbation patients and thus assist clinicians in determining appropriate intervention to improve asthma management and outcomes.

Mining Associations between Drug Abuse, Age, and Suicide Attempts

Brinda Somasundaram, MS
George Mason University, Fairfax, Virginia

Introduction

According to the Substance Abuse and Mental Health Services Administration (SAMHSA), drug-related suicide attempts in the U.S. has dramatically increased by 41% between 2005 and 2011. This rate is increasing given easy access to both prescription and over-the-counter medications, combined with different drugs including synthetics, making combinations highly lethal. According to the National Comorbidity Survey in 1999, individuals with a substance use disorder are almost 6 times more likely to report a lifetime suicide attempt than those without a substance use disorder. In our study, we use Association-Mining Algorithm (Market-Basket Analysis) to find the most common drug-cocktail combinations related to suicide when admitted in the Emergency Department (ED).

Methods

Data: Drug Abuse Warning Network (DAWN) data collected between 2005 and 2011, were analyzed for Emergency Department (ED) visits involving drug combination-related suicide attempts among patients for the various age categories. ED visits in DAWN include only suicide attempts that involve drugs, but are not limited to drug overdoses.

Tools Used: We used the Data Mining tool Weka, to apply the association mining algorithm to find best rules (most common combinations) of our values for every patient record. The data have been pre-processed using SQL, only records indicating suicide as a reason for hospital admission and records with confirmation of drug abuse were used. Each record values were binarized for the presence or absence of drugs. The data were divided into subsets based on ten age categories such as age 5 or younger, 6 to 11, 12 to 17, 18 to 20, 21 to 24, 25 to 29, 30 to 34, 35 to 44, 45 to 54, 55 to 64, age 65 or older, -8 (age undocumented). The binary data subsets related to suicide were imported to Weka and association mining algorithms (Apriori and FP-Growth) were applied to find the most common combination of drugs used for every age category.

Results

Among patients with suicide attempts, alcohol was almost always present when using drugs. Patients in the age category 45-54 had the highest suicide attempts. These patients most frequently combined alcohol, cocaine, and heroin. Patients in the age category 35-44 had the second highest suicide attempt. Alcohol, heroin and cocaine were the most frequently used. The patients in the age category 12-17 had the sixth highest suicide attempts. Interestingly, these patients frequently were on alcohol, Ibuprofen and Acetaminophen, in that order.

Conclusion

Suicide is a significant public health problem. Health providers should be aware that individuals with substance use disorders are at elevated risk for suicide, take note and educate the patients about the lethality of both drug usage and combining drugs for recreational and non-recreational use. The presented study indicated that adults and teenagers who attempt suicide differ in drugs they are intoxicated with. While alcohol is the main drug in all categories, cocaine and heroin is present in adults, while Ibuprofen and Acetaminophen is present in teenagers.

Exploration of Semantic Expressions to Define Classification Rules

Margarita Sordo, MSc, PhD,1,2,3 Benjamin J. Gross, MD, MMSc,1
Priyaranjan Tokachichu, MD, MS,1 Christopher J. Vitale, PharmD,1
Saverio M. Maviglia, MD, MSc,1,2,3 Roberto A. Rocha, MD, PhD1,2,3

2Brigham and Women’s Hospital, 3Harvard Medical School, Boston, MA

Introduction

Creating classification rules for clinical decision support, data reporting, and clinical registries requires manual selection of concepts from reference terminologies into value sets. Manual selection of concepts based on terms and synonyms easily becomes a difficult and time-consuming task that requires specific terminology expertise, and frequently leads to inconsistent and inaccurate value sets. An alternative approach is to rely on semantic relations among concepts in a reference terminology. This alternative approach requires similar expertise and is only possible when the reference terminology associates and decomposes concepts using semantic relations. These semantic properties enable a more sustainable approach that relies on the meaning of the concepts to be gathered.

Methods

We propose the use of queries defined using semantic expressions to automatically select concepts required for value sets. Our clinical knowledge management system (CKMS)1 enables the implementation of queries using semantic expressions. These expressions can reference any semantic relation defined within the system, including those obtained from reference terminologies such as SNOMED CT.2 Given the large number of classification rules that we need to create and maintain, we have been exploring the use of queries created using SNOMED CT semantic relations to generate disease-specific value sets. We implemented a small number of queries and have been evaluating the resulting value sets to confirm the utility of the new method. By using semantic relation:value pairs to identify desirable concepts, we can traverse ontologies to identify relevant concepts based on their clinical meaning. For example, we used the following to identify all relevant concepts for a) Bacterial Pneumonia: causative agent: bacterium (organism) and finding site: lung structure (body structure) and pathological process: infectious disease (disorder); b) Autism: is-a: Pervasive developmental disorder and semantic group: mental or behavioral dysfunction.

Results

Semantic relations in SNOMED CT reflect a hierarchical structure that allows us to select a starting point at the appropriate level, retrieve related concepts in different parts of the terminology, and narrow down our query to specific concepts. This is the case with Autism, where our starting point was the is-a relation Pervasive developmental disorder (which turned out to be too general for our purposes, returning diseases not related to Autism, e.g. Rett’s disorder). Adding semantic group: mental or behavioral dysfunction limited results to concepts specific to Autism. As for Bacterial pneumonia, we selected the semantic relations based on the etiology of the disease: bacterial infection in the lungs. This allowed us to retrieve concepts representing this etiology, even though neither “bacterial” nor “pneumonia” were present in the concept description, “Abscess of lung and mediastinum”.

Conclusions

Queries using semantic expressions seem to provide a powerful alternative to manually searching and retrieving concepts using terms and synonyms. Selecting concepts based on their meaning offers a reliable method to define value sets for classification rules. By taking advantage of semantic relations present within reference terminologies, we can tailor the scope of our search (Autism example) and build queries based on the etiology of a disease (Bacterial Pneumonia). Moreover, such queries can automatically update resulting value sets when reference terminologies are updated. We will continue to evaluate this method, taking into account limitations imposed by existing reference terminologies, including comparisons with manually defined value sets.

Multi-Agent System Architecture to Measure Patient Engagement Based on Automatic Patient Authored Text Analysis

Fábio Rezende de Souza BSc1,2, Márcia Ito MD, PhD2, Maíra Gatti De Bayser, PhD3
1Universidade Federal do ABC, Santo André, SP, Brazil; 2IBM Research, São Paulo, SP, Brazil, 3IBM Research, Rio de Janeiro, RJ, Brazil

Introduction

The impact of chronic health conditions in the population requires the adoption of methods to improve the effectiveness of clinical treatments. Patient Engagement can be defined as a set of actions that a patient takes to obtain the greatest benefit from his/her clinical treatment [1]: improving a patient engagement produces a positive impact on his/her treatment outcomes. A multi-agent software architecture was created to implement the method proposed in [2] which assess a patient engagement by classifying sentences of a Patient Authored Text1 (PAT).

Summary description of the Multi-Agent Architecture to Measure Patient Engagement

A PAT Corpus is received by the Engagement Analyzer Agent (a1), which delegates the text processing task to the PAT Analyzer Agent (a2). Agent a2 communicates with the Semantic Analyzer Agent (a4), different language processing services and a lexical database, in order to break the original corpus into functional segments and perform a semantically-based annotation to each one of them. Having this information, Agent a1 asks to the Engagement Degree Classifier (a5) to calculate patient’s engagement degree. In its turn, Agent a5 asks to the Perceptions Classifier Agent (a3) to find and retrieve different types of patient’s perceptions on each functional segment, and based on this information, a5 weighs those perceptions and classify them as being positive or negative, later returning this information to a1. Agent a1 informs the engagement degree to agent a6, and requests information on the engagement stage (according to a previously chosen model of behavior change). Agent a6 returns the information to a1 alongside suggestions on clinical interventions that could improve patient engagement, retrieved by agent a7. Knowledge bases containing information about previous PAT classifications can be used to improve classification of new PAT. The system output is a complete report on patient's engagement information. Figure 1 shows the system architecture.

Conclusion

We introduce a multi-agent software architecture to measure a patient engagement on a health treatment, as the implementation of the theory method proposed by [2]. We consider this could help us to analyze a patient behavior over different perspectives and scenarios.

The Phenotype Execution and Modeling Architecture: A Roadmap Towards Next-Generation Phenotyping Using Electronic Health Records

Peter Speltz¹, Luke V. Rasmussen², Richard Kiefer³, Jennifer A. Pacheco², William K. Thompson², Guoqian Jiang³, Jyotishman Pathak⁴, Joshua C. Denny¹
¹ Vanderbilt University, Nashville, TN; ² Northwestern University, Chicago, IL; ³ Mayo Clinic College of Medicine, Rochester, MN; ⁴ Cornell University, New York, NY

Introduction
A limitation within the space of electronic health record (EHR)-based phenotype algorithm development is the lack of portability. Currently, phenotypes that are shared on websites such as the Phenotype Knowledgebase (PheKB.org) are implemented independently by different institutions using an amalgamation of custom code (such as SQL), natural language processing (NLP), and frameworks, which execute against various standard and custom data stores. Porting phenotypes implemented in this way to other institutions is cumbersome, time-consuming and error-prone. We have proposed the Phenotype Execution and Modeling Architecture (PhEMA) as a means to minimize the effort to streamline phenotype implementation by standardizing phenotype development and execution against i2b2 and OHDSI data repositories, as well as data stored in local, non-standard data models.

Methods and Results
PhEMA is comprised of multiple components supporting standards-based phenotyping (Figure 1). The Phenotype Authoring Tool (PhAT) is a web-based tool for creating phenotype algorithms utilizing the Quality Data Model (QDM), an information model for representing EHR-based electronic clinical quality measures (eCQMs). We have incorporated PhAT into PheKB.org, enabling PheKB users to launch PhAT to create and save computable phenotype definitions. PhAT also allows the reuse of value sets from the NLM’s Value Set Authority Center (VSAC), as well as the ability to compose new value sets in a local repository. PhAT phenotypes can be exported in various computable formats to be executed externally.

We are currently able to generate an HL7 Health Quality Measure Format (HQMF) representation of the phenotype definition logic, executable KNIME (knime.org) Analytic Platform workflows that may be configured against a local data repository or i2b2, and preliminary work has been completed in generating a JSON representation of VSAC value sets that may be run from within the OHDSI data analytic tools (e.g., ATLAS). Future integration with PheKB will automate publishing the executable formats on PheKB.org for others to download. We have demonstrated portable execution against both local databases and i2b2 instances at up to 8 sites with different EHRs for several phenotypes (e.g., T2DM, BPH), and have compared the results with the original phenotypes.

Conclusion
Portable phenotypes depend on standardization and interoperability. With the increased adoption of common data models for EHR research data warehouses, a set of common phenotype modeling and architecture tools will provide portability of phenotypes, speed up development of algorithms, and increase the availability of portable algorithms. This will in turn increase the overall quality and use of phenotypes in research. PhEMA aims to support standard phenotyping against the most used common data models while still being adaptable to local data models. The tools are still evolving and larger scale experiments and evaluations will be done.

Essential Components of a Patient Engagement Platform for Comprehensive Cancer Care

Daniel Stein, MD, PhD¹, Rimma Belenkaya, MS, MA¹, Erdeta Bani, MPA¹, Olga Strachna, MS¹, Peter D. Stetson, MD, MA¹

¹Division of Health Informatics, Memorial Sloan Kettering Cancer Center, New York, NY

Introduction
As healthcare organizations adopt patient-centered care models, they require tools to capture patient history, symptoms, and more formally constructed patient reported outcomes (PRO). While the number of these systems has increased, they are generally one-off tools and, “vary dramatically in their focus and features.”¹ Until such systems are standardized generally available, organizations must share experience in developing them to determine best practices around the tools to collect data from patients, and how to integrate into clinical systems and workflow.

Methods
Over the past 15 months, we developed and implemented a patient engagement platform, MSKEngage. The multidisciplinary team that worked to create this system consisted of software developers, informatics, clinician stakeholders, and patients. In addition to weekly development sprints, the interdisciplinary team met at least biweekly to review development progress and to collect and incorporate feedback. Beyond the core engagement platform that delivers surveys, we report on essential components required to make the collection of patient generated data automated, relevant, safe, and effective.

Results
Since our launch in January 2016, 3,234 patients have completed 8,554 PRO instrument submissions through MSKEngage. In the table below, we summarize the key components we discovered were essential for an implementation that integrated into existing systems and workflow:

Table 1. Categories and specific features of key components implemented in our patient engagement platform.

Conclusion
Beyond the survey tool itself, there are numerous important components required when developing a comprehensive and integrated patient engagement platform, from governance of survey items, to multiple user interfaces, to advanced cohort management, scheduling, notification and reporting components. Specialized (e.g. cancer centers) and generalized healthcare organizations can benefit from sharing experiences and best practices as we work to integrate patient engagement systems into clinical practice.

Technology Integration Officer: A New Residency Leadership Position

Kevin U. Stephens Jr., M.D., M.B.A, Rachelle E. Toman, M.D., Ph.D., FABC
1Georgetown University-Providence Hospital, Washington, D.C.

Introduction
The widespread adoption of electronic health records has created an increasing demand for physicians who work with information technology departments to support clinical practice and health systems. This has led to the growth of positions such as Chief Medical Informatics Officer. The need to train physicians for these roles has culminated in the board-certified subspecialty of clinical informatics where physicians are trained to transform healthcare by “analyzing, designing, implementing, and evaluating information and communication systems that enhance individual and population health outcomes, improve patient care, and strengthen the clinician-patient relationship”1. However, many residents are unaware of this field and even less have structured meaningful experiences in clinical informatics. To increase the exposure of resident physicians to this field in a practical way, we created a new residency leadership position entitled Technology Integration Officer (TIO).

Technology Integration Officer: Role & Responsibilities
The official description of this role is to: identify and promote the use of technologies to support resident achievement, collaborate with appropriate technical staff to optimize available hardware and software to meet the needs of residents, and advocate for resident technological interests.

The TIO worked with the Medical Director to develop a longitudinal project to enhance the use of technology within the residency program. The project chosen for this past year was implementing secure texting among the residency program. The TIO was responsible for developing an implementation plan, collecting initial survey information, running a test pilot, and finally implementing secure texting among the residency program.

Additionally, the TIO was responsible for identifying and circulating an “App of the Month” among residents and faculty with a mobile app related to improving patient care.

Lastly, the TIO served as a liaison between the residency and the information technology staff/hospital leadership. During the first year of this position, there were two relevant committees that the TIO served on: The Physician Governance Committee and the Clinical Transformation Committee. Both committees were composed of key hospital leadership from different departments (e.g., pharmacy, laboratory, and nursing) with a goal of preparing hospital and medical departments to operate in an advanced clinical electronic environment.

Results
An end of the year survey sent to residents and faculty showed that 92% view the TIO as a good addition to residency leadership positions. 100% reported that providing resident input on EHR optimization and sending out an “App of the month,” were important roles for the TIO. 75% reported educating the residents on clinical informatics, 84% reported serving as a technology resource for residents, and 53% reported completing a longitudinal project, like secure texting were important. Only 23% of the residents and faculty were aware that clinical informatics is a board certified sub-specialty.

Conclusion
The role of TIO is a new residency leadership position that can offer resident physicians meaningful exposure to clinical informatics and project management early in their career. In the future, the TIO role will respond to the feedback of the survey by continuing to expand the TIO’s role as an advocate for EHR optimization (e.g., by having the resident undergo EHR super user training), providing formal lectures to residents on clinical informatics, and improving the perception of the longitudinal projects.

Content for Visualizations to Enhance HIV-Related Communication Between Patients and Health Care Providers
Samantha Stonbraker PhD, MPH, RN1,3, Sheyla Richards BA2, Mina Halpern MPH3, Suzanne Bakken PhD, RN1, Rebecca Schnall PhD, MPH, RN-BC1
1School of Nursing, 2College of Physicians and Surgeons, Columbia University New York, NY, 3Clínica de Familia La Romana, Dominican Republic

Introduction
Many persons living with HIV (PLWH) who attend Clínica de Familia in La Romana (CFLR), Dominican Republic may not understand the health information they receive. Information visualizations can help health care professionals provide the complex health information needed for self-management to patients with limited health literacy and recently, are being designed in various settings and to address the information needs of individuals living with various health conditions. A preliminary step in the design of visualizations is to determine necessary content for inclusion. The purpose of this study was to establish content for visualizations by combining patient and healthcare providers’ perspectives on what information is the most useful for effective self-management.

Methods
This study was guided by an adapted version of Wilson’s model of Information Behavior which depicts how information moves within a system. Data collection with 107 patients is reported elsewhere. Interviews with 40 healthcare providers who provide services to HIV positive patients at CFLR were conducted from Jan - Mar 2017. During both patient and provider interviews, participants were asked what information is the most useful for patients to improve self-management. Providers were also asked what information was the most important to teach patients during a clinical visit. Responses from patients and providers were coded and then frequencies of priority topics were compared to identify and prioritize the information that is the most important to share with PLWH. Identified priorities were then compared with findings from the scientific literature to confirm completeness and accuracy. The prioritized list of information needs formed the basis for what content to include in visualizations to promote HIV-related communication.

Results
Demographics of the 107 patient participants are reported elsewhere. The interdisciplinary team of providers included 13 physicians, 10 nurses, 4 community health promoters, 5 mental health counselors, 2 pharmacy technicians and 6 from other positions such as program directors or research assistants. The average age of providers was 38.2 years (Range 25-62) and the average length of time working at the clinic was 5.13 years (Range 0.25-25).

Patient responses (n=104) regarding what information is the most useful for self-management were medications/adherence (54.8%) methods of protection/prevention (13.5%), mental health support (9.6%), general health management (8.7%), healthy eating (4.8%), appointment adherence (2.9%), and other non-specific information (5.8%). Of healthcare providers’ responses (n=40), information about medications/adherence (30%) was also identified as the most useful for patients’ self-management. Providers identified other useful topics to be: free services at the Clinic (22.5%), mental health support (12.5%), HIV in general (12.5%), methods of protection/prevention (7.5%), transmission (5%), other health conditions (5%), laboratory values (2.5%) and family planning (2.5%). While patients and providers agreed on the most useful information for self-management, responses differed in that patients focused on a few central ideas whereas providers identified a wider range of information topics.

Conclusions
PLWH and their healthcare providers identified some similarities and some differences in what information is useful for effective self-management. Future work will be to conduct participatory design sessions to create the visualizations that incorporate the information that both patient and health care providers identified as necessary.

Selection and On-boarding of Health Information Exchange Partners:
The DoD and VA Approach

Norman E. Stone III MD¹, Steven F. Kator, MD¹, Roger B. Price MPA², LeAnn Roling RN³, Crystal A. Baum MBA⁴, Kimberly A. Heermann-Do MHA², Margaret Donahue MD³, Lauren C. Thompson, PhD¹

¹ DoD/VA Interagency Program Office, Rosslyn, VA ² Defense Health Agency, Falls Church, VA ³ Veterans Health Agency, Washington, DC ⁴ Defense Health Management Systems, Rosslyn, VA

Introduction & Background
The DoD and VA operate two of the largest healthcare systems in the United States, with 200 hospitals, 1,842 clinics, 18.5 million beneficiaries, and combined budgets of over $221 billion.¹,²,³ Additionally, the Departments purchase over $25 billion in health care from civilian physicians and institutions.¹,⁴ The purpose of this study is to (a.) review the current status of health data exchange between the Departments and civilian partners, and (b.) describe the processes used to identify and on-board health data exchange partners.

Materials & Methods
DoD and VA process documentation and interoperability reports were reviewed, summarized, and compared. The Departments’ enterprise data repositories were queried for purchased care data.

Results
The DoD maintains connections to 23 community partner institutions, exchanging approximately 100,000 health documents per month. The VA maintains connections to 96 community partner institutions and regional HIEs, exchanging approximately 150,000 health documents per month. The DoD utilizes an “opt-out” policy, whereas the VA utilizes an “opt-in” policy. 185 DoD beneficiaries have opted-out of health information exchange (0.2% of 9.49M beneficiaries); 979,696 VA Veterans have opted-in (16% of 6.26M Veterans treated in FY2016; 11% of 9.05M enrolled Veterans).

The Departments evaluate candidate partners based on purchased care dollars spent and number of patients treated. Both Departments are signatories to the eHealth Exchange’s Data Use and Reciprocal Support Agreement (DURSA), and require eHealth Exchange participation by candidate partner institutions.

Conclusion
The DoD and VA exchange a substantial amount of health data with community partners, and regional HIEs. There are opportunities to expand participation with community partners and regional HIE’s, and to exchange a greater quantity and variety of documents. Expansion should be guided by cost and quantity of care purchased for each community partner.

Operationalizing Patient Generated Data Collection through Engagement and Iterative Visualization Design

Olga Strachna, MS¹, Erdeta Bani, MPA¹, Daniel Stein, MD, PhD¹, Peter Stetson, MD¹
¹ Division of Health Informatics, Memorial Sloan Kettering Cancer Center, New York, NY

Introduction and Background

Patient-generated data (PGD) in the form of patient reported outcomes (PRO) and care experience outcomes are becoming widely and routinely collected across various healthcare settings. The goal is to utilize this information to assess patients' well-being and perception of experience as related to their treatment, not only as a population but also as individuals. Enabling clinicians to truly leverage PGD within their established workflows remains a challenge. Beyond merely integrating PDG into the medical record, this new data must be translated into clinical insights and actionable knowledge at the right time. Furthermore, successful integration of PGD into clinical practice requires clinician engagement, as well as patient engagement within the process.

Methods

We deployed a human-centered design framework for visualizing PGD data as it is collected, and for converting PGD into actionable knowledge for clinicians. The design approach was conducted in iterative phases of complexity, where the clinical staff provided feedback throughout each cycle of dashboard deployment. One end goal was to increase clinician understanding of information collection bottlenecks so that they can better engage their patients. A second end goal was for the care team to analyze the patient responses at the population level, and at the individual level. This would allow clinicians to reflect on clinically meaningful differences to track over time across a population of patients, while at the same time allowing them to communicate more effectively with individual patients within the normal clinical workflow. We tested the design concepts by performing cognitive walk-through exercises, such as reviewing data across a panel of patients, sharing the data with care team members, and estimating the quality or meaningfulness of the data. We also collected feedback on visual design preferences, points of comparison as well as selecting a subset of filters to drill down to some common key questions.

Results

Through our electronic PGD collection tool we captured a wide breadth of data from patients, including quality of life data obtained before and after treatment, a surgical experience questionnaire and a 10-day daily symptom tracker of adverse events post-surgery, as examples. For every instrument deployed we engaged clinicians to develop an analytical dashboard for tracking high level summary measures and measures of patient and system engagement, such as portal sign up rate, survey opening rate, completion rate and patient response times. In addition, a population-level dashboard was developed that allowed care teams to review aggregate patient responses. We found that in order for the clinical dashboards to be successfully adopted by clinicians it was important to normalize scores, to track changes in scores over time as absolute and relative differences, and to maintain consistency in scoring results based on directionality of the data across all questions asked.

Discussion and Conclusion

We have found that the most important factor in successfully integrating PGD into clinical care is the early engagement of clinician stakeholders in the design, deployment and data analysis phases of each project. This was addressed by creating workgroups around reviewing data, which become the standard operating procedure for each instrument. Each workgroup established a regular meeting time to review operational data and tracking of patient engagement metrics. They reflected on the quality of the data and requested changes to the instruments, such as a reduction in questions asked or tuning of notifications received by the care team. In summary, early clinician involvement in deployment of PGD collection, and visualizations of the data are key factors for success of PGD projects.

Trend Analysis of EHR Events to Facilitate Hypothesis Generation and Data Quality Assessment

Yohan Sumithipala¹, Vojtech Huser¹
¹Lister Hill National Center for Biomedical Communications, National Library of Medicine, National Institutes of Health, Bethesda, MD

Introduction

Common Data Models (CDMs) for Electronic Health Record (EHR) data facilitated the creation of software tools that help with data characterization and quality assessment. In 2016, an informatics group named Data Quality Collaborative (DQC; repository.edm-forum.org/dqc) proposed a set of pre-computed and highly stratified data characterization measures that produce comparable and standardized outputs from multiple common data models, such as Sentinel, Patient-Centered Outcomes Research Network (PCORnet) and Observational Medical Outcome Partnership (OMOP). DQC measures can be further analyzed without requiring access to sensitive patient-level data. Using these DQC data measures, our study develops methods for analyzing temporal trends in EHR events to identify trend patterns, such as significant decline in event prevalence, that lead to hypothesis generation, epidemiologic analysis, or a data quality inquiry.

Methods

Using DQC compliant measures from the Achilles tool, created by the Observational Health Data Sciences and Informatics (OHDSI) consortium, we analyze temporal EHR event trends for structured data about drug ingredients, drug products, procedures, lab results, and diagnoses. We use rule-based, statistical, and machine learning approaches to classify each temporal trend (such as use of a certain drug ingredient) into several categories (e.g. significantly rising, relatively constant, significantly declining, or indeterminate). Because the population observed within the dataset can change over time, we stratified the analysis by age decade (0-9, 10-19, etc.) and normalized the trends to prevalence per 1000 people. We used 1 year temporal intervals, to eliminate seasonal variation.

Our rule-based approach uses goodness of linear fit to determine clearly rising or declining events. In the statistical approach, we used an ARIMA model that can account for inherent autocorrelation of time series data. We also piloted a machine learning approach.

Preliminary Results and Discussion

Our analysis (written in the R programming language) utilizes CSV input files with DQC measures data. For OMOP datasets, we also created data extraction script that uses standard OHDSI R packages. The results presented below were generated using a claims dataset from the Innovation in Medical Evidence Development and Surveillance program of the Reagan-Udall Foundation for the FDA. To eliminate rare events, we only considered event-age decade strata with a minimum prevalence of at least one person per ten thousand people in at least one calendar year. To illustrate the size on three event types, we analyzed 1,689 drug ingredients, 12,488 procedures and 8,654 diagnoses. Illustrative results for ingredients are the following: 642 drug ingredients passed the minimum prevalence threshold, and a pre-defined trend category was assigned to 577 of them (34% of all 1,689 ingredients). Examples of rising ingredients include ondansetron, cefdinir, nebivolol, mupirocin, or gadobutrol; declining ingredients include tegaserod, isomethptene, nabumethone, verapamil or triamterene. Additional results for other event types are available on the project website (github.com/OHDSI/StudyProtocolSandbox/tree/master/OHDSITrends). We further developed methods that allow trend examination of multiple events related to each other into event groups (e.g., ingredient-drug class, drug product-drug class, ingredient-disease indication or procedure-procedure group). Our work has limitations inherent to the EHR-only population (rather than general population). Because a single dataset may not cover all age-decades, we also created a framework that aggregates significant trends across multiple datasets.

Clinical Machine Comprehension Using Case Reports

dr. Simon Šuster, prof. dr. Walter Daelemans
University of Antwerp, Antwerp, Belgium

Machine reading and text comprehension aim at complete large-scale understanding of natural language texts\(^1\). A system is expected to read a document and answer questions about it. The task, which resembles question answering, could have important applications in the clinical setting\(^2\). Recently, there has been growing interest in the development of machine comprehension algorithms and datasets, but these works are limited to the general newswire domain\(^3,4\). Our work represents a first step towards studying machine comprehension \textit{in the clinical domain}.

We set up a task in which a system is presented with a query (a sentence with a missing entity) and a document, and is then expected to infer the answer (the missing entity) from the unstructured document. Our dataset is constructed from BMJ Case Reports, the largest online collection of clinical case reports. Each case report includes a “Learning points” section which summarizes the document; we automatically create queries by taking each sentence in that section, identifying clinical concepts in it, and removing one concept. For example, from a report describing comorbid disorders of ADHD, we would obtain the query \textit{Patients with ADHD have higher incidence of \_\_\_\_\_\_\_.} The goal would be to correctly predict the missing entity \textit{enuresis}. As the phrasing in the summarizing sections of the case reports often differs from the one in the document, machine reading systems need paraphrasing and inference capabilities to provide the right answer, which makes the task challenging.

In the poster, we will report the performance of baseline vector-similarity matching and of a state-of-the-art reader based on recurrent neural networks. We will also show how evaluation poses a particular challenge: Often a good answer might be given, but which might not be exactly the same as the expected one. Returning to the example above, in addition to “enuresis”, an equally good answer would be “bedwetting”. We give credit to such answers by expanding the answer set with synonyms available from the UMLS\(^\text{TM}\) Metathesaurus\(^\text{TM}\). To find out how difficult answering is for humans, we carry out a manual analysis on a hundred document-query pairs. We report some of the dataset statistics in Table 1.

\begin{table}[h]
\centering
\begin{tabular}{|l|c|}
\hline
Number of clinical cases & 12300 \\
Average number of queries per case & 9 \\
Average length of a case (tokens) & 1414 \\
Number of “problem” answers & 74,000 (67\%) \\
Number of “treatment” answers & 24,000 (22\%) \\
Number of “test” answers & 12,000 (11\%) \\
\hline
\end{tabular}
\caption{Selected statistics of the case report dataset.}
\end{table}

Sharing exome sequencing data between Clinical Sequencing Labs and Healthcare Providers

Rajeswari Swaminathan, MS¹, Yungui Huang, PhD¹, Katherine Lintner, PhD¹, Matthew Pastore, MS, LGC², Sayaka Hashimoto, MS, LGC², Theodora Jacobson, MS, LGC², Danielle Mouhlas, MS, LGC², Simon Lin, MD, MBA¹

¹Research Information Solutions and Innovation, The Research Institute at Nationwide Children’s Hospital, Columbus, Ohio, USA; ²Institute of Genomic Medicine, Nationwide Children’s Hospital, Columbus, Ohio, USA

Introduction

Genome sequencing is being rapidly adopted for clinical diagnostics. Approximately 1 in 4 patients tested with whole exome sequencing gets diagnosed with a genetic disease. Clinical sequencing laboratories return a summary report of results to clinicians and in addition, with appropriate consent from the patient, may also provide the raw sequencing data in the form of FASTQ or VCF files. Although healthcare providers typically prefer to contact the ordering lab for a reanalysis of the data with emergence of new information in the knowledgebase, having access to the raw data provides them with the flexibility to take a deep dive into variants beyond those discussed in the clinical summary; this becomes important especially when patients decide to enroll in a research study. Currently, sequence data is either shipped through hard drives or transferred over the network and there is no strict protocol governing this process. We highlight the workflow of transfer established between our institution and a major clinical sequencing laboratory. We aim to understand the current state of genomic data exchange between healthcare providers and genetic laboratories and discuss some of the key lessons learned.

Methods

During the observation period of this study, from April 2016 to December 2016, the genetics clinic at our institution sent all clinical WES orders for their patients to one of the major clinical sequencing laboratories and tracked the entire process from consenting the patient to receiving the raw data. The Clinical Lab uses a “Managed File Transfer System” to facilitate the transmission of data between organizations. A detailed workflow of the transfer process is depicted in Figure 1

Results

The first lesson learnt is that the entire process is manually controlled, leaving room for errors. Email notifications are sent manually once the sequencing is complete and currently there is no easy way to know if all consent forms got received at the laboratory end. For 2 out of the 19 patients, data was available for download from Baylor but the consent forms were missing initially and took a while to be retrieved. Secondly, different patient identifiers were used through the entire process leading to confusion. 4 patients had a DNA Sample number mentioned in their consent forms, which is an identifier used by the clinical laboratory, whereas our institution uses Patient Name + DOB to uniquely identify a sample, thus demanding an extra mapping phase to complete the validation process.

Discussion

Consortiums like the Global Alliance for Genomics and Health provide a standardized interoperable genomics framework to assist data sharing between researchers and clinicians. [1]. In order to avoid the high costs associated with current genomic data transfer methods, data can be stored in centralized cloud based repositories and inter operable systems can be developed on top of it to provide seamless access to the data in a secure manner.

Identifying Disease Hierarchical Relation with Concept Embeddings and Distant Supervision

Lingyi Tang, MS, Yaoyun Zhang, PhD, Hua Xu, PhD
School of Biomedical Informatics, The University of Texas Health Science Center at Houston, Houston, TX, US

Introduction

The hierarchical relation, also called the hypernym-hyponym relation, is one type of essential relations to structure biomedical concepts in knowledge bases and ontologies. It is critical to support a wide range of biomedical applications. However, it is both time-consuming and labor-intensive to update the rapidly emerging biomedical concepts and their hierarchical relations manually. Moreover, current works in this field mainly leverage lexical-syntactic patterns and domain knowledge to extract hypernym-hyponym relations from biomedical text, which can only cover a small proportion of complex linguistic structures. To address these problems, this study proposed to apply a novel word embedding-based approach developed by Fu et al. 1,2 to identify hypernym-hyponym relations between concept pairs, with identifying disease hierarchical relations as the use case.

Method

As illustrated in Figure 1, our automatic system for disease hierarchical relation identification is built on the distant supervision framework. Firstly, distributional word representations (i.e., embeddings) trained from the abstracts in the MedLine corpus are used to generate distributional representations of disease concepts. Then we further expand the original method to accommodate multiple-word concepts, by integrating single-word embeddings to construct distributional representation of multiple-word concepts. Next, existing knowledge of hypernym-hyponym relations in the Disease ontology is employed to train the relation identification model, without any manual annotation. To further improve the relation identification model, samples are first clustered into different groups, each of which represents a similar disease category, and an identification model is then built for each cluster using the logistic regression algorithm based on concept embeddings.

Results & Conclusion

Evaluation with a test set of relations in the Disease ontology demonstrated that the performance of our proposed approach is promising, with a precision of 82.18%, a recall of 83.00% and a F-measure of 82.59%. Figure 2 illustrates the learning curve of the hierarchical relation identification model by tuning the relative error threshold of the logistic regression algorithm. We will leverage additional ontologies such as UMLS and SNOMED-CT to expand our training set in the next step. Furthermore, we will develop such embedding-based novel approaches for extracting hypernym-hyponym relations of other concept types such as chemicals and genes in the biomedical domain.

A Practical Scientific Workflow of Sharing Large Selected Dataset from Clinical Research Data Repository

Shiqiang Tao, PhD¹, Steve Roggenkamp, BS¹, Guo-Qiang Zhang, PhD¹
¹Institute for Biomedical Informatics, University of Kentucky, Lexington, KY

Abstract
Clinical research data repositories allow researchers to navigate and select target dataset and download it under certain data use agreement, but the data downloading efficiency and reliability become challenges when the selected data set is very large (terabyte level). To address these challenges, we implemented a data sharing workflow which integrates rsync for efficient and reliable file transferring and SSH for authentication. Our preliminary results showed that the new scientific workflow achieved more than 10 times of the reliable file transferring speed compared to previous HTTP file downloading.

Introduction
The Center for SUDEP Research (CSR) ¹ is a the NINDS-funded Center for SUDEP Research. CSR built a central data repository integrating epilepsy data captured from participating institutions. This central data repository provides a much larger patient data pool for Analysis. In addition, CSR informatics core created a comprehensive infrastructure called MEDCIS² to manage researchers’ access to the data repository. MEDCIS allows researchers to navigate patient data by characteristics such as demographics, diagnoses, medications, and symptoms. Researchers can build queries by customizing those characteristics and then retrieve the data set that matches the queries. MEDCIS previously provides a web interface for downloading the selected data set, but it is not ideal in neither speed or reliability. In this work, we describe a workflow designed for MEDCIS that can practically handle terabyte-level data downloading reliably and securely.

Methods
We designed a scientific workflow of 9 steps illustrated in Figure 1. First of all, we create a shared account on the CSR data server only for data downloading purpose. The workflow starts by generating a pair of SSH keys: a public key and a private key. Researchers keep the private key and upload the public key to MEDCIS. The public key is added to the authorized keys of the shared account on CSR data server. Then researchers continue to use MEDCIS to finish their data selection process. After that, researchers can generate a data downloading request letting MEDCIS know that they want to download data using the new workflow. A unique data-download token is generated together with the creation of the data downloading request. MEDCIS creates a folder with the token as the name and prepares all selected data files under that folder. At last, MEDCIS sends back a command to researchers with which they can start to download the data. The command uses rsync to handle data transfer and the authentication is done automatically by the SSH key configuration.

Results
CSR central data repository is located at Case Western Reserve University in Cleveland. We moved 215 files of total size 31.3 GB data to University of Kentucky in Lexington, which took 46.5 minutes with an average file transfer speed 11.2MB per second. Data transfers to University College London showed that data transfer among different continents could also achieve speed around 10 MB per second.

Conclusion
We design and implement a scientific workflow for sharing accurately selected data set from large clinical research data repository. Our preliminary test suggests that the workflow can achieve a practical transferring speed for terabyte-level. The workflow simplifies the authentication using SSH keys and with rsync, it can pick up from where it is left off if interrupted.

Developing a framework for a comprehensive data-sharing program
Asba Tasneem, PhD, Karen Chiswell, PhD, Brian McCourt, Matt Gross, Eric Peterson, MD, MPH, Michael Pencina, PhD
Duke Clinical Research Institute, Durham, NC, US

Introduction
There has been a surge in calls to improve transparency in clinical research.⁴ In response, many in academia and industry have developed platforms for sharing clinical trial data.⁴ The Duke Clinical Research Institute (DCRI) launched Supporting Open Access for Research (SOAR)—an initiative that includes the DCRI, academia, and industry designed to enable clinical research data sharing for the benefit of the broader research community. Under SOAR, Bristol-Myers Squibb (BMS) collaborated with the DCRI to enhance transparency of its clinical trial data-sharing program.⁵ In separate collaborations with SAS Institute, Inc. (SAS) and the American Heart Association (AHA), the DCRI has made accessible to researchers data from the Duke Databank for Cardiovascular Disease (DDCD).⁶,⁷

Methods
We developed a workflow to improve operational efficiency in processing data-sharing requests. Data requests (including data use agreement) are assessed for completeness, then reviewed by the SOAR-appointed Independent Review Committee (IRC) with expertise in biostatistics, research ethics, patient privacy, and the clinical specialty of the proposal. Upon approval from the IRC, the de-identified dataset(s) are provisioned for use via a secure analytics environment. The IRC also reviews the results prior to submission to assess concordance with the stated analysis plan.

Results: Analysis datasets, Secured environment, and Governance

Datasets: The DDCD is among the largest and oldest single-site cardiovascular databases in the world. The DukeCath analysis dataset, extracted from the DDCD and de-identified, includes ~150,000 cardiac catheterization procedures conducted in ~84,000 adult patients at Duke between 1985 and 2013. The DukeCath dataset is shared in two ways: 1) the de-identified research dataset is made available through SAS and AHA platforms; 2) an anonymized educational dataset is available via the SAS platform or direct distribution.⁵,⁷

Environment: The datasets are provisioned to investigator(s) in a secured analytics environment where access is controlled at user level and all exports of patient-level data are restricted without additional approvals. The analytics platform is equipped with statistical analysis tools to aid research analysis. The SAS environment provides SOAR sharing and analytical capabilities plus opportunity for collaborative analysis with industry datasets. The AHA Precision Medicine Institute platform (in development by Amazon Web Services) provides sharing and analytical capabilities plus prospective integration with related cardiovascular clinical and laboratory data.⁶

Governance: The Duke University Institutional Review Board approves all SOAR practices and use of the DukeCath data. The SOAR IRC reviews and evaluates each request for 1) statistical analysis plan, 2) plan to protect patient privacy, 3) dissemination plan, and 4) qualification of the investigator(s). BMS uses SOAR IRC services for reviewing in-scope proposals. As of February 2016, all eight BMS requests were approved by the IRC for data sharing and the first DukeCath researcher is accessing the production system.

Conclusion
The primary purpose of the SOAR program is to facilitate open sharing of clinical research data with responsible researchers to promote open science and allow investigators to verify reported results as well as pursue interesting secondary uses of existing data. This increased transparency will inform science and improve patient care. We plan to evaluate additional clinical research datasets and share eligible datasets with researchers and educators.

An Evaluation of Syntactic Dependency Parsers on Clinical Data
Stuart J. Taylor, BS\(^1\), Travis R. Goodwin, MS\(^1\), Sanda M. Harabagiu, PhD\(^1\)
\(^1\)University of Texas at Dallas, Richardson, Texas

Introduction
With electronic medical records becoming more widely adopted, the potential to extract information from the narratives in medical records is increasing. In clinical decision support systems, quality control, medication reconciliation, and other biomedical applications\(^1\), Natural Language Processing (NLP) techniques can be used to automatically discern knowledge from text. The accuracy of NLP techniques often heavily depends on the type of data used to train or develop them. Advanced NLP techniques – like semantic role labeling – require accurate syntactic parsing. Syntactic parsing reveals the syntactic structures (e.g. trees) in which words participate and discovers the syntactic roles of the words in a sentence. In this work we evaluate whether existing annotated clinical text is sufficient to train state-of-the-art neural parsing methods.

Methodology
We used the MiPACQ\(^1\) clinical text corpus with a random 17:1:2 split for training, development, and testing. We trained and evaluated two neural parsers: (1) Stanford’s greedy transition-based parser\(^2\); (2) SyntaxNet\(^5\), Google’s globally normalized transition-based parser; and two non-neural parsers: (3) OpenNLP’s\(^\ast\) chunking shift-reduce parser; (4) ClearParser\(^3\), a shift-pop transition-based dependency parser used by cTAKES\(^4\). Additionally, we evaluated the performance of each parser on clinical text when using their general (i.e., non-clinical) pre-trained models.

Results
We computed the Unlabeled Attachment Score (UAS) on the clinical test data to perform our evaluations. The UAS is the percentage of words which have the correct syntactic head. Syntactic heads are used to encode parent-child relations in a parsing constituent (e.g. in “stimulation increases flow” the noun “stimulation” is the child of the verb “increases” because the verb is the head of the phrase and there is a NOMINAL SUBJECT relation between the head and the noun). The results on the test set are shown in Table 1. The UAS-G column shows the UAS score for each parser when using the pre-trained general-purpose model, and the UAS-C column shows the UAS score after training each parser with the clinical training data.

</tr>
<tr>
<td>ClearParser</td>
<td>39.11%</td>
<td>83.08%</td>
</tr>
<tr>
<td>SyntaxNet</td>
<td>63.76%</td>
<td>85.19%</td>
</tr>
</tbody>
</table>

Conclusion
While SyntaxNet performed the best after training on clinical text, all parsers showed improvement. These results suggest that the MiPACQ corpus is sufficient to train neural syntactic parsers. Interestingly, the parsers which performed the best with the pre-trained model performed the worst after being trained on clinical text. Directions for future research include: (1) tuning hyper-parameters; (2) incorporating more training data; and (3) evaluating on additional types of clinical data.

Overcoming Policy and Operational Challenges for Health Data Exchange Using a Validation Service for Patient to Provider Relationships

Sidney N. Thornton, PhD1,2, Shan He, PhD1, Darren K. Mann, BS1, Iona Thraen, PhD2,3, Matt Hoffman MD4, Wu Xu, PhD2,3
1Intermountain Healthcare, Salt Lake City, UT; 2University of Utah; 3Utah Department of Health, Salt Lake City, UT, 4Utah Health Information Exchange, Salt Lake City, UT

Introduction

The network of connectivity between healthcare systems broadens for Health Information Exchange, yet workflow barriers persist. Useful data do not always arrive at the right place in time to make informed decisions. Available data from external sources is frequently left unviewed and unincorporated in the provider’s system. Disclosures of patient data solely for undesignated future access is suboptimal for privacy and risk management policies. Intermountain Healthcare, an integrated delivery network serving Utah and southern Idaho, creates more than 18,000 clinical summaries every day for exchange, but until recently, has witnessed only a few dozen records accessed daily by the community care team. Workflow automation of data integration has been complicated by data quality concerns that can be rectified in part through relationship validation. Other policy barriers to external data usage include local rules prohibiting the open exchange of the state government held data. Recently, stakeholders in Utah described an exchange framework (ThSisU)1 to accommodate policy and operational concerns that would facilitate workflow automation for external data integration. The framework includes a foundational component to automatically validate patient-to-provider treatment relationships using central data governance. Standard-based exchange protocols initiate the relationship validation services that in turn call encounter or registry services convenient to the local system as trusted sources of patient and provider relationship data.

Methods

Three early adopter use cases are examined to determine how the relationship validation service improves the appropriate and timely uptake of inter-organizational data, while balancing local policies and privacy interests. The first use case uses an administrative scheduling process as a source of attestation of relationship to automatically pull clinical summary data (Cross Community Access/XCA) into the external organization EHR. The second use case leverages the patient matching service (Cross Community Patient Discovery/XCPD) to access a provider attestation list that in turn sends a filtered view of the facility encounter notifications to the external notification service. The third use case requires the relationship validation to link government Fact of Death information to the external provider organization (XCPD and Cross-Enterprise Reliable Document Interchange/XDR).

Results

In use case 1, the population of persons whose health care is shared across the exchanging organizations exceeds five thousand daily encounters. Appropriate data integration for patients with validated providers in both organizations improved from less than 1% to over 60% with improved workflow and data quality. In use case 2, nearly 2.5% of the facility encounters have attested relationships that are received by the external providers. With the implementation of the relationship validation service, nearly 24,000 daily PHI events are protected from inadvertent disclosure thereby supporting the local policies of minimum necessary data while still meeting the community purpose of the notification system. In use case 3, attestation of patient-to-provider relationship through the patient matching process has enabled the incorporation of Fact of Death data from 0% (since 2014) to over 99% in a manner acceptable to policy of the State’s Risk Management.

Discussion and Conclusion

Additional use cases are in various stages of development for care coordination, public health, and shared financial risk that will leverage the statewide service for patient-to-provider relationship validation. The centralized function of the relationship validation service adapts to a variety of technical platforms suggesting reasonable scalability. Simpler transactions and workflow automation would be supported by a single authoritative source of relationships with central data governance. Future investigations will study workflow behavioral tied to system enhancements.

Assessing Data Quality within Health Information Exchanges: 
A Case Study for Supporting Emergency Department Research

Margaret M Thorsen, BA1, Indra Neil Sarkar, PhD, MLIS1,3, Elizabeth Chen, PhD1,3, 
Elaine Fontaine, BS2, Gregory Walker, PhD2, Megan Ranney, MD, MPH1,4 
1Alpert Medical School, 3Center for Biomedical Informatics, 4Department of Emergency 
Medicine, Brown University, Providence, RI; 2Rhode Island Quality Institute

Introduction
Health information exchanges (HIEs) support the potential for improving healthcare quality, reducing unnecessary 
treatments, and promoting provider communication. Most HIE research to date has focused on issues of usability, 
implementation, and clinical decision making.1 The utility of HIE data for clinical research and population health 
analyses has yet to be fully explored.2 For instance, HIE data from state-based exchanges could be a source of 
robust, multi-source data to inform public health surveillance and interventions. However, little is known about the 
quality of HIE data for enabling their use for research purposes. Emergency Department (ED) data are well-suited 
for exploring HIE-based clinical research, as the ED is accessible to patients irrespective of health insurance status, 
referral, or ability to pay. Furthermore, EDs have started to engage with HIEs3 for conducting clinical or population 
health research. The objective of this study was to conduct a preliminary characterization of data quality within a 
single, statewide HIE and provide an early perspective on the challenges in using HIE data for supporting 
subsequent retrospective research studies. We also sought to compare the quality of HIE data to institutional EHR 
data (a typical source for research) – both in terms of representativeness and of meeting HIE standard requirements.

Methods
Rhode Island’s opt-in HIE, “CurrentCare,” is owned and operated by the Rhode Island Quality Institute (RIQI). 
Over 350 practice sites in Rhode Island, including all major hospital networks, use CurrentCare (comprised of 442 
data sources). Fifty percent of statewide ED visits in Rhode Island occur at a single hospital network. De-identified 
data from this hospital EHR and CurrentCare were analyzed in aggregate for all patients who had visited an ED in 
the hospital system between August 1, 2015 and March 31, 2016 focusing on: age, gender, race/ethnicity, diagnosis 
codes, problem list, Primary Care Physician status, and disposition. This study was deemed exempt by the IRB. The 
content of the CurrentCare HIE data fields of interest were compared to terminology standards (e.g., those defined 
for the HL7 Continuity of Care Document [CCD]).

Results & Discussion
Sample size, mean age, gender, and primary care access were determined. Disposition, race, and ethnicity were the 
most challenging to map to a standard. For instance, more than 40 non-standard values were found in the HIE data 
for race. This study revealed data standardization challenges, which are an artifact of multi-source HIEs, which can 
pose significant barriers to the prospective use of HIE data for research. Next steps will include the development of 
systematic methods for mapping heterogeneous values for similar concepts to recognized standards, further 
exploration and addressing data quality issues (e.g., accuracy and completeness), and examination of the use of HIE 
data in comparison to ED patient records from the electronic health record (EHR), a widely used source for research 
data. Collaboration between clinicians, hospitals, EHR vendors, clinical informaticians, and HIE curators is essential 
for the future success of HIEs as both a statewide clinical and research tool. Future efforts should quantify these data 
discrepancies and explore strategies for overcoming these barriers to enable HIE-based research without changing 
data collection processes.

Customization of a Commercial CPOE System to Improve Patient Safety

Clare L. Tolley MPharm1, 2, Neil W. Watson MBA MSc 2, Andrew Heed2, Andrew K. Husband PhD MSc4, David W. Bates MD MSc3, 4, 5, Sarah P. Slight PhD MPharm PGDip1, 2, 3

1School of Medicine, Pharmacy and Health, Durham University, U.K.; 2Newcastle upon Tyne hospitals NHS Foundation Trust, U.K.; 3The Center for Patient Safety Research and Practice, Division of General Internal Medicine, Brigham and Women’s Hospital, Boston, MA, USA; 4Harvard Medical School, Boston, MA, USA; 5Harvard School of Public Health, Boston, MA, USA.

Abstract: This study explored how a commercial CPOE system had been customized by both the organisation and users following implementation, and what benefits and challenges they faced. Certain work processes became more efficient and safer; however, some system design issues and a limited use of Clinical Decision Support (CDS) prevented the users from realizing its full potential.

Introduction: The Health Information Technology for Economic and Clinical Health (HITECH) Act encouraged widespread adoption of commercial Computerized Provider Order Entry (CPOE) in the U.S.1 Once implemented, these systems are often customized to improve their usability, patient safety and quality of care. The aim of this study was to explore how a world-leading, commercial CPOE system had been customized after its implementation in a large U.K. teaching hospital, and what the benefits and challenges were.

Methods: We obtained the necessary ethical and institutional approvals, and recruited staff across four adult wards (renal, cardiology, general medicine and surgery) in a U.K. teaching hospital and members of the implementation team. One researcher conducted 32 unique semi-structured interviews with doctors (n=16), nurses (n=8) and pharmacists (n=8) between Mar ‘15 and Aug ‘16, lasting between 17-70 minutes and performed 35 hours of ward-observations. Users were asked about their experiences of using the system and any customized features. All interviews were transcribed verbatim and the transcripts checked. These data were analysed using the framework approach, which supports an inductive approach to theory development, where there are pre-set aims and objectives. Qualitative data analysis software NVivo version 10 was used; a list of themes were developed inductively, using the ‘constant comparison’ technique and explanations for recurring patterns in these data were sought, discussed amongst the research team, refined and presented.

Results: Participants highlighted a number of key benefits and challenges with CPOE customization. 1) Some users changed the screen layout to improve the visibility of important information (e.g., a medication’s stop date). However, this came at a cost, as other information was now no longer visible; one nurse was concerned she was ‘missing drugs and doses’ (P4; Nurse). 2) The organization developed order sentences and order sets to improve the safety and efficiency of certain tasks, such as prescribing regimes that were error prone, which was considered “a really good way of preventing that error from happening again”(P30; Pharmacist). However, some users had difficulties remembering the ‘key trigger words’ to identify them, which limited their use. 3) Tailored alerts such as a warning issued to nurses if they were about to administer acetaminophen too early, improved the safety of the administration process. However, some users reported insufficient use of alert functionality and actively requested that more alerts e.g., drug-drug interactions for high-risk combinations be switched on (e.g., if multiple drugs that cause bleeding were prescribed). 4) The organisation modified the system to enable blood glucose levels to be reviewed and insulin to be prescribed electronically and reviewed from the same screen. However, if prescribing remotely, there was “a danger of just looking at a computer screen,(...) and going “oh right, yeah, the BM [blood glucose level] is high let’s give them something”, but you don’t actually know what’s going on’(P23; Pharmacist). 5) The organisation developed a pharmacy task list, which helped users efficiently target high-risk patients, but some warned it lacked the sensitivity to identify all cases and patients could be overlooked.

Conclusions: Users described several benefits and challenges in customizing this system and the effect on patient safety. Further research should focus on whether similar problems have emerged with other commercial systems and how to address these, and whether customisation had any measurable impact on patient outcomes.

A Random Forest Model for Detecting Somatic Mutations from Unpaired Cancer Samples

Sophie Tu, PhD¹, Bin Zhou, MS¹, Da Wei Huang, MD², Roland Schmitz, PhD², George W Wright, PhD², Louis M Staudt, MD, PhD², Calvin A Johnson, PhD¹

¹Center for Information Technology, National Institutes of Health, Bethesda, MD; ²National Cancer Institute, Bethesda, MD

Introduction

Due to the complexity of cancer genome rearrangement as well as sample impurity and sub-clonal mutations, regular SNV callers such as GATK and HaplotypeCaller, which rely on a ploidy assumption, do not work well on whole exome cancer samples. MuTect2¹, which was specifically developed for such a situation, albeit with paired-normal samples, is regarded as one of the most reliable cancer SNV callers². However, cancer genome studies without paired normal samples cannot take advantage of tools such as MuTect2. In this work, we hypothesize that a machine-learning model can be trained from MuTect2 scores on paired samples to detect somatic mutations from toxicity scores.

Methods and Results

We downloaded 37 cancer-normal pairs of diffuse large B-cell lymphoma (DLBCL) exon-seq datasets from The Cancer Genome Atlas (TCGA). The fastq sequencing files were first aligned to the human genome HG19 via BWA according to TCGA guidelines. MuTect2 was used to make both somatic and germline SNV calls. Those calls that passed statistical filters and fell into coding regions were added to the training and holdout sets. A random forest model was trained on a total of 4990 calls from these samples. The feature space comprised intrinsic data such as mutation rate, read depth, and duplication status as well as scores from 24 toxicity assessors (e.g. SIFT, PolyPhen2, etc.) Figure 1 compares the ROC of the random forest model with the sensitivity and specificity scores of the individual toxicity callers. Other classification methods similarly demonstrated the benefit of aggregating toxicity scores as a feature-space representation in discriminating between somatic and germline mutations.

Conclusion

As our results suggest that the random forest model can achieve a high degree of agreement with MuTect2, we believe that this classifier can be a useful tool to filter SNV lists derived from regular mutation callers on sequencing data from cancer samples when matched normal samples are not available.

A Decision Support Tool to Help Providers Address Perinatal Depression

Bengisu Tulu, PhD¹, Nicolas Adami-Sampson¹, Trivani Shahi¹, Nicholas Shannon¹, Leif Waugh¹, Drew Wethern¹, Nancy Byatt, DO², Tiffany A. Moore Simas, MD², Kathleen Biebel, PhD²

¹Worcester Polytechnic Institute, Worcester, MA; ²University of Massachusetts Medical School, Worcester, MA

Introduction

Perinatal depression, the most common complication related to childbirth, affects approximately 1 in 7 pregnant and postpartum women and is often under-recognized.¹ Currently, obstetric providers face challenges in diagnosing perinatal depression efficiently and effectively partially due to lack of access to validated decision support tools for diagnosis. We developed a mobile app that guides obstetric providers through the process of screening and assessing patients for perinatal depression, and identifying appropriate stepped treatment options for patients who screen positive.

Methods

Using Ionic open source framework and rapid application methodology, we developed a multi-platform (web, iOS, Android) app and evaluated its usability. After developing a paper prototype, we implemented the first prototype and conducted a usability study with seven participants who were obstetricians. During the interviews, participants were asked to use the app and comment on its features and ways the app can be improved. We developed a second prototype based on these comments and conducted a second usability study with 12 obstetricians in a focus group setting.

Results

The app is designed to provide evidence-based guidance to the obstetric providers based on the Edinburgh Postnatal Depression Scale (EPDS) score of a patient. After a user provides the EPDS score, the app navigates through the decision algorithms to determine the most appropriate course of action for the providers to suggest based on the severity range determined using the EPDS score and the evaluation conducted by the providers. We asked 12 participants in our focus group to spend some time using the app before they engaged in discussion and took a brief survey. Table 1 presents survey responses (5-point Likert Scale) we gathered from 12 participants.

Table 1. Usability Focus Group Survey Responses

<table>
<thead>
<tr>
<th>Questions</th>
<th>Mean</th>
<th>Std. Dev.</th>
</tr>
</thead>
<tbody>
<tr>
<td>How valuable would this app be in clinical settings? (1-Not Valuable, 5- Very Valuable)</td>
<td>4.67</td>
<td>0.492</td>
</tr>
<tr>
<td>How useful would this app be to you? (1-Not Useful, 5- Very Useful)</td>
<td>4.75</td>
<td>0.622</td>
</tr>
<tr>
<td>How would you rate the app’s design? (1-Poorly designed, 5- Well Designed)</td>
<td>4.33</td>
<td>0.778</td>
</tr>
<tr>
<td>How often do you see patients for whom this app might be useful? (1-Almost Never, 5- Very Often)</td>
<td>3.75</td>
<td>0.866</td>
</tr>
</tbody>
</table>

Conclusion

Usability studies reported in this abstract showed that the app satisfies a need and the app can be useful in clinical settings. We received a number of requests to continue using the app after the focus groups. Given the demand for this decision support app, we are planning to evaluate the feasibility and effectiveness of using an easily accessible mobile health based pocket tool for perinatal depression decision support in clinical settings in our next study.

Creating RDF Data on Trauma Care Organizations from Questionnaires

Joseph R. Utecht, BA\textsuperscript{1}, Jonathan P. Bona, PhD\textsuperscript{1}, Mathias Brochhausen, PhD\textsuperscript{1}
\textsuperscript{1}University of Arkansas for Medical Sciences, Little Rock, AR, USA

Background

Assessment of trauma systems and trauma centers positively affects patient outcomes\textsuperscript{1,2}. However, assessment of these organizations often falls short because of a lack of comparability regarding organizational components and their implementation. The CAFE project (https://cafe-trauma.com) addresses this problem by enabling comparison of different roles (e.g. trauma medical director), the different components (e.g. multidisciplinary stakeholder group) and their requirements, privileges, and obligations, which we have found to be different from organization to organization. To allow the comparison of these properties in a web-based self-assessment environment we use semantic web technologies. To this end we develop a user-friendly questionnaire allowing respondents to enter data stored in RDF to compare organizational components in real time. This approach has two immediate benefits: a) we take advantage of the graph-based nature of RDF to easily produce graphical representations of organizational structures, and b) we use built-in automated reasoning in combination with OWL ontologies to classify and uncover differences between superficially identical organizational roles and components. A key ontology developed specifically for our applications is the Ontology for Organizational Structures of Trauma Centers and Trauma Systems\textsuperscript{3}.

Methods

To support our requirement of allowing user-friendly data entry, we developed a tool to create the appearance of a traditional web questionnaire. To prevent any interruption for the respondent while the server processes previous answers, we chose to build the interface as a separate web application in Angular2 (https://angular.io). To provide semantically-rich data, the server-side component will not only record the answer in a relational database, but simultaneously create a pre-configured RDF (https://www.w3.org/RDF) representation of the answer in a triplestore.

Results

The result of this work is available on Github (https://github.com/cafe-trauma/documentation). Fig. 1 shows the steps of acquiring RDF data through a questionnaire built using our tool. The first step is the creation of the questions, for example “Does your trauma center have a trauma registrar?” Next the administrative user defines the RDF representation for the answers, in this case, the representation of the trauma registrar, the trauma center, and the fact that the trauma registrar is an organizational member of that trauma center. The tool then builds a traditional web questionnaire with a yes/no question “Does your trauma center have a trauma registrar?” As respondents answer this question the RDF representation is created in a triplestore and their answer is recorded in a relational database. From the respondent’s point of view the questionnaire does not differ in any way from a typical web questionnaire.

Discussion

Once the CAFE project is finished our aim is to use the ontology and the data created to link it to outcome data. The methodology presented in this paper is not restricted to the domain of the CAFE project, but is applicable to multiple domains of biomedical research and medicine. In addition to trauma care, we have also successfully implemented questionnaires collecting data on potential drug-drug interactions using this methodology.

Acknowledgements

The research presented in this paper is funded by the National Institute of General Medical Sciences of the National Institutes of Health under award number 1R01GM111324.

Systematic Evaluation of Smartphone Applications on Spinal Cord Injury Self-Management

Gary Vargas¹, Spyros Kitsiou, PhD², Ben Gerber, MD., MPH¹
¹College of Medicine ²Department of Biomedical & Health Information Sciences, University of Illinois at Chicago, Chicago, IL 60612

Introduction

Smartphone applications (apps) have been gaining popularity in lifestyle and chronic disease self-management. However, little information is available on apps that address chronic spinal cord injury (SCI) management and prevention of complications. This study aims to conduct a content analysis of the functional characteristics, consumer interaction features, and usability of mHealth apps currently available in the Google Play store for self-management of chronic complications of spinal cord injury.

Methods

A comprehensive search was performed between October 22 and 29, 2016, in the Google Play store to identify SCI-related apps using relevant keywords (e.g. spinal cord injury, paraplegia, and autonomic dysreflexia). Inclusion criteria included apps that were free, provided education, symptom monitoring, or self-management of aspects relevant to SCI and were available in English or Spanish. Apps that were provider-focused, aimed at phone accessibility features, or were limited to only users with app-specific access rights were excluded. One author (GV) systematically assessed apps using an evaluation tool that incorporated multiple content and usability criteria. PubMed and clinicaltrials.gov were also queried to investigate whether any of the identified apps have been evaluated in pilot studies. iOS apps were not included due to time and resource constraints.

Results

Out of the 702 search results, twenty-eight apps met the inclusion criteria and were evaluated. 18% (n=5) of apps were specifically targeted at SCI pts. 14% (n=4) and 68% (n=19) were aimed at patients with disabilities and the general public, respectively, but had functionality that overlapped with SCI patients. Of the apps evaluated, 32% (n=9) provided SCI education, 57% (n=16) symptom monitoring options, and 54% (n=15) supported SCI self-management regimens. Multiple apps were dual-focused. The most common SCI topic included bowel and bladder education and management. Topics rarely addressed were respiratory, sexuality/fertility, pressure ulcer, and travel/transportation management. Only 3 education-focused apps cited organizations or scientific studies as references. Common monitoring features included bowel and bladder management (32%, n=9; 32%, n=9, respectively), followed by medication (18%, n=5), pain (14%, n=4), and blood pressure monitoring (14%, n=4). Forty percent (n=11) of apps included reminders and alarms for scheduled medications and bowel/bladder programs. 11% (n=3) also included treatment strategies for autonomic dysreflexia. Usability varied widely among all apps. Seven percent (n=2) of apps crashed at least once during testing. 71% (n=20) of the apps used images to support educational information or display user monitoring trends. Twenty-two percent (n=6) included graphs/images that lacked labeling of axes/lines or had minimal contextual information to support them. No associated pilot studies were found for any of the apps evaluated.

Conclusion

There are few Android apps designed specifically for SCI patients available. Also, there is much variability in usability, educational content, symptom monitoring, and self-management options in those that do exist. As no pilot studies were found for the apps evaluated, it remains unknown whether these apps can improve self-management for chronic SCI patients or support caregivers’ efforts in SCI management. Given that 20% of yearly recurring costs for chronic SCI patients represents home health regimens, and that preventable conditions such as urinary and skin complications contribute to other costly emergency hospitalizations, these self-management apps may present an additional means of improving self-management regimens, preventing complications and decreasing costs. Future work must evaluate the iOS and web apps available to SCI patients.

Representation and Validation of Reference Content Sources Within a Commercially Available Knowledge Management System

Christopher Vitale PharmD,1 Priyaranjan Tokachichu MD,1 Daniel Kim,1 Margarita Sordo PhD,1,2,3 Saverio Maviglia MD, MS,1,2,3 Roberto A. Rocha MD, PhD1,2,3
1Clinical Informatics, Partners eCare, Partners Healthcare System, 2Brigham and Women’s Hospital, 3Harvard Medical School, Boston, MA

Introduction
The effective integration of reference terminology sources (e.g., SNOMED CT, LOINC) within knowledge and terminology engineering processes is a critical requirement to enable the creation and maintenance of interoperable knowledge assets [1]. At Partners, we implemented a multi-step process to normalize, import, and validate reference sources using a commercially available knowledge management system (KMS) [2]. Once integrated, reference terminology concepts can then be easily linked to local knowledge artifacts, allowing not only streamlined authoring, but also effective management of dependencies as sources evolve over time.

Methods
We developed a semi-automated process that (a) verifies the integrity of a new reference content release file, (b) identifies content changes by comparing to a prior release, (c) classifies identified changes as new, revision, or deprecated, (d) creates a new code system revision to bundle all identified changes within the new release, and (e) transforms changed content into the normalized meta-schema used by the KMS. At the end, this process generates an XML file that is used to import new release content into the KMS. The KMS implements a well-defined asset lifecycle and custom validation rules to manage dependencies between code system revisions. Gaps and inconsistencies are automatically verified during import based on preconfigured rules, generating error logs that guide improvements. Customized portions of the process are required for each content type due to source files that use non-standard formats, as well as to target specific previously identified error types.

Results
We have successfully integrated multiple reference terminology releases using the KMS tool (see Table 1). The integration of a new source includes an initial modeling effort to faithfully represent the reference content using the KMS meta-schema, plus the configuration of the software tools used during the semi-automated process. Once the first release of a given reference source is successfully imported into the KMS, subsequent releases require less effort, unless errors are identified. We have identified and reported over 4200 errors in various releases.

Table 1: Reference terminologies integrated with the knowledge management system (KMS)

<td>Inconsistent concept metadata</td>
</tr>
</tbody>
</table>

Conclusion
Integration of reference sources with local knowledge artifacts is necessary to support interoperability and knowledge sharing. Although the representation of reference terminologies within a KMS is a continuous and time-consuming process typically performed by content vendors, doing so locally allows for detection and resolution of content errors via customized validation rules, as well as prevention of future errors through ongoing dependency management. Implementing such processes can take an experienced clinical informatician weeks to months, but once in place takes minutes to execute. Efforts to normalize and validate reference sources would be greatly simplified if they were distributed using standard formats, such as Common Terminology Services 2 (CTS2) [3].

Toward Integrated Memory Assessment in Primary Care

Lisa M. Vizer, PhD¹, Daniel Kaufer, MD¹
¹University of North Carolina, Chapel Hill, NC

Introduction
Alzheimer’s disease (AD) and neurocognitive disorders (NCD) present a daunting economic and psychosocial challenge to families, healthcare systems, and society. We are seeing a rapid growth in those affected—estimated at more than 5 million in the US—coupled with a lack of therapeutic interventions. To achieve therapeutic success with NCD, patients’ cognitive decline must be identified early. Although cognitive screening for early detections is required during the Medicare Wellness Visit (MWV), we lack a standard protocol. Thus, primary care clinicians face a requirement with unclear standards, methods, and billing procedures, leading to inconsistency and inadequate documentation across the healthcare system. Additionally, scant resources are available to primary care physicians once they identify patients needing follow-up. Primary care physicians are currently unable to bill for cognitive testing as part of the annual MWV, and may not have access to guidance on interpretation of test results. Thus, we describe a proposal for combining cognitive screening and follow-up assessment for people with suspected NCD.

Proposed Solution
The senior author and colleagues conducted a randomized controlled trial evaluating an educational intervention on memory disorders care for primary care providers (Lathren et al., 2015). Data from this study show that while primary care providers could efficiently integrate cognitive screening into their practice flow, referring patients for a comprehensive memory disorders evaluation remained problematic. Ongoing work led by the senior author investigating a tablet-based cognitive testing protocol has also identified that many individuals who test positive on a memory disorder screen are not aware that they have a problem. To address these problems we propose a system for cognitive screening and triage along with a billable follow-up neurocognitive assessment protocol. This procedure is designed to support the annual MWV in primary care settings and provide remote consultative assistance to primary care physicians regarding need for follow-up. This approach will help distinguish AD and non-AD clinical profiles using a tablet-based screener; positive screens for possible AD will then return to the primary care setting for a remote-access, computer-based neurocognitive assessment similar to what is typically conducted in a memory disorders clinic. The tablet-based and computer-based testing will incorporate standard assessments adapted to administration in primary care along with novel assessments designed to provide a more holistic approach to cognitive screening. The multidimensional nature of the screening will help identify specific non-AD symptom profiles to prompt referral to a memory clinic and facilitate identification of extenuating factors contributing to cognitive complaints (e.g. sensory impairment, depression).

If screening indicates, the system will prompt a computer-based neurocognitive assessment that will meet Medicare guidelines for a billable procedure. A primary care clinic can use the new G0505 code for “Cognitive and functional status exam” or a clinic visit code for the primary care venue and a procedure billing code for the memory care clinic remote-testing service. Ultimately, we envision physician extenders (e.g. nurse practitioners) collaborating on test supervision and follow-up planning in the primary care setting, with test scoring, interpretation, and feedback recommendations coming from the memory clinic. This approach, utilizing primary care providers as “first-responders” in memory care, could readily be scaled up to provide coverage for an entire healthcare system, and in turn, provide a platform for implementing and disseminating “best practices” and research advances in the field.

Conclusion
Shifting from the current “passive referral” model for all suspected NCD patients to a focused “active triage” model through a billable remote assessment integrated into primary care may positively disrupt screening and follow-up care for neurocognitive disorders. Refining the standard assessments to give finer-grained insight into extenuating factors such as mood and sleep disturbances, differentiate amongst dementias, and incorporate feedback from a memory care nurse practitioner enables more support for primary care providers, improved care for patients, and more efficient use of memory care resources. This system is also scalable throughout the health system and facilitates rapid institution of cutting edge research and new treatment protocols.

Introduction

Older adults (65+ years) with longstanding type 1 diabetes (T1D) have more frequent and severe hypoglycemia for many reasons including comorbid conditions that impact glucose variability; changes in mobility, vision, dexterity, and cognitive ability that impact problem-solving skills and self-management; hypoglycemia unawareness; and reduced social support. Munshi1 found communication with an educator by telephone between visits to be important when working with older T1D adults. Weinstock2 found hypoglycemic unawareness and glucose variability to be associated with low blood sugar, and called for more research to assess interventions for severe hypoglycemia.

Technology such as continuous glucose monitoring (CGM) found to help younger individuals may be particularly useful in older adults experiencing high glucose variability and hypoglycemic unawareness. However, older adults may experience barriers adopting the technology. In this poster we describe the diabetes management platform (DMP) and research study we designed to address these barriers. We are currently enrolling participants into a randomized controlled trial to determine if the DMP reduces hypoglycemia in older adults with T1D.

Platform

The DMP (Figure 1) incorporates glucose, insulin, and activity monitoring, direct patient feedback, and automated monitoring of continuous data to enhance provider decision-making and feedback to the patient and caregiver.

Figure 1. Diabetes Management Platform: 1) Tablet with preloaded software collects data from blood glucose (BG) meter, CGM, insulin pump or pen, and activity tracker; 2) patient having hypoglycemia enters contextual information about hypoglycemic event; 3) Clinical decision support (CDS) system analyzes DMP data to suggest insulin dose adjustments for clinician review; 4) Geriatric-specific education and clinician messages sent to the patient.

Conclusion

This poster describes the DMP components, study approach, and preliminary findings concerning barriers and enablers based on interviews with early participants. Novel Pedigree Analysis Allows for Genetic Heterogeneity to Aid in Gene Discovery for Common, Complex Diseases

Rosalie G. Waller, HBS1, Todd M. Darlington, PhD1, Myke Madsen, MS1, Robert J. Klein, PhD2, Steven M. Lipkin, MD, PhD3, Celine M. Vachon, PhD4, Nicola J. Camp, PhD1

1University of Utah School of Medicine, Salt Lake, UT; 2Icahn School of Medicine at Mount Sinai, New York, NY; 3Weill Cornell Medical College, New York, NY; 4Mayo Clinic, Rochester, MN

Introduction

Together, common, complex diseases are the leading cause of morbidity, yet the genetic factors for these conditions are least understood. Missing heritability exists for the majority of complex diseases, demonstrating genetic factors contribute significantly to risk. Thus, understanding the genetic factors involved in common, complex disease is important for treatment decisions in precision medicine. Rare, risk variants have been suggested as a source for missing heritability; however, identifying these variants remains a challenge due to genetic heterogeneity and complex inheritance patterns. Localizing inherited, chromosomal regions to target the search for rare-risk variants is instrumental to discovering genetic factors involved in complex disease.

Methods

We developed a gene mapping strategy, based on the Shared Genome Segment (SGS) method, that utilizes high-risk pedigrees (HRPs) sufficiently large to singularly identify likely-inherited, chromosomal segments. The strategy addresses intra-familial, genetic heterogeneity by optimizing over all possible subsets of cases in a HRP. Key to the strategy is the derivation of significance thresholds for segment interpretation. These thresholds address the genome-wide search and the multiple testing, inherent from the optimization, through use of distribution fitting and the Theory of Large Deviations. We applied this new SGS strategy to 11 extended, Utah, multiple myeloma (MM) HRPs, and subsequent whole-exome sequencing (WES) in SGS regions of interest in 1064 MM/MGUS (monoclonal gammopathy of undetermined significance—a precursor to MM) cases and 964 controls from a jointly-called collaborative resource, including cases from the initial 11 HRPs and from an additional 57 families. MM is a complex cancer of plasma cells with 30,330 new cases annually. Thus far, no inherited risk variants have been identified for MM.

Results

Application of our new SGS strategy to the 11, MM HRPs identified a genome-wide significant, 1.8 megabase (Mb), shared segment at 6q16 in one HRP. WES in this region revealed a stop gain variant and a missense variant in USP45, a gene known to influence DNA repair through the nucleotide-excision repair (NER) complex, in two families. Additionally, a 1.2 Mb, shared segment at 1p36.11 is inherited in two Utah HRPs. WES in this region revealed 2 missense variants in ARID1A, a key gene in the SWI/SNF chromatin remodeling complex, in one of the HRPs sharing the segment and in another MM/MGUS family. We extended our WES analysis to the complexes of USP45 and ARID1A. In the analysis for the NER complex, we identified a genome-wide suggestive, 0.8 Mb, shared segment at 19q13 containing 2 NER genes, and ClinVar pathogenic variants in 2 additional NER genes in early-onset, sporadic MM cases. In the analysis for the SWI/SNF chromatin remodeling complex, we identified a marginal, genome-wide suggestive, 1.5 Mb, shared segment at 3p21 containing 1 SWI/SNF gene. Finally, burden testing was significant for 7 of the 22 NER complex genes and 8 of the 15 SWI/SNF chromatin remodeling complex genes.

Discussion

Our results provide compelling, segregating risk genes and variants for MM and demonstrate a novel strategy to use large HRPs for risk-variant discovery more generally in complex disease. Specifically, our results support a role for NER and chromatin remodeling in MM risk. Prior literature suggests both complexes are essential to cancer prevention and are mutated in multiple malignancies. Our HRP analysis strategy can be mutually beneficial in a collaborative setting containing both extended HRPs and smaller families. Post-hoc, additional value could be gained from demographic and/or clinical data on the sharing subsets shedding light on other shared characteristics that may aid future mapping. In sum, our strategy addresses gene-discovery challenges in common, complex diseases and aids in risk-gene mapping to inform precision medicine therapies.
Visual Exploration of Metabolic Networks to Provide Context for Metabolic Profiling in Precision Medicine

T. Cameron Waller, B.S.\textsuperscript{1,2}, Jared Rutter, Ph.D.\textsuperscript{1,3}, Alexander Lex, Ph.D.\textsuperscript{2,4}

\textsuperscript{1}Department of Biochemistry, University of Utah School of Medicine, Salt Lake City, Utah; \textsuperscript{2}Scientific Computing and Imaging Institute, University of Utah, Salt Lake City, Utah; \textsuperscript{3}Howard Hughes Medical Institute, University of Utah School of Medicine, Salt Lake City, Utah; \textsuperscript{4}School of Computing, University of Utah, Salt Lake City, Utah

Metabolism is an integral part of the biological systems of cells, tissues, and organisms. It is a cooperative and continuous system with tens of thousands of individual genes, transcripts, proteins, and metabolites. Catabolic processes degrade food to liberate energy and materials while anabolic processes harness this energy and utilize these materials to synthesize and assemble all cellular components. In these ways, metabolism sustains life and all of its diverse processes. It is little wonder that metabolic defects contribute to the pathology of many human diseases, including obesity, diabetes, cardiovascular disease, and cancer.

In their study of metabolism, investigators need tools to access the vast complexity of the metabolic system. As current interest in metabolism is increasingly interdisciplinary, this accessibility is a challenge for novices and experts alike. Scientists and engineers from diverse backgrounds consider metabolic phenotypes and mechanisms, and metabolic profiling in the clinic is an important aspect of precision medicine. Another challenge is the shift in experiments from reductionist to systemic scales. Modern technologies, especially the omics technologies (genomics, transcriptomics, proteomics, and metabolomics), measure biological entities at nearly comprehensive scales. Both the reliable design of these experiments and the accurate interpretation of their results requires consideration of context, including an holistic perspective of the entire metabolic system.

Current analyses risk over-simplifying metabolism and neglecting its real context. Most available tools represent metabolism as a collection of separate pathways, such as Glycolysis, Pentose Phosphate, and the Citrate Cycle. While these pathways are conceptually simple, they neglect metabolism’s extensive connectivity and continuity across pathways. Experimental results from omics technologies are frequently relevant to multiple pathways. Identifying relations between these is laborious, and there is a great risk of arbitrarily or subjectively ignoring relevant parts of the system.

We aim to provide a versatile tool for the objective and dynamic exploration of metabolic networks. We adopt a common model for these networks—with reactions as relations between metabolites as entities—and derive information from reconstructions of systems biology. As this network for human metabolism is large (roughly 13000 nodes and 43000 links), our tool supports dynamic, custom queries to select portions of the network that match the user’s interest. Queries consider both attributes and topology of the network. To query by attributes, a user might select metabolites and reactions in a specific metabolic pathway or cellular compartment. To query by topology, a user might select metabolites and reactions either within a specific proximity to a single metabolite or within shortest simple paths between multiple metabolites. We find that specific queries with multiple criteria are necessary to select subnetworks that are sufficiently simple for exploration. We are developing a visual interface to facilitate the construction of these queries and to communicate relevant information about the network concisely and clearly. We hope that our tool will promote basic discovery and translational interpretation to support metabolic profiling in precision medicine.
Matching Consumer Health Vocabulary with Professional Medical Terms Through Concept Embedding

Yue Wang, MS1, Jian Tang, PhD2, V.G. Vinod Vydiswaran, PhD3, 4, Kai Zheng, PhD5, Hua Xu, PhD5, Qiaozhu Mei, PhD2, 1
1Department of Electrical Engineering and Computer Science, University of Michigan, Ann Arbor, MI; 2School of Information, University of Michigan, Ann Arbor, MI; 3Department of Learning Health Sciences, University of Michigan, Ann Arbor, MI; 4Department of Informatics, University of California, Irvine, CA; 5School of Biomedical Informatics, The University of Texas Health Science Center at Houston, Houston, TX

Introduction: Matching consumer health vocabulary with professional medical terms is an important task for medical information retrieval, knowledge sharing, and effective health communication. Previous approaches studied mining consumer health vocabularies (CHV) with hand-crafted heuristics on medical search logs1 and community-generated content2. Though the professional-consumer concept pairs mined through these approaches are very accurate, many relevant pairs could be missing. In other words, the recall is low. In this pilot study, we propose to match professional-consumer concept pairs through text embedding approaches. Text embedding approaches have proven to be very effective in capturing the similarity between words and phrases3, which can yield high recall of professional-consumer concept pairs. We first learn the representation of the medical concepts with a large amount of unlabeled text. Afterwards, the professional-consumer concept pairs are matched according to the similarities of their embeddings.

Methods: We first learn word embeddings from large-scale text corpus and then represent a medical concept as the average of word vectors it contains. Three corpora are used to train word embeddings: 2.2 million MedHelp posts (consumer-generated text), 7 million Medline abstracts (professional-generated text), and 4.7 million Wikipedia articles (general-domain text). We use the Skip-gram model1 to learn word embeddings and calculate the similarities between concepts as the cosine similarity of their word embeddings. The results are evaluated using a ranking-based metric, the mean reciprocal rank (MRR). Given a professional (consumer) concept in a CHV pair, we rank candidate medical concepts by cosine similarity to the query. Ideally, the corresponding concept in the pair is ranked high.

We use a large collection of candidate medical concepts and ground truth professional-consumer concept pairs. We collect all English medical concepts in the UMLS as the concept collection and use two existing CHVs as the ground truth pairs: CHV-1 from Vydiswaran et al.2 and CHV-2 from Zeng et al.1 To ensure fair comparison between word embeddings learned on different corpus, we filter out concepts that contain out-of-vocabulary words for any corpus. This gives us 494K medical concepts from UMLS, 892 concept pairs from CHV-1 and 124K concept pairs from CHV-2. We randomly select 1000 pairs from CHV-2 to make the sizes of CHV-1 and CHV-2 comparable for evaluation.

Results and Discussion: Our initial results show that it is feasible to identify alternative medical concepts by using professional or consumer concepts as queries in the concept embedding space. The MRR values indicate that on average, a professional or consumer concept is about 14th closest to its counterpart in CHV-1 and about 7th closest in CHV-2. Note that this is only the result on a small subset of the large medical concept collection where we have ground truth. We will generate an extended list of related concept pairs and pseudo-label them as professional- or consumer-oriented using the propensity measure2. This list can then be checked by medical experts and expand current CHVs. This will open up the opportunity to build more extensive CHVs with minimal effort from practitioners.

To make the concept embedding specialize in professional-consumer vocabulary translation and continuously improve itself, we are developing a semi-supervised representation learning algorithm. The algorithm uses a small set of known CHV pairs as the supervision signal, and learns word embeddings (and the way to compose word embeddings into a concept embedding) such that consumer concepts and professional counterparts are close to each other. With more and more supervision pairs, the recommended alternative concepts will become more precise.

Utility of Anti-hypertension Prescription Orders in Predicting Future Hypertensive Instability Events

Xuan Wang, MS1, Lujie Chen, MS1,2, Marilyn Hravnak, PhD3, Gilles Clermont, MD4, Michael R. Pinsky, MD4, Artur Dubrawski, PhD1

1School of Computer Science and 2Heinz College, Carnegie Mellon University; School of Nursing3 and School of Medicine4, University of Pittsburgh, Pittsburgh, PA

Introduction

Accurate prediction of the cardiorespiratory instability (CRI) risk in monitored stepdown unit (SDU) patients may prepare clinical teams to anticipate CRI more accurately and respond sooner to improve outcome. While previous work has explored methods for non-specific CRI risk prediction using static information available at SDU admission time, we hypothesize that provider’s prescriptions accruing dynamically over the admission stay (specifically for anti-hypertension medication [anti-HTN]) may have utility in predicting specific CRI events (hypertension [HTN-CRI]), if we view the prescription as a proxy of the dynamic information collected from multiple sources which might not otherwise be captured or leveraged.

Methods

Noninvasive vital signs (VS) were collected at 1/20Hz frequency over 15 months from bedside monitors in a 24-bed SDU, including heart rate (HR), respiratory rate (RR) and peripheral oximetry (SpO2); systolic (SBP) and diastolic (DBP) blood pressure measurements were intermittently recorded. From Electronic Health Records, we extracted providers’ prescription orders during SDU stays, patients’ medical history for hypertension, and demographics. We identified 382 SDU events (cases) during which patients developed at least one instance of HTN-CRI (VS exceeded SBP >200 or DBP>110mmHg) and 2074 controls without any HTN-CRI. We recorded whether or not these patients had anti-HTN medications prescribed prior to their initial HTN-CRI during their SDU stays. We excluded anti-HTN prescribed within the hour before HTN-CRI to reduce the bias from concomitant reactivity, e.g. anti-HTN prescribed from HTN-CRI events at sub-threshold levels.

Results

56% of HTN-CRI cases and 38% of controls had an anti-HTN prescribed (p-value <0.001). We evaluated the utility of anti-HTN orders predicting HTN-CRI risk by constructing models incorporating potential confounding covariates. Table 1 shows the output from three logistic regression models when covariates are sequentially added: starting age on admission, then HTN history on admission, and finally accruing anti-HTN orders over admission. All coefficients for covariates of interest are positive and statistically significant (p-values in parentheses). In addition, the likelihood ratio tests (last column) comparing subsequently enriched models show improvement at each step, supporting our hypothesis that accruing anti-HTN prescriptions carries additional information in predicting future HTN-CRI events over information available at time of SDU admission alone.

Table 1. Output from logistic regression models with factors sequentially added.

<td>0.551(&lt;0.001)</td>
<td>Model 3 vs Model 2 P-value &lt;0.001</td>
</tr>
</tbody>
</table>

Conclusion

Assuming anti-HTN is a surrogate for pre-existing hypertension, this analysis demonstrates the potential utility of leveraging the history of concomitant cardiovascular modulating therapies as an identifier in predicting future HTN-CRI events. Thus, dynamic information encoded in providers’ prescription orders may be used to update the baseline prediction of relevant CRI events using only historical information. Future work will explore prescription related markers for predicting other CRI events such as tachycardia and hypotension. We envision this approach will open avenues for building models that could provide more actionable and specific information of future CRI events, helping facilitate the personalized monitoring paradigm.
Semantic Representations of Medical Terms: A Comparison Study of Word Embeddings Trained on Clinical Notes and PubMed Articles

Yanshan Wang, PhD\(^1\), Naveed Afzal, PhD\(^1\), Liwei Wang, PhD\(^1\), Feichen Shen, PhD\(^1\), Hongfang Liu, PhD\(^1\)

\(^1\)Division of Biomedical Statistics and Informatics, Department of Health Sciences Research, Mayo Clinic, Rochester, MN

Introduction

With the availability of large quantities of health data, deep learning has become more and more prevalent. The word embeddings learned by deep neural networks have seen tremendous success in various natural language processing (NLP) applications. Word embeddings trained on common domain data have been shown to carry syntactic and semantic meanings of words. Training word embeddings usually requires an adequately large corpus. In medical domain, clinical notes and biomedical articles are two resources that could serve as training data. In this study, we answer the question: Do the word embeddings trained by these two resources perform differently on representing semantics of medical terms?

Methods

In our studies, we utilized the word2vec model, skip-gram, to evaluate the word embeddings. Word2vec is based on the assumption that words occurring in similar contexts tend to have similar meanings. Based on a training corpus, it uses a deep neural network to embed words into a continuous vector space. In our implementation, we set the minimum number of times a word must appear in the corpus to 7, the window size to 5 words, and the number of dimensions in feature space to 60.

Two corpora were utilized to train the word embeddings: EHR Corpus and PubMed Corpus. EHR Corpus contains clinical notes for a cohort of 113k patients receiving their primary care at Mayo Clinic, spanning a period of 15 years (1998-2013). PubMed Corpus contains 1.25 million articles from PubMed Central. Minimum pre-processing was conducted including punctuation removal, digits replacement, etc. We also compared the trained word embeddings with two public pre-trained embeddings: Google News and Wikipedia.

Four datasets were utilized to evaluate the word embeddings for capturing medical term semantics. Dataset 1 contains 30 medical term pairs with manually generated similarity scores; Dataset 2 contains 34 medical term pairs with similarity scores; Data 3 consists of 101 clinical term pairs whose similarity was determined by physicians from the Mayo Clinic; Data 4 consists of 725 clinical term pairs whose similarity was determined by residents from the University of Minnesota Medical School.

On each dataset, the word embeddings were evaluated based on their Pearson correlation coefficient with the similarity scores determined by human experts.

Results

The results of Pearson correlation coefficient on four datasets are listed in Table 1. Overall, the similarity results using word embeddings trained on PubMed Corpus are the closest to human experts’ results. However, there is no statistical significance between the word embeddings trained on EHR Corpus and those on PubMed Corpus. Both word embeddings are significantly superior to the pre-trained word embeddings on Wikipedia and Google News.

<table>

Table 1. Pearson correlation coefficient of four datasets.

Conclusion

There is no statistical significance between the word embeddings trained on EHR Corpus and PubMed Corpus in regards of semantic representations of medical terms. However, the word embeddings trained on medical domain data are superior to those trained on common domain data.
Neural Network Word Embeddings for Text Classification of MeSH terms.

Walter Wang, MSc, Yindalon Aphinyanaphongs, MD, PhD
NYU Langone School of Medicine, New York City, New York

Introduction
In recent years, neural network and deep learning approaches have redefined benchmarks in vision, natural language, classification, and prediction. A common biomedical task is assigning MeSH terms to MEDLINE documents. In this work, we apply two popular neural network classifiers\(^1,2\) to the benchmark OHSUMED dataset, a collection of 50,000 Medline abstracts, to a 23 label classification task established in prior work\(^3\). One of the key contributions of the neural network approach is their ability to generate unsupervised semantically relevant word embeddings. For every token, an \(N\) dimensional vector is created such that similar words appear close together in the Euclidian space\(^4\). This work evaluates \(1\) the usefulness of semantic word embeddings for classification performance on a benchmark task and \(2\) the value of general vs domain specific embeddings for a task.

Methods
For pretraining, we tested three different sets of word representations. The first set are word vectors built using the skip-gram model\(^5\) on the full OHSUMED dataset. The second set is a pretrained word vector dataset from Google News\(^6\). The third set is a pretrained word2vec dataset from Pubmed and Pubmed Central articles\(^6\).

Using FastText for text classification and a Tensorflow implemented convolutional neural network\(^7\), we report the recall-precision breakeven point. The loss function is an approximation of the sigmoid cross entropy with logits optimized for the multi-label classification task.

\[
\text{loss} = \max(x, 0) - x \ast z + \log(1 + e^{z}), \quad x = \text{logits, } z = \text{labels}
\]

Results
The reported result is an average of the breakeven points across the 23 label benchmark classification tasks.

Discussion
Word vector based pretraining are useful and produce significant improvements in classification. Both types of pretrained neural networks outperform Support Vector Machines. The specific embeddings from the actual dataset surprisingly perform better than general purpose word embeddings either produced from Google or from Pubmed.

Come Together: a multi-hospital transition in reporting strategy from untethered databases to integrated warehouse solutions

Emily C. Webber, MD¹,², Phillip S. Cadle³, Cara L. Willey RN, BSN³, Michael Schwarz MBA³, Rebecca Rose, MD¹
¹Indiana University School of Medicine, Indianapolis, IN; ²Regenstrief Institute, Indianapolis, IN; ³Indiana University Health, Indianapolis, IN

Introduction
Access and management of clinical data is an important part of leveraging the electronic health record (EHR) for operational reporting, quality improvement efforts and research. In a large health care organization, standards for operational reports is important for accuracy and longitudinal outcome tracking. The objective of this project was to evaluate and reconcile several sources of operational and clinical reports for a multi-hospital neonatology group into the health care organization data warehouse.

Methods
Evaluation of reports. Prior to the project, clinical data was manually transcribed from the clinical EHR into a neonatal database housed outside of the enterprise data warehouse. The database was found to have approximately 400 custom reports, the majority of which were operational reporting, quality reporting and one time reports (frequently to determine a cohort of patients with a specific profile). Despite this large number of reports, only about 12 reports were routinely obtained by different facilities, and slightly different sources (physician, nursing or EHR numbers) were used by each facility (Table 1). In addition to the primary neonatal database, different locations used variable sources for standard reporting and there were additional manual steps to reconcile gaps in standard reports.

EHR and Data Warehouse design. Using the previous database and clinical pathways as a guide, a standard form for targeted clinical assessments and quality elements was implemented in the EHR. The form contained approximately 300 unique clinical data fields; the fields as well as other selected clinical data and diagnoses is loaded daily into a custom data mart in the enterprise data warehouse. Curating a data mart of neonatology patients allowed for strategic mapping to other databases of hospital data and use of analytical resources and tools already adopted across the health care organization. Analysts and neonatologists created web-based dashboards which present a catalog of standard reports as well as elements for creating custom queries in the clinical data in the data mart.

Results
Since implementation, facilities utilize the same reports leading to both collaborative validation and improved ease of shared objectives. Use of the reports has led to improvements in the EHR form. Additional routine reports have been identified and redundant reporting processes reduced. Clinicians and other members of the medical team utilize validated query tools to run shared reports allowing for comparisons between facilities.

Conclusions
By working directly with clinicians, warehouse and informatics analysts were able to curate a high impact and clinically relevant data mart, which can adapt to include new elements as needed. By integrating into the shared data warehouse, the clinical teams at different facilities now have improved data integrity and depth.
Resident Physician Efficiency in the Electronic Medical Record (EMR): sustaining improvements
Emily C. Webber, MD1,2, Ellen Klink, MD1, Andrew O’Brien, MD1, Courtney Hines3
1Indiana University School of Medicine, Indianapolis, IN; 2Regenstrief Institute, Indianapolis, IN, 3Indiana University Health, Indianapolis, IN

Introduction: Resident physicians comprise a large portion of the physician workforce utilizing the EMR in many health centers and have a different workflow from non-resident physicians. The objective of the project was to redesign the resident EMR position to promote efficiency in finding information in the chart as well as perception in ease of use.

Methods: The project involved a redesign of the resident EMR view with a focus group, EMR process reports (click counts and time in different parts of the chart) and a survey before and after the change.

- Update of resident physician view. A multidisciplinary group of residents redesigned the resident EMR view. This was done by analyzing the clicks for buttons or links, removing and reordering the remaining links, and adding the ability to change between views based on the specialty needed that month.

- Evaluation of EMR process reports. The vendor EMR utilization analytics tool evaluated process outcomes for all residents in all settings for 5 months prior to the change and 6 months after including: the number of times they needed to navigate between different sections of the chart to find data (“tab hops”), time spent in chart review and time required to find a patient (patient discovery).

- Survey assessment. A voluntary, anonymous electronic survey was conducted pre- and post- the EMR change.

Results: The resident EMR view was changed for 1564 residents in May 2016 (Figure 1, month 5). Tab hops, chart review and patient discovery time all decreased after the change. The tab hop control chart (Figure 1) revealed the average number of tab hops/patient declined by 2.03/patient. Upper control limit (UCL) and LCL (lower control limits) seen below. Patient discovery declined by 6 seconds/patient, and chart search time by 23 seconds/patient on average.

Residents responding to the survey (171 pre-EMR change, 198 approximately post-EMR change) reported more often being able to find information, as well as improvements in productivity and workflow (Table 1).

Table 1. Resident survey responses pre and post the EMR change.

Conclusions: Early results show a trend in the decrease in the overall amount of time by residents spent searching in the EMR as well as discrete navigation (ie. tab hops). Additional months of data collection are required to evaluate whether this represents a more permanent shift in these measures. The survey of perceptions reflected positive changes (ie. residents responded that the EMR performed searching and other functions more consistently in the post survey). Both objective measures of time as well as perceptions of efficiency are needed to evaluate the success and value of optimization in the EMR. Although promising, these metrics should continue to be evaluated to see if the time savings are sustained.
Measures of Improvement: Combining Satisfaction Survey and Time Measures to Identify Impactful Optimization

Emily C. Webber, MD1,2, Wanita Kumar, MD1, Jeff Aldrich3, Cara Willey, RN3, Zach Gordon, MD1,2, Erika Green, MD2, Matthias Kochmann, MD2, Dan Seitz, MD1,2, and Jason Schaffer, MD1
1Indiana University School of Medicine, Indianapolis, IN; 2Regenstrief Institute, Indianapolis, IN; 3Indiana University Health, Indianapolis, IN

Background Electronic health record (EHR) implementation has been widespread over the last decade; however, there is little published data regarding evaluation of continuous EHR improvements. Some EHRs can provide data from embedded tools to measure time spent on ordering, number of clicks and other process measures. Surveys and interviews with users provide important context regarding perceived value and satisfaction of these measures. The objective of this project was to compare EHR measures of time and actions with survey responses pre- and post- EHR enhancements. This would allow us to determine if improvements in time savings correlated with perceptions of efficiency and higher satisfaction.

Methods A project team of physicians and clinical informatics analysts devised a strategy for using the vendor EHR analytic database and survey data to evaluate the effectiveness of updated EHR functionality.

Vendor analytic database The vendor EHR database was used to track key performance indicators such as total time in chart per patient, time for chart review, ordering and documentation and navigation before and after the EHR updates. The database is administered by the EHR; it analyzes active time and activities in the chart by applying a proprietary analysis of mouse and keyboard input. The data can be filtered by provider position and other elements.

Survey A five question, web-based, IRB-approved survey was administered to all providers who received the updated functionality. Questions were modelled on validated end-user computing satisfaction1. All providers were provided a link to a pre-survey for two weeks prior to the updated EHR functionality and a post-survey 1 month after the update. Results were reported on a Likert scale with 1 indicating least satisfied and 5 indicating most satisfied.

Results A summary of the efficacy of the implementation for each provider group using both the EHR process metric and survey was provided (Fig 1). The documentation time per patient (graph on left) was determined by averaging the total time spent in the documentation tasks per patient/per number of providers in the group. Further filtering by individual provider was also provided.

Figure 1. Sample report including EHR vendor process metric and survey results.

Results 1659 providers in 12 different service lines received updated functionality in their EHR, with approximately 10% responding to the pre and post survey. All 12 service lines showed decreased times for chart search, order and documentation in the EHR database report. On the survey, 10 out of the 12 service lines increased scores on all five questions on their post-survey. Two service lines had lower satisfaction responses on their post-survey.

Conclusions The survey responses for the majority of the providers reflected higher satisfaction on all five questions; however, two groups were less satisfied despite objective measures of improved efficiency (as reflected by EHR database reports of process outcomes). Process measures like time metrics are insufficient as a sole determinant of the effectiveness and value of improvements in EHR usability. Evaluations are more comprehensive if they include assessments like surveys to reflected perceived value.

Using Statistical Models to Predict Senior Patients’ Use of Smartphone Apps for Managing Parkinson’s Disease – A Preliminary Study from A Service Learning Project

Duo (Helen) Wei
Computer Science and Information Systems – BUSN
Stockton University, Galloway, NJ 08205

Introduction
Approximately four million people worldwide suffer from Parkinson’s disease and nearly one million people in the U.S. are living with Parkinson’s disease (PD), with between 50,000 and 60,000 new cases diagnosed each year, according to the National Parkinson’s Foundation. PD is incurable but medications and appropriate interventions can control symptoms for many years. With the advent of internet and mobile phone technologies, people are increasingly interested in using Smartphone technology to manage their health. Although senior people are those groups that are in urgent need of help, due to the limitation of the resources, personal health status, and the lack of technical background, seldom do they expose themselves to the application of technology to manage their health. In this project, we aim to investigate: (1) what are the major factors that influence the senior PD patient’s inclination to use Smartphone apps for managing their health? (2) how to predict a PD patients’ inclination of using Smartphone apps?

Method
Students in Medical Informatics class, taught by the author (DW), organized a workshop for senior patients with Parkinson’s disease focusing on health management through technology in the spring of 2016. The workshop was held at the Capital Health Medical Center as a service learning project for the course. Student utilized knowledge acquired during the class to introduce one of the most popular Apps called “Parkinson’s Central Toolkit” including informational apps, medication and symptom management, with the goal of helping those struggling with PD increase their knowledge of resources that they had in an effort to promote a better quality of life. After conducting the workshop, surveys were distributed, which were designed to learn patients’ demographic information and their habits of using technology. Based on the survey results, we extracted five most important factors: gender, age, the perception of the severity of PD patients, operating systems (Android vs. iOS), and daily used ratios. We first used the logistic regression model to see each factor against their inclinations of using the Smartphone app. Then we applied the multiple regression model to predict the use of Smartphone app based on the above mentioned five factors.

Results
Twenty PD patients were involved in the workshop and among which 18 patients turned in the survey. There were fourteen completed surveys and the four incomplete surveys (<50% complete) were not included in the statistical analysis. Among the fourteen patients, there were eight males and six females. The survey, containing 15 mandatory questions and five optional questions, was designed to use paper-based format and was distributed after the workshop. In the survey, patients were asked questions about their demographic information, their perceptions of the severity of the disease, their level of technology backgrounds, and their uses of the Smartphone. Logistic regressions and multiple regressions have been applied for the modeling. According to the statistical model, there were no statistically significant association between the response variable (the inclination to uses) and the terms (such as age, gender, and the severity of the disease). By applying the goodness-of-fit tests, it is determined that the predicted probabilities deviate from the observed probabilities in a way that the binomial distribution does not predict (p-value >= 0.05). The multiple regression models show that there is a statistically significant association between the inclination of usage and patient’s gender. That being said, male patients are more likely to choose to use Smartphone app that their female counterparts.

Discussion and Conclusion
Smartphone apps lead to a revolution in patient health management. In this research, PD patients are informed of the technological tools available to them and ways to utilize the apps. Statistical models are employed to analyze and predict patients’ usage of Smartphone apps. Results show that male patients have higher inclination of Smartphone app usage than female, which is partially due to the fact that females tend to be less interested in technology than male according to early research. Therefore, educators should involve more female in STEM on educational level. Besides, Smartphone app developer may consider to develop more female friendly products. A larger sample set is needed to get a more precise result and a better-fitted model. We are going to organize two workshops to engage more patients in the community. In the future research, we are going to investigate not only PD patients but patients with other diseases. The research will also focus on which Smartphone app features are most important to a particular patient community.

Using a Convolutional Neural Network model for Automatic Medical Subject Headings (MeSH) Assignment

Wei Wei, PhD, Zhanglong Ji, PhD, Lucila Ohno-Machado, MD, PhD
University of California, San Diego, La Jolla, CA, USA

Introduction
Medical Subject Headings (MeSH) is a controlled vocabulary thesaurus used primarily for indexing biomedical publications. Assigning MeSH terms enables efficient retrieval of biomedical publications via PubMed. Most assignment methods use manually extracted features, including the state-of-art model. Inspired by the performance of the Convolutional Neural Network (CNN) model for feature extraction in the text mining research, we studied the contribution of automatically generated features from CNN for the MeSH term assignment task.

Methods
Kim’s CNN model was adopted to generate distributed representations (i.e., CNN features) from abstracts and MeSH term candidates. The model by Huang et al. served as the baseline. The baseline model includes three features (i.e., additional features) that do not require extra training data:

- neighborhood feature: the number of similar articles in which a MeSH term candidate appears,
- overlap feature: number of unigrams/bigrams overlapping between MeSH term candidate and the abstract, and
- translation feature: the probability of translating the abstract into the MeSH term candidate.

The neighborhood feature has a dominant impact on the performance (see Table 1, row 2), while the other features are valuable supplements. We analyzed the contribution of CNN features alone, together with the neighborhood feature, and with all the three features. The performance was evaluated on NLM2007, a National Library of Medicine (NLM) benchmarking dataset, and measured by Mean Average Precision (MAP), which is the average precision values at ranks of relevant items (i.e., MeSH terms). The scripts and the configuration of CNN are available from https://github.com/w2wei/ConvNet_MeSH.

Results
A combination of the CNN and additional features achieved good MAP in this dataset, comparable to just using the 11 manual features in the baseline model (see Table 1).

Table 1. The performance of CNN features alone and with the additional features.

<table>
<thead>
<tr>
<th>Features</th>
<th>MAP</th>
</tr>
</thead>
<tbody>
<tr>
<td>Baseline (11 manually extracted features)</td>
<td>0.626</td>
</tr>
<tr>
<td>neighborhood</td>
<td>0.602</td>
</tr>
<tr>
<td>CNN</td>
<td>0.335</td>
</tr>
<tr>
<td>neighborhood + CNN</td>
<td>0.602</td>
</tr>
<tr>
<td>neighborhood + CNN + overlap + translation</td>
<td>0.646</td>
</tr>
</tbody>
</table>

Conclusion
The model built with CNN and the three features helped improve MAP in the NLM2007 data set. Neither the CNN features nor the selected additional features require extra training data.

Computing Performance Analysis on Clinical Document-level Classification
Wei-Hung Weng, MD1,2, Kavishwar B. Wagholikar, MBBS, PhD2,3, Henry C. Chueh, MD2,3
1Department of Biomedical Informatics, Harvard Medical School, Boston, MA;
2Laboratory of Computer Science, Massachusetts General Hospital, Boston, MA;
3Department of Medicine, Massachusetts General Hospital, Boston, MA.

Effective computing is critical for developing machine learning-based solutions. In particular, machine learning tasks related to the clinical decision often require real-time modeling and evaluation to provide timely treatment and management. Machine learning based-natural language processing (NLP) techniques allow researchers to construct automated document classifiers to categorize clinical documents based on their content and document-level information without manual processing. Nevertheless, the NLP approach usually creates a higher dimensional feature space, which takes an abundant time to train the classifier if the training corpus is large. There is also the lack of studies on performance analysis on clinical document classification tasks.

We performed document classification tasks based on the medical subdomain of the clinical document using two datasets -- 431 publicly available clinical notes and reports from the Integrating Data for Analysis, Anonymization, and Sharing (iDASH) data repository, as well as 91,237 Massachusetts General Hospital (MGH) clinical notes from the Research Patient Data Registry (RPDR) data repository of Partners HealthCare system. For each dataset, we applied seven clinical feature representation methods and five supervised learning algorithms to construct 35 classifiers. For all classifiers with different size of feature spaces (Table) and algorithms, we evaluated the model performance using performance score (PS), which was defined by 

$PS = \text{sigmoid}(\text{standardized } F_1 \text{ score}) \times [1 - \text{sigmoid}(\text{standardized processing time})]$. 

The standardization and sigmoid transformation were applied to $F_1$ score (classifier performance) and processing time (machine performance) to ensure that scales of $F_1$ score and processing time are consistent and comparable. For all classification tasks, we used the virtual machines on the Partners ERISOne Linux Cluster, with four CPU cores (Intel Xeon 3.47GHz) and 16GB RAM memory.

We found that using the classifiers trained by support vector machine (SVM) with linear kernel yielded the most effective computing performance across two datasets. The appropriate feature representation method, such as using medical concepts with semantic restriction, can additionally augment the performance. We found that the clinical document classification tasks based on the medical subdomain of the document could be done within the acceptable effectiveness, regarding model performance and speed in the scale of ninety thousand documents. We plan to execute and evaluate the same task on a larger analytical platform for scaling up.

Developing an Evaluation Plan for Nationwide Data Infrastructure Programs

S. West, PhD1; J. Amoozegar, MSPH1; M. Ashok, PhD1; J.E. Richardson, PhD, MS, MLIS1; B.H. Blumenfeld, MD, MS1; S. Lumsden, RN, MS2; C. Cravens, MPH2

1RTI International, Durham, NC
2HHS/Office of the Assistant Secretary for Policy and Evaluation, Washington, DC

Introduction

Between 2003 and 2010, Congress enacted three laws that authorized research and funding to expand the number of studies on the outcomes and effectiveness of treatments and interventions used in health care. Most recently, the Patient Protection and Affordable Care Act (ACA) of 2010 established a trust fund for patient-centered outcomes research (PCORTF), with a small portion (4%) for HHS to coordinate relevant federal health programs to build data capacity for research. Through a coordinated effort, federal agencies have a undertaken a portfolio of projects (N=30) focused on collecting, linking, and analyzing research data in a manner that supports research networks and the interoperability of health data. Evaluators from RTI International designed a multilevel evaluation to assess the impact of the work done on the portfolio of data infrastructure projects and to identify gaps for future development activities.

Methods

We developed a multilevel evaluation plan for PCORTF data infrastructure initiatives incorporating an HHS provided strategic framework. The framework contains five “functionalities”, which represent required core functions for enhancing data infrastructure for research: 1) use of clinical data for research; 2) standardized collection of standardized clinical data; 3) linkage of clinical and other data for research; 4) collection of participant-provided information; and 5) use of enhanced publicly funded data systems for research. Achieving these functionalities should make clinical data more usable for research. The five functionalities are organized by “components”: standards, services, and policies and governance (SSPG); these components are further broken down into more specific sub-components referred to as developmental components (DCs). The EP’s measurement strategy integrates the Evaluation Planning Incorporating Context (EPIC) model, a maturity schema, and input from a technical panel with program evaluation, informatics, and outcomes research expertise. The maturity schema guides data collection and analysis, with an emphasis on mapping project goals and activities to DCs, gauging their level of achievement and assessing their status within and across projects. In aggregate, the EP measures the degree to which each data infrastructure project and the entire project portfolio, enable the five functionalities.

Results

The EP is driven by three overarching evaluation questions: 1) What specific contributions did each project towards creating clinical data infrastructure for conducting research? 2) How has the project portfolio enabled the functionalities to address the collection, linkage, and analysis of data? and 3) How have the funded projects (to date) built data capacity and advanced researchers’ ability to capture, store, access, link, exchange, and analyze data securely and efficiently? The maturity schema delineates the increasing levels of maturity (signifying a progressively increasing degree of sophistication) required for DCs to enable functionalities from a process perspective. We determined which levels of achievement were required to fully operationalize each functionality. To determine how well the functionalities are supported by levels of achievement across the portfolio, we are reviewing project documents to assess project activity status. This will allow us to determine progress at each level of achievement for each functionality’s DCs. We will compile findings across all projects before Fall 2017.

Discussion

The primary challenge we noted in conducting the EP is the need for additional information beyond what exists in the project’s statements of work and progress reports from the federal agencies overseeing the projects to HHS, especially for projects in progress at the time of evaluation. We have addressed some of these informational gaps by conducting project-specific literature searches, which we will supplement with calls to project directors. The key anticipated challenge in executing the plan is providing results in an actionable way that allows us to assess the comprehensiveness of the project portfolio and identify gaps in the infrastructure for collecting, linking, and analyzing electronic data for research. The evaluators are using a heat map model to graphically depict levels of maturity in an intuitive way to present results to stakeholders.

Project A-G-T-C: Adding Genetic Test data in Clinical data warehouse

Jonathan Wickes; Hyeoneui Kim, RN, MPH, PhD; Hyun-Dae Kim; Jihoon Kim, MS; Wenhong Zu, PhD; Lucila Ohno-Machado, MD, MBA, PhD; Olivier Harismendy, PhD

Department of Biomedical Informatics, University of California, San Diego, La Jolla, CA

Introduction and Background
An increasing number of patients are now undergoing molecular testing as part of their clinical care and those test data should be made available for patient care and patient centered outcome research. However at UCSD Medical Center, the data is currently deposited in a highly heterogeneous format in the Electronic Health records (EHR). For example, the results of several tests performed by the UCSD laboratory are deposited into the laboratory test results table in a structured format while those of many tests performed by third party vendors are upload as a PDF report. Not surprisingly, the vendor produced test results have not been incorporated into UCSD’s Clinical Data Warehouse (CDW). Therefore, none of useful queries, which can be as simple as identifying which patient underwent genetic testing and as refined as knowing the patients who carry a specific mutation in a specific gene, were possible neither in EHR nor in CDW. To address this challenge, we started developing the procedure that parses and standardizes vendor produced genetic test results to make them available in the CDW. As a feasibility study, we processed the test results from a genetic test vendor, Foundation Medicine (FM), and incorporated them into the CDW.

Methods
Upon IRB approval, we obtained genetic test results produced by FM for the past 4.5 years (08/2012-08/2016) in XML (before PDF rendering) as well as in PDF. This includes 1,669 reports of 1,594 patients. By reviewing several reports in PDF, we identified the fields that hold meaningful information thus need to be included in the CDW. Next we wrote an XML parser that takes the XML formatted test results and extracts those fields with meaningful information. Following the recommendation of the Clinical Genomics Working Group of HL7 we standardized gene names with HUGO Gene Nomenclature Committee (HGNC) standard; variant names with the variant description nomenclature of Human Genome Variation Society (HGVS); variant name, variant types (inferred based on the results) and specimen types with Logical Observation Identifier, Names, and Codes (LOINC); and specimen collection sites with Systematized Nomenclature of Medicine - Clinical Terms (SNOMED-CT).

Results
The overall workflow is summarized in Figure 1. A new Genetic Test Results table (Box 1) was added to CDW and linked to the Patient table using a medical record number. Six dictionary tables were implemented to accommodate the standardized code sets. Majority of the test results (93%) were successfully standardized with the data standards listed above. We created our own local code sets as an interim solution to incorporate a few variant types reported by FM that were not included in the LOINC by the time we completed this study. The fidelity of this implementation was validated with 3 data query use cases: (1) number of patients with TP53 nonsense tumor mutation, (2) number of male and female with any tumor mutation in PIK3CA, and (3) number of patients with cancer carrying a non-VUS NF1 tumor mutation.

Discussion
We successfully processed the genetic test results from a third party vendor laboratory Foundation Medicine and imported them into UCSD’s CDW in a standardized manner. This feasibility study showed that the current data standards provide quite good coverage for encoding the important information on the genetic test data. Standard development for genetic test information is an on-going effort thus we anticipate that the revision of the current mapping will be necessary. As this feasibility testing was done using the data from a single vendor, the generalizability of the resulting process and pipeline is not guaranteed. We plan to refine our approach by applying it to the test results from various vendor laboratories.

Secure Text Messaging to Improve Workflow Efficiency and Provider Satisfaction in Administration of Radiation Therapy

Aaron Wild, MD1, Erik Anderson, MD, PhD1, Natalie Lockney, MD1, Suchit Patel, MD, PhD1, Robert Samstein MD, PhD1, Amy Xu, MD, PhD1, Keri Martin2, Aaron Ostrovsky, MPH2, Chhavi Kumar, MD3, Daniel Stein, MD, PhD2

1Department of Radiation Oncology; 2Division of Health Informatics; 3Department of Medicine; Memorial Sloan Kettering Cancer Center, New York, NY

Introduction
A key to delivering high quality, high dose radiation treatments is optimal patient set-up on the treatment machine on each day of treatment. A secure, two-way text messaging (STTM) system was implemented for use between the radiation therapy technologists (RTTs) at treatment machines, and attending physicians, who previously relied on one-way text paging, email, and phone. Previous studies of app-based communication systems in other clinical domains have shown improvements in clinician efficacy and satisfaction1-2. Our objectives were to determine if this also would apply in Radiation Oncology by: 1) reducing the time from patient setup films to radiation treatment and 2) improving provider satisfaction with the communication system between RTTs and attending physicians.

Methods
The system used was the Voalte platform (Voalte, Inc., Sarasota, FL). A smartphone-based app was installed on the attendings’ personal phones, and a web-based client was installed on the RTTs’ workstations. The participants could send and receive text messages in real time. The software also displayed the users’ roles, availability, and message status. During the two-month study period, STTM was the preferred method of communication for: (1) notifying attendings that patient setup films were ready for review and (2) notifying RTTs that the films had been reviewed and signed by the attending physician, permitting radiation treatment to proceed. We recorded length of time from films acquisition to approval for 20 treatments before and 20 treatments after the new STTM system was instituted. Mean times were compared between pre- and post-intervention using a two-tailed paired t-test for normally distributed data. To evaluate satisfaction, we conducted pre- and post-intervention surveys of 20 RTTs. Survey response scores were statistically assessed using the Wilcoxon rank sum test for datasets without normal distribution.

Results
Mean time from patient setup films to signing of films by the attending physician was not reduced by the STTM system at 4.8 mins (SD, 3.1) pre-intervention vs. 8.2 mins (SD, 5.2) post-intervention. There was a trend towards reduction in time after implementation of the STTM system when films were signed before/after normal business hours by a non-service attending at 7.2 mins (SD 3.7) pre-intervention vs. 4.7 mins (SD, 1.4) post-intervention (p=0.15). Survey data indicated that when compared with standard communication between RTTs and attending physicians, the implemented STTM system was more effective in: (1) reducing the need to be in a specific hospital location to initiate or receive communication (p=0.015); (2) reducing the time between sending a message and receiving the desired response (p<0.001); (3) allowing for both sending and receiving communication (p<0.001); (4) allowing for ease of delegation of tasks to colleagues (p<0.001); (5) decreasing dependence on telephone calls (p<0.001); and providing general satisfaction with communication tools (p=0.002).

Conclusion
Based on the study results, we conclude that implementation of the STTM system provides a valuable means of significantly enhanced communication between RTTs at treatment machines and attending physicians. We expect that as familiarity with the new STTM system increases over time, objective improvements in workflow efficiency and treatment times will become manifest. This study adds to the literature on the utility of secure text messaging and we will continue to explore the ways that app-based communication can enhance clinical workflow and care.

Data Cleaning for Peace Corps’ Population Health Surveillance

Thomas M. Wilkinson, MD, Rennie W. Ferguson, MHS, Daniel Murphy, Adrianna Evans, Susan J. Henderson, MD, MPH; United States Peace Corps, 1111 20th St. NW, Washington DC 20526.

The problem: Using the Peace Corps electronic medical record (EMR) system, Peace Corps Medical Officers (PCMOs) have an opportunity to select ‘Epi codes’ to add epidemiological context about clinical findings. PCMOs are in the best position to provide accurate data for population health surveillance, since they provide direct care to Peace Corps Volunteers (PCVs) and are aware of the clinical context; however, given other demands on PCMO time, epidemiologic data collection can become a lower-priority task. In a survey conducted by the Centers for Disease Control and Prevention in 2016, a large number of PCMOs (41%) reported that it was ‘somewhat difficult’ to find an appropriate Epi code in the EMR. The Peace Corps Office of Health Services (OHS) Epidemiology and Surveillance Unit (Epi Unit) extracts epidemiological data from the EMR on a monthly basis, and the Epi codes are reviewed for accuracy based on manual chart review. Given the limitations on PCMO time and constraints within the current release of the EMR, we estimate that approximately one-third of appropriate Epi codes (28-40%) were not recorded between January and November 2016. Correcting this deficiency during data cleaning places an untenable burden on the Epi Unit and likely yields incomplete and possibly inaccurate datasets.

The solution: The primary data error we are seeking to correct is the absence of an appropriate Epi code. The code represents contextual information surrounding a patient encounter, it is only occasionally predictable from a related diagnosis code, and its absence constitutes a type of error that is difficult to detect or correct through automation. We designed a number of interventions to improve the initial capture of Epi codes by PCMOs at the point of care, but our focus was to support the data cleaning process itself. We decided to use simple methods to leverage existing unstructured data that PCMOs were already entering into the EMR, and to combine that with structured and semi-structured data from elsewhere in the chart into a single pipelined process for data cleaning.

1. Pre-analyze, annotate, and store textual data from sources such as History of Present Illness or consultation discussion threads, using regular expressions to match keywords, their spelling variants, and synonyms.
2. Assemble comprehensive sets of related data which all stem from a given patient encounter, including the textual data, any associated scanned documents, and structured data elements from the chart, such lab orders, the problem list, and the medication list.
3. Using Microsoft Access, create a data cleaning console, and present the datasets in a single stream for manual review, with highlighted keywords and URL links to supporting documents according to which Epi codes are being reviewed at the time.
4. Finally, record the human cleaner's decision as to whether a presented dataset in fact satisfies criteria for adding the Epi code in question, or not, so as to accumulate a corpus of text, documents, and data elements that can be used in the future as a reference set for machine learning.

The above process produces a moderately high recall with a moderately low precision, and was designed to simplify the manual review process, rather than try to replace it. Epi codes can be added or removed directly, based on a pre-assembled and annotated dataset, minimizing the need for detailed, time-intensive chart reviews. Looking ahead, we will use the accumulated corpus of datasets and Epi code decisions to build dynamic, context-sensitive, suggested coding for the PCMOs.

Exploration of Contextual Digital Data as a Source of Patient Safety Insight

Dana M. Womack, MS, RN, Michelle R. Hribar, Ph.D., Paul N. Gorman, MD
Oregon Health & Science University, Portland, OR

Abstract
Although analysis of operational data has led to safety improvements in non-clinical domains, patient safety research in informatics traditionally prioritizes electronic health record data over contextual workplace data. Preliminary findings from an exploratory analysis of contextual data include verification that these data reflect daily rhythms of care and may contain actionable insights. Current research seeks to identify hidden patterns in contextual digital data that may serve as early indicators of patient safety risk.

Introduction
Elimination of preventable harm in healthcare settings is an urgent priority. Although high reliability organizations “recognize that the earliest indicators of threats to organizational performance typically appear in small changes in the organization’s operations”1, hospitals currently lack real-time visibility into the moment-to-moment activities of clinical staff and patients. Transactional records and log files produced by workplace tools such as medication dispensing, nurse call, and communications systems contain temporal information about granular patient care activities. These contextual digital data are not included in the electronic health record, however, they may serve as a source of data in healthcare improvement research and expand the types of data used in future early warning systems.

Exploratory Analysis of Contextual Digital Data
Although contextual digital data is imperfect, “when data about workers and work environments come to exist in sufficient volume, and are increasingly ubiquitous, there is the potential for significant changes not only in the work we study, but also in how we study it and the depth of understanding that can be achieved”2. To explore this possibility in a healthcare setting, data for a 30-day period were extracted from five hospital operational systems. Over 40,000 time-stamped events were collected with an overall mean of 60 events per hour. Locked door entry was most frequent at 17.5 events/hour overall, followed by staff communication (16.1/hour) and medication dispensing (13.2/hour).

![Figure 1. Medication dispensing by hour of day and day of week reveals twice daily peak administration times](image)

Figure 1. Medication dispensing by hour of day and day of week reveals twice daily peak administration times

Exploratory data analysis confirms that contextual digital data reflects recognized daily rhythms, such as higher activity during daytime hours than nighttime hours. Peak medication administration times mirrored the hospital’s twice daily medication schedule (Figure 1). Bed exit alarms were seen in the exploratory dataset at irregular intervals. As an example of future application to patient safety research, bed exit alarm data could contain patterns, that when combined with additional contextual data, may inform the development of proactive interventions to reduce patient falls. Evaluation of relationships between contextual activity patterns and safety risk is the next step in this research.

Conclusion
The use of contextual digital data in safety research is new to the field of clinical informatics. Preliminary exploration has confirmed that operational data reflects daily rhythms. Current research seeks to find hidden patterns as early indicators of safety risk. Through exploration of relationships between temporal activity patterns and patient safety, this study will lay a foundation for proactive monitoring of latent safety conditions in the hospital setting.

Factors Affecting the Decision of Heart Failure Patients to Accept Telehealth Services in the Home: An Integrative Review

Kyungmi Woo, MA, BSN, RN, Ph.D.(c) 1, and Dawn Dowding, Ph.D., RN, FAAN 1, 2
1Columbia University School of Nursing, New York, NY, USA; 2Center for Home Care Policy & Research, Visiting Nurse Service of New York, New York, NY, USA

Abstract

Telehealth is an effective intervention for helping heart failure patients manage their symptoms at home. However, the refusal rate for telehealth services among eligible patients is reported to be between 24-70%. The aim of this review was to identify factors that may affect patients’ decisions to adopt or refuse telehealth services. Factors identified included concerns over equipment or technology, concerns over service change, ease of use, access to care, knowledge of telehealth and its benefits, cost, and privacy.

Introduction

Heart failure (HF) affects about 5.7 million adults in the USA and related deaths increased from 81.4 per 100,000 in 2012 to 84.0 in 2014.1 2 Telehealth (TH) is one intervention that can assist patients with heart failure manage their symptoms at home and has been shown to reduce all-cause 30-day readmissions from 19.3% to 5.2%.3 However, it has been reported that between 24-70% of eligible patients refuse telehealth.4 The purpose of this integrative review was to identify factors affecting HF patients’ decision making to accept or refuse TH services in the home.

Method

Electronic databases (Medline, CINAHL, Cochrane Library, Embase, Scopus, Web of Science, OpenGrey) were searched using both medical subject headings (MeSH terms) and key words. Studies were included if they reported original data related to the acceptance of TH among HF patients in home care. The initial search yielded 208 articles; after screening of titles, abstracts and full text 5 studies were included in the final review. All studies were appraised for quality using the Mixed Methods Appraisal Tool (MMAT).

Results

Four out of the five included studies reported positive patient attitudes toward the use of TH. Refusal rates reported in the included articles ranged from 29% to 37%. Several factors were found to be related to decision-making regarding TH acceptance. These include: concerns over equipment or technology, concerns over service change, ease of use, access to care, knowledge of telehealth and its benefits, cost, and privacy.

Conclusion

Results of the review identified specific patient concerns about the use of TH and factors that could boost HF patient’s adoption of TH. Overall general perceptions toward TH are positive in this population. Building upon these positive views, healthcare providers can create and implement practices that further promote the use of TH in HF patients.

A Phenome-Wide Association Study (PheWAS) of Iron Deficiency in a Large Electronic Health Record Database

Patrick Wu, BS1; Joshua C. Denny, MD1,2; Wei-Qi Wei, MD, PhD1
1 Department of Biomedical Informatics, Vanderbilt University School of Medicine, Nashville, TN 37203
2 Department of Medicine, Vanderbilt University School of Medicine, Nashville, TN 37232

Introduction: The phenome-wide association study (PheWAS) method was originally developed to discover phenotype associations for target genetic variants, but its utilization has been further extended to find links between laboratory data and phenotypes1. A recent study suggested an association between iron-deficiency anemia & hearing loss2. We sought to replicate their findings and to explore the breadth of biological insults associated with iron deficiency using PheWAS.

Methods: We conducted a PheWAS analysis using data from the Electronic Health Record (EHR) at Vanderbilt University Medical Center (VUMC). We have identified 1,862 cases (male: Total Iron Binding Capacity (TIBC) >450 µg/dL & Ferritin <24 ng/ml; female: TIBC >450 µg/dL & Ferritin <15 ng/ml) and 30,277 controls (male: TIBC = 250-450 µg/dL & Ferritin = 24-336 ng/ml; female: TIBC = 250-450 µg/dL & Ferritin = 15-204 ng/ml) from the cohort that met our medical home criteria3. We performed the analysis using the R PheWAS package4.

Results: In this study, we found highly significant associations between iron deficiency with anemias and digestive disorders. Further, in addition to replicating the finding of combined hearing loss in males, we observed a new clinical association between iron deficiency with depression in female individuals.

Conclusion: In this PheWAS analysis, iron deficiency was clinically associated with hearing loss and depression in male and female individuals, respectively.

**Toward Reading Comprehension of Online Health Information: An Initial Annotation**

Danny T. Y. Wu, PhD, MS¹, Seung-Hyun B. Ko¹, Chris A. Feak, PhD²

¹University of Cincinnati Department of Biomedical Informatics, Cincinnati, OH; ²University of Michigan English Language Institute, Ann Arbor, MI

**Introduction**

Online health information is widely accessible and can provide patients and others with medical knowledge. It is also beneficial in facilitating patient-provider communications. Despite these expected benefits, the full potential of online health information cannot be achieved without individuals being able to read the text and comprehend the content. This highlights the importance of having a reliable means of ensuring that online health information is produced in a highly comprehensive manner to patients and others.

While computational methods for assessing the readability of online health information has been developed and widely used, such as the Flesch-Kincaid Ease Formula, very few exist that accurately and reliably quantify the elements contributing to reading comprehension of online health information. The goal of this study is therefore to develop such a computational method and improve the comprehensibility of online health information in the long run. The research team utilized a scientific writing technique called “old-new” information flow¹ to assess the comprehensibility of online health information. This is consistent with research in Applied Linguistics showing that when a text is written such that the information in a sentence proceeds from given or familiar to new, this is a strong indicator of text comprehensibility.

**Method**

MedlinePlus health topics were selected as a highly readable online health information based on our previous research². Since this corpus is claimed to be carefully maintained “in language that laypeople can understand”, it is an ideal source to examine how old-new information is followed. We hypothesized that the Medline Plus health topics strictly follow this progression of information to achieve their high level of reading comprehension. To facilitate the annotation process, we extracted medical concepts from the health topics using MetaMap and presented the concepts along with the original text using the brat rapid annotation tool (http://brat.nlplab.org/).

**Results**

A total of 993 Medline Plus health topics were downloaded from MedlinePlus on Nov 2016 as one XML file. Each health topic and its attributes were parsed using the Python BeautifulSoup library and stored in a SQLite database. Through the brat rapid annotation tool, two native English-speaking college students are able to highlight medical concepts in each sentence and link the concepts between sentences to indicate the old-new information flow. Moreover, human annotated concepts can be compared with those identified by MetaMap to explore which semantic types of medical concepts play a significant role in information flow (Figure 1). A simple measure based on the number of linkages between sentences has been developed to assess the validity of this approach. This annotation task will be extended to other online health information, such as ClinicalTrials.gov and PubMed abstracts, to ensure the effectiveness of the computational method.

**Conclusion**

This manuscript presents the initial effort to collect human annotations in preparation for the development of a computational method capable of quantifying the old-new information flow of online health information, which has implications on generating writing suggestions to improve the comprehensibility of online health information.

Classification method of dental electronic health record data potentially improves precision treatment

Di Wu, PhD
Department of Biostatistics, Department of Periodontology, University of North Carolina, Chapel Hill, North Carolina 27599

Abstract: The statistical method Latent (Hidden) Class Analysis, derived from the available dental DARIC study, was used in the local electronic health records collected in periodontal clinics at UNC, for novel classification of dental patients and teeth to subtypes, which results suggest different treatment effects for patients in the different newly classified dental clinical subtypes.

Introduction: The rationale for creating new personalized dental therapies is based upon the observation that not all patients respond favorably to a standardized care. The Latent (Hidden) Class Analysis (LCA) classification model has previously built [1], that provides parameters for other dental cohort to classify individuals into seven latent periodontal profile classes (PPC) classes based on 224 dichotomous clinical variables (from 32 teeth). The tooth-level LCA classified teeth into seven latent tooth profile classes (TPC), based on 14 categorical clinical parameters [2]. The combination of PPC and TPC allows the dental treatment evaluation at both the patient and tooth levels. We hypothesized that the LCA method with multiple clinical measures can better refine clinical phenotypes and provide insight into creating effective measures of treatment outcomes.

Methods: We accessed the dental electronic health records (EHR) for patients over the past 5 years, from the periodontal clinics at UNC, that include the clinical variables required to calculate PPC and TPC as well as the demographic variables and the treatment information. 3,704 subjects were placed into the novel LCA classifications (7 PPCs) and each of their teeth into one of the 7 TPCs. The criteria on the baseline data for follow-up exam data period and tolerance of missing teeth were applied. Treatment responses for scaling and root planning vs surgery were compared across PPCs and TPCs.

Results: For the teeth with severe TPC, significant difference of improvement at probing depths and bleeding on probing levels was observed for the patients who received surgery as compared to those who received scaling and root planing. By comparison, using the conventional American Dental Association (ADA) definition of classification of severe disease, no significant difference was observed when comparing scaling and root planing vs following surgery.

Conclusion: This LCA-based classification method may be more sensitive than the conventional classification method for detecting certain types of treatment responses. Furthermore, it suggests that measuring treatment outcomes might be streamlined based upon LCA classifications.

Detecting Contradictory and Consistent Citations in Biomedical Literature

Jun Xu, Ph.D., Yonghui Wu, Ph.D., Yaoyun Zhang, Ph.D., Qiang Wei, M.S., Hua Xu, Ph.D.
School of Biomedical Informatics, The University of Texas Health Science Center at Houston, Houston, Texas, USA

INTRODUCTION
Lack of reproducibility in scientific studies is an increasing concern in biomedical research.¹ The scientific community has made many concerted efforts to improve reproducibility, such as raising research standards, promoting data sharing and re-use, and examining results through replication etc.² However, the current efforts require substantial resources and take long time to establish. Here we propose to develop novel citation analysis approaches to identify irreproducible studies. Scientists use citations to compare research findings with others, build strong and multi-faceted arguments, and report consistencies and contradictions among relevant studies. Hot research topics often bring many follow-up studies to examine new findings and compare with existing findings to report consistencies or raise contradictions. Figure 1 shows an example of the consistencies and contradictions among citations, where findings from the follow-up studies (reference ids: 12-15) contradict the findings reported in previous studies (reference ids: 9-11). Automatic detection of consistent and contradictory relations among biomedical literature citations could help researchers to understand author’s stances on specific scientific claims, which may be used to identify possible irreproducible studies. However, very few studies have explored the automatic detection of contradictions and consistencies through citation content analysis. To the best of our knowledge, this is the first study that investigates automatic methods to detect contradictory and consistent citations based on their stances on a specific claim.

MATERIALS AND METHODS
Data Set This study started with 34 eligible clinical studies collected by a review paper². We collected all the publications citing these 34 studies from the Open Access subset of PMC and extracted paragraphs containing citations referring to the above referenced 34 studies. Then, we developed annotation guidelines and manually annotated these paragraphs using three categories: Consistent, Contradictory, and NA. Figure 2 shows examples from our manual annotations. Through annotation, we constructed a corpus containing 2,210 relations (#Consistent: 632; # NA: 1,429; #Contradictory: 149) identified from 1,013 sentences.

Machine Learning Approach We extracted words, biomedical effects related lexicons (e.g. “increase” and ‘negative’) and syntactic components combining positions of the words (before, between or after the target pair) as features from the citing sentence. We developed a machine learning based relation classification system using the Support Vector Machines algorithm.

RESULTS

Table 1 shows the 10-fold cross-validation results for citation relation classification. The model combining all features achieved the best performance (Accuracy: 0.896, Micro-F: 0.896 and Macro-F: 0.781).

DISCUSSION and CONCLUSION
Automatic detection of contradictory and consistent citations could help biomedical researchers to understand author’s stances on specific scientific claims, which may be used to further identify possible irreproducible studies. We developed annotation guidelines and constructed the first data set for biomedical citation relation analysis. Preliminary results indicate that the citation relation classification is a challenging problem. To the best of our knowledge, this is the first study exploring automatic detection of contradictions and consistencies from biomedical literature through citation content analysis.

Evaluation of Automated Spectrographic Seizure Detection Using Scale Invariant Feature Transform and Support Vector Machines

Peter Yan, MD1,2, Fei Wang, PhD2, Ramin Zabih, PhD3, Zachary Grinspan, MD, MS2,4

1Dept. of Neurology, Weill Cornell Medicine, NYC, NY; 2Dept. of Health Policy & Research, Weill Cornell Medical College, NYC, NY; 3Dept. of Computer Science, Cornell Tech, NYC, NY; 4Dept. of Pediatrics, Weill Cornell Medicine, NYC, NY

Introduction. Subtle and non-convulsive seizures (NCS) are difficult to clinically diagnose. The bedside clinician must rely on the electroencephalogram (EEG) as the primary diagnostic tool. EEG is complex. It contains 18-channels and requires neurophysiologist interpretation (gold-standard). In critically ill patients, the EEG workflow is laborious and may delay treatment by hours.[1] Thus, automated seizure detection would be valuable. EEGs can be processed into spectrograms, colored images that represent the EEG’s frequency content changing over time. One popular technique is the Compressed Spectral Array (CSA), but it remains complex, consisting of eight spectrograms.[2] We have previously developed the Median Power Spectrogram (MPS) that not only provided improved spectral resolution, but was less complex (1-3 spectrograms) and maintained seizure detection comparable to CSAs (mean 77% sensitivity and 72% specificity when used by bedside clinicians). Furthermore, users required only 5-minutes of training.[3] We hypothesize that Scale Invariant Feature Transform (SIFT) descriptors, a common image descriptor in computer vision[4], may be used with Support Vector Machines (SVM) to auto-detect seizures in spectrograms, and SVMs using SIFT descriptors from the MPS will outperform those from the CSA.

Methods. EEGs: 282 randomly selected 2-minute EEG segments, 50% containing seizures. Two minutes is the typical clinical window for treatment decisions. Seizures were annotated by neurophysiologists from Boston Children’s Hospital and Weill Cornell Medical Center. EEGs and annotations were acquired from the PhysioNet EEG database.[5] Spectrograms: CSAs and MPS images were generated via short time Fourier Transform (1024 point, 4s window, 1s step) from EEGs. 8-spectrogram CSAs were created using a cosine taper.[2] Single spectrogram MPS was created with multi-taper spectral estimation. Image Processing: SIFT descriptors were created over a 2D 4x4 grid (16 bins) moving across the image at 50% bin width. To determine the optimal bin size (in pixels [px]) for calculating SIFT descriptors, SIFT descriptors were calculated at various bin widths (8px by 2px incrementing to 24-px) for all images. Classification: Quadratic kernel C-SVMs were trained using SIFT descriptors. Hyper-parameters (kernel scale & C) were optimized using grid search. SVM performance was assessed using 10-fold cross validation in all optimization iterations. MATLAB v2017a was used in all steps.

Results. The optimal SIFT descriptor bin widths were 10px for CSA and 20px for MPS images. Using the optimized SIFT descriptors hyper-parameters, the MPS SVM performance was 91% sensitivity, 92% specificity, 0.98 AUC. The mean CSA SVM performance (across 8 spectrograms, all using optimized SIFT descriptors and hyper-parameters) was 66% sensitivity, 88% specificity, and 0.86 AUC.

Conclusion. Seizures can be identified on EEG spectrograms using SIFT descriptors and SVMs. The MPS trained SVMs outperformed CSA trained SVMs. Seizure detection using MPS based SVMs can provide rapid bedside seizure detection with high performance compared to current clinical practice, where inter-neurophysiologist agreement on EEG interpretations is at best modest and 20% may be inaccurate.[6]

Preliminary Study of the Portability of an Automated Text Categorization Model to Identify Unsuspected Lung Nodule Findings in Radiology Reports

Jianji Yang, PhD1, Theodore B. Wright, MD1,2, James Morrison, MD1,2
1VA Portland Healthcare System; 2Oregon Health & Sciences University, Portland, OR

Introduction
The Unsuspected Radiologic Findings (URF) Registry, a web-based tool developed at The VA Portland Healthcare System (VAPORHCS), helps expedite the diagnosis of lung cancers by ensuring that incidental lung nodules are identified and managed in a timely manner1. During dictation of a radiology report, a unique URF code is added to the results of the study at the discretion of the radiologist. The presence of this code is used as the inclusion criterion for the Registry. To improve the accuracy of the registry, a text categorization model was developed to identify nodule-positive reports with missing URF codes by analyzing the report text2. The model was developed using a linear-kernel Support Vector Machine trained on a bag-of-words representation of the Impression text of fifty-thousand radiology reports. It performed well with F1 & F5 scores of 0.98 in evaluation. In November 2016, VA Puget Sound Health Care System (VAPSHCS) implemented the URF Registry and their radiologists began adding URF codes to nodule-positive cases. Before implementing the text categorization model to identify cases with missing URF codes at VAPSHCS, the model’s portability was evaluated by comparing its performances at VAPORHCS and VAPSHCS.

Methods
We applied the model to both VAPORHCS and VAPSHCS lung-related radiology reports from 1/1 to 3/2/2017 to classify each case as either nodule-positive or nodule-negative. We defined true positives as cases that had a URF code assigned by radiologists, while false positives had no associated URF code. We then calculated the performance measures of recall, precision, F1 and F5. As the model aims to provide a safety net to capture all nodule-positive cases, we report F5 scores (emphasizing recall) as the key measure for performance. Finally, false positives from VAPSHCS were further reviewed by an Internist at VAPORHCS (TBW) to evaluate the error rate of URF coding.

Results
At VAPORHCS, 766 (6%) out of 12,499 lung-related imaging studies had a URF code. At VAPSHCS, 172 (2%) out of 7,816 were URF-coded. Compared to VAPORHCS, model performance dropped in all categories at VAPSHCS, with the precision for nodule-positive suffering the most. Please see Table 1 for a summary and comparison of model performance. After expert review, 71 (43%) out of the 167 false positive cases at VAPSHCS were found to be nodule-positive actually. This is a significantly higher rate than reported by prior studies at VAPORHCS (10%)2.

</tbody>
</table>

Discussions and Conclusions
Model performance at VAPORHCS remained high and consistent with past results2. The prior probability for nodule-positivity appears much lower at VAPSHCS than VAPORHCS. This might be due to URF under-coding early in the implementation, or could reflect a true lower incidence of URF. The additional 71 node-positive cases found after expert review support the first possibility. They also partially explain the drop in precision (0.68 to 0.22). Other factors affecting the portability, e.g. difference in narrative style and URF coding guidelines, will need further exploration.

In conclusion, we show that porting an automated text categorization model to a new corpus led to an expected drop in performance. We also show that the model is capable of uncovering human error and finding room for improvement in an early implementation of the URF registry. However, while the baseline model might be used to identify reports with missing URF codes and provide feedback for improving clinician coding adherence early in an implementation, re-training of the model using a local corpus should be performed as this should further improve model performance.

Visualizing Social Support Mechanisms in English and Spanish Tweets to Meet Self-Management Needs of Family Dementia Caregivers

Sunmoo Yoon, PhD¹, Niurka Suero-Tejeda, MA¹, Robert Lucero, PhD², Suzanne Bakken, PhD¹

¹Columbia University School of Nursing, New York, NY, ²University of Florida College of Nursing, FL, USA

Abstract
We analyzed 314,000 dementia related tweets collected on World Alzheimer’s Day in 2015 and 2016 applying network analysis, topic modeling, and visualization techniques to gain insights about dementia caregiving.

Introduction
The incidence of dementia is increasing. Although belongingness is a human basic need, in our previous studies we observed many isolates in Twitter social networks who do not receive feedback from others ¹. The study purpose is to visualize social support networks and topics to gain insights about dementia caregiving.

Methods
Using NodeXL and Ncapture, we extracted 314,000 Tweets mentioning Alzheimer’s and dementia/demencia related keywords from Tweet corpora collected on World Alzheimer’s Day in 2015 and 2016. We applied Latent Dirichlet allocation (LDA)-based topic modeling (Figure 1)², network analysis, and novel visualization techniques.¹

Results
48 different languages were detected. LDA revealed self-management concerns of dementia caregivers including role (i.e. finding providers), medical (i.e sleep, symptom awareness) and emotional (i.e. stress, depression) management. The proportion of isolates, who express their opinions and feelings but receive no feedback, was substantially decreased in 2016 (P< .0001) as compared to 2015(Figure 2).

Conclusion
Application of mining and visualization techniques provided knowledge for insights regarding dementia caregiving and self-management needs for the person with dementia and the dementia caregiver. The topic modeling findings such as early diagnosis from English and family caregiving supports from Spanish corpus will be used for a targeted intervention development for English- and Spanish-speaking Hispanic dementia caregivers.

Novel Visualization of *Clostridium difficile* Infections in Intensive Care Units

Sean C. Yu, MS\(^1\), Courtney L. Hebert, MD, MS\(^1\), Albert M. Lai, PhD\(^2\), Justin Smyer, MLS(ASCP)CM, MPH, CIC\(^1\), Jennifer Flaherty, RN, MPH, CIC\(^1\), Julie Mangino, MD\(^1\), Susan Moffatt-Bruce MD, PhD, MBA\(^1\)

\(^1\)Ohio State University Wexner Medical Center, Columbus, OH, USA; \(^2\)Washington University, St. Louis, MO, USA

**Introduction**

Approximately 1 in 25 inpatients in U.S. acute care hospitals develops at least one healthcare-associated infection (HAI), and *Clostridium difficile* (CDI) is the most common pathogen\(^1\). CDC National Healthcare Safety Network (NHSN) publishes reporting guidelines to track HAIs including CDI. It is widely known that HAI CDI can be transmitted via contact with contaminated hospital sources, and there have been efforts to incorporate geospatial and temporal dimensions for CDI surveillance\(^2\). However, most studies do not leverage geographic information systems (GIS) nor do they have a path towards operationalization of real-time analytics or visualization tools to track HAIs.

**Methods**

Lab results and admission discharge transfer (ADT) data on all patients admitted to the Ohio State Wexner Medical Center (OSUWMC) from 1/1/2015–12/1/15 were extracted from the information warehouse and processed in accordance with CDC NSHN guidelines to identify HAI CDI cases. Results were validated against the infection preventionist (IP)-curated surveillance database as a gold standard. We obtained GIS files for the hospital and used them to prototype a dashboard in Tableau (Seattle, WA). The dashboard shows OSUWMC intensive care unit floor plans and allows the user to visualize HAI CDI cases within an adjustable time period as dots in the room of attribution. Rooms that a patient was housed in from 2 days before to 7 days after diagnosis are shaded, so the user can see rooms that may have been contaminated during that time period. The user can also select single or multiple rooms to drill down and identify details of patient(s) with CDI in those rooms. We performed a formal usability study for this dashboard with four Clinical Epidemiology staff using a think-aloud protocol\(^3\) and anonymous survey.

**Results**

Using integrated data, we were able to automate HAI CDI surveillance and display results on an interactive map of the ICUs. During the study period, we recorded 253 HAI CDI cases throughout our multi-hospital system. Our simple algorithm correctly identified all 253 HAI CDI cases with a PPV of 97.31%. On the survey, all users “strongly agreed” that the dashboard would be a positive addition to Clinical Epidemiology and would allow them to present HAI information to others more effectively. All “agreed” or "strongly agreed" that they felt confident in manipulating the dashboard to demonstrate to others and that it was easy to learn and use. Respondents also suggested improvements to specific features including improving the intuitiveness of changing the date ranges, adding isolation information, and showing present on admission CDI cases.

**Conclusion**

Given success with surveillance automation and visualization and positive responses from the initial round of usability testing, we are now developing a second web application-version for improved flexibility, extensibility, and the capacity to integrate with existing systems including the EHR. We anticipate that this application will be leveraged for use with other HAIs and hospital events that would benefit from spatiotemporal visualization.

Subtype Discovery for Autism Spectrum Disorder by Comorbidity Analysis

Kun-Hsing Yu, MD, PhD¹, Nathan Palmer, PhD¹, Isaac S. Kohane, MD, PhD¹
¹Department of Biomedical Informatics, Harvard Medical School

Introduction

More than 3.5 million Americans suffer from autism spectrum disorder (ASD), costing $236 billion annually in medical and behavioral interventions. ASD patients have a wide range of clinical manifestations and prognosis. However, the current classification guideline (Diagnostic and Statistical Manual of Mental Disorders, 5th Edition; DSM-5) only accounts for disease severity and intellectual or language impairment. A richer and clinically relevant subtyping system will better distinguish ASD patients with different medical needs and different underlying biology. To address this challenge, we studied the comorbidities of ASD patients in a nationwide health insurance database and identified the phenotypical differences between patients with different patterns of comorbidities.

Materials and Methods

Using the unidentifiable member claims data from Aetna, a total of 132,211 ASD patients were found using the PheWAS code 313.3, and a 1:1 age-and-gender-matched control cohort was selected from this dataset. To identify the phenotypical differences between ASD patients with and without certain comorbidities, all PheWAS codes between the comorbidity groups were examined. Specifically, for each of the known ASD comorbidities (Cᵢ), such as epilepsy, inflammatory bowel disease (IBD), and obsessive-compulsive disorder (OCD), ASD patients with and without Cᵢ were separated into two groups (Gᵢ₊ and Gᵢ₋), and the prevalence rate of each PheWAS phenotype (Pⱼ) between age 0 and 19 was calculated for both groups. For each Pⱼ, Wilcoxon rank sum test was employed to identify its prevalence rate difference between Gᵢ₊ and Gᵢ₋, and the odds ratio (OR) was estimated to determine the effect size. The same procedure was repeated for the control cohort. Benjamini-Hochberg procedure was employed to control the false discovery rate (FDR) at 0.05. All analyses were performed using R version 3.3 with R packages icd and NMF.

Results

We found that ASD patients with epilepsy were more likely to suffer from primary pulmonary hypertension (OR=4.80), somatoform disorder (OR=3.89), aphasia (OR=3.58), esophagitis (OR=2.96), and cystic fibrosis (OR=2.37), comparing with those without epilepsy. Similarly, ASD patients with IBD were more likely to have celiac disease (OR=9.87), immunity deficiency (OR=8.33), and chronic sinusitis (OR=2.25) comparing with ASD without IBD. Moreover, ASD patients with OCD were more likely to develop tics and chorea (OR=4.16) and irritable bowel syndrome (OR=2.46) but are less likely to have cystic fibrosis (OR=0.40). These differences (FDR<0.05) were not observed between non-ASD participants with and without epilepsy, IBD, or OCD, respectively, and the ORs in ASD patients with two comorbidities were not simple multiplications of the ORs obtained from patients with one comorbidity. Comparing to ASD patients, non-ASD children were more likely to have influenza and clavicular fracture. The modularity of these comorbidities indicated that ASD might constitute many dissimilar disease subtypes.

Discussion

To our knowledge, this is the first systematic analysis of the ASD comorbidity patterns in a large national cohort. We demonstrated that patients with different comorbidities have dissimilar clinical phenotypes. For instance, ASD patients with IBD had higher risks of many immune-related disorders. However, these immune disorders were not enriched in ASD patients without IBD or IBD patients without ASD, indicating that ASD-IBD could be a distinct ASD subtype with unique clinical manifestations. These findings have direct implications in the clinical managements of ASD patients. Further studies are needed to explore the biological mechanisms underpinning these phenotypes.

Utilizing EHR-based Recruitment Methods

Marianne Zachariah1,2, Carina V. Hampp1,2, Ruby Y. Wan, MS1,2, Amanda L. Do, MPH1,2, and Douglas S. Bell, MD, PhD1,2

1UCLA Clinical & Translational Science Institute (CTSI), Los Angeles, CA; 2UCLA David Geffen School of Medicine, Los Angeles, CA

Introduction

Traditionally, studies involving patient recruitment have relied on methods such as flyers and advertisements, physician referrals, and in-clinic recruitment. Unfortunately, these methods typically result in low enrollment rates. Electronic health record (EHR)–based recruitment methods offer an alternative, and possibly more effective approach. For this study, we evaluated: 1) the extent to which research studies involving patient recruitment at UCLA utilized EHR-based methods, 2) considerations that may be needed when adopting EHR-based recruitment methods, and 3) the success of EHR-based recruitment methods.

Methods

All studies for which data has been provisioned by the UCLA CTSI Informatics Program for recruitment efforts were selected for review. Each study’s IRB application was analyzed, and information related to study methods and recruitment was summarized. Variables of interest were identified, including whether traditional recruitment methods were used in conjunction with EHR-based methods vs. EHR-based methods only, the outreach methods (in-clinic, flyers/ads, referrals letters, telephone, email), on whose behalf outreach was conducted, if physician approval to approach patients was obtained, the department of principal investigator (PI), the study’s level of sensitivity, and whether any patient complaints were received. Enrollment statistics were also requested for each study and compared to recruitment methods and recruitment language.

Results

Of the 27 studies reviewed to date, 78% (21) used a combination of traditional recruitment methods (e.g. ads/flyers, physician referral) and EHR-based recruitment methods while 22% (6) relied solely on EHR-based recruitment methods. Of the studies that used traditional recruitment approaches, 86% (18/21) involved in-clinic recruitment or physician referral, 71% (15/21) used ads/flyers, and 14% (3/21) reached out to patients who participated in other studies. Focusing only on EHR-based methods, 52% (14/27) of studies obtained physician approval before contacting patients, 70% (19/27) sent letters to a list of eligible patients, 11% (3/27) sent emails or patient portal messages, 67% (18/27) telephoned patients, and 4% (1/27) provided physicians with a list of their eligible patients and asked for assistance with recruitment. For the studies that used EHR-based methods to identify patients for outreach via a letter, email, portal message, or telephone call (25/27 studies), patients were informed that they were being contacted on behalf of either the study’s PI (72%, 18), a department chair (8%, 2), the patient’s own physician (16%, 4), or it was ambiguous (24%, 6). The studies spanned 13 departments or divisions (e.g. 19% nephrology, 15% rheumatology, 11% general internal medicine), and 15% (4/27) were on a sensitive topic (e.g. drug abuse) while 85% (23/27) were not sensitive. Patients from 2 studies (7%) complained about the outreach to the IRB. One complaint was related to a violation of the IRB-approved outreach protocol. The other was related to contacting a patient who had died. Results for enrollment statistics are pending as data collection is still ongoing.

Discussion & Conclusion

Preliminary analysis indicates that most studies (78%) use a combination of traditional recruitment methods and EHR-based recruitment methods, suggesting that researchers still believe that traditional recruitment methods are effective. The most common traditional method of recruitment is in-clinic recruitment or physician referral (86%), which suggests that researchers believe that face-to-face interaction is important. The most common EHR-based outreach method is mailed letters (70%), which is costly compared to email, but email is utilized much less (11%). Low use may be attributed to security/privacy concerns from the IRB and the fact that some patient subgroups would be underestimated. When patients were contacted by letter, email, portal message, or telephone call, the EHR-supported outreach was most often conducted on behalf of the PI (72%). Most studies requesting data for recruitment purposes were not related to a sensitive topic (85%). Further analysis of results from these recruitment efforts will investigate how enrollment rates were affected by the factors listed above.
Recommending education materials for diabetic questions using information retrieval approaches

Yuqun Zeng$^{1, 2}$, Yanshan Wang$^2$, Feichen Shen$^2$, Sijia Liu$^2$, Liwei Wang$^2$, Majid Rastegar Mojarad$^2$, Xusheng Liu$^1$, Hongfang Liu$^2$
$^1$The Second Clinical College, Guangzhou University of Chinese Medicine, Guangzhou, Guangdong, P.R. China $^2$Division of Biomedical Statistics and Informatics, Mayo Clinic, Rochester, MN, USA.

Background
Self-management is crucial to diabetes care and providing expert-vetted content for patients’ questions is crucial in facilitating patient self-management.

Objective
To investigate the use of information retrieval (IR) techniques in recommending patient education materials for diabetic questions of patients.

Methods
We compared two retrieval algorithms, one based on LDA topic modeling (TMB) and one based on semantic group (SGB), with the baseline retrieval models, vector space model (VSM) in recommending diabetic patient education materials (144 materials from patient education database at Mayo Clinic) to diabetic questions posted on the Tudiabetes forum (7,510 diabetic questions). The evaluation was based on a gold standard made by two experts with high agreement, and the experts manually assigned all diabetic education materials with the relevancy (0-2 ranking) to give 50 randomly selected diabetic questions. The performance was assessed using a precision algorithm of top ranked documents.

Results
Corpus analysis indicates language used by diabetic questions is different from patient education materials, the Heatmap of forum question category and PEM topic shows in Figure 1. TMB outperformed other retrieval algorithms (Figure 2). For example, for the top retrieved document, the precision of TMB, SGB, and VSM model is 67.0%, 62.8%, and 54.3% respectively.

Conclusion
The study demonstrated topic modeling can mitigate the vocabulary difference and achieved the best performance in recommending education materials to questions. One direction for future work is to assess the generalizability of our findings and extend our study to other disease areas, other patient education material resources, and online forums.

Towards Improving the Quality of Medicaid Data: Identifying Data Defects in a Large Healthcare Administration System

Yili Zhang, MS, Pratik Tamakuwala, BE, and Güneş Koru, PhD
University of Maryland, Baltimore County, Baltimore, MD

Introduction
As the use of information systems in healthcare increases, data quality problems are encountered at an increasing rate in healthcare organizations.¹ A lack of data quality can result in imprecise, useless, or even misleading results which detract from the quality of reports produced and decisions made.² Medicaid data have served as a useful resource for various healthcare research activities, however, the deficiencies in the Medicaid data often increase the difficulty in obtaining useful results.³ Thus, effective data maintenance and cleaning become crucial to improve the quality and utility of the Medicaid data. In this research study, we focused on the first step to improve the quality of data in the Provider, Procedure, and Diagnosis subsystems of a Medicare and Medicaid Management Information System (MMIS). Specifically, we identified the types of data defects, created a taxonomy of data defects, and finally detected all of the data defects in the MMIS data automatically with respect to the taxonomy created. In this context, a data defect refers to a discrepancy between the actual and expected values held by a data item which requires a corrective change.

Methods
As the first step, all of the available and relevant documents kept in the organization were reviewed. Next, a descriptive analysis was performed to better understand the data and create a data defect taxonomy with essential data defect categories. Then, an extensive literature review was performed to supplement more categories to the taxonomy of the data defects. A data quality toolkit (DQT) was developed to detect the data defects automatically and efficiently according to the created taxonomy. Finally, DQT was run on the datasets to detect the existing defects in various categories. The datasets subject to defect detection consist of 1.5 million, 700 thousand, and 200 thousand records for the Provider, Procedure, and Diagnosis subsystems, respectively.

Results
The taxonomy of data defects includes six major categories: Missing data, wrong value, syntax violation, semantic violation, duplicate, and ambiguous value. These major categories are further divided into eighteen subcategories. Corresponding to this defect taxonomy, DQT detected more than three million data defects in the MMIS data, which is more than the number of records since each record has multiple columns and the value in each column could violate one or more rules. The syntax violation category had the highest number of defects, followed by the missing data and semantic violation categories. Most of the syntax violation defects were about the invalid values of certain Medicaid codes. Wrong value usually occurred due to large amount of implausible high or low values. These problem areas should be the focus of future organizational initiatives for data quality improvement.

Conclusion
The results contribute to the body of knowledge in this area by providing (i) refined and detailed taxonomy of data defects, (ii) effective and efficient methods to detect data defects, and (iii) the prevalence and distribution of data defects in a large MMIS. So far, there has been no study which created a taxonomy of data defects for the healthcare data and detected the data defects automatically. This research takes the first step to make the Medicaid data an even more useful resource for healthcare research. More generally, it makes a timely contribution for improving data quality as we make progress towards learning health systems.

A Twitter Study of the Relationship between the Geographic Variations of HPV Vaccination Rates and Online Information in the United States

Hansi Zhang, BS1, Yunpeng Zhao, BS1, Christopher Wheldon, PhD2, Xinsong Du, BS1, Terrell Brown, PhD3, Yi Guo, PhD1, Stephanie Staras, PhD1, Jingcheng Du, BS4, Cui Tao, PhD4, Jiang Bian, PhD1

1University of Florida, Gainesville, FL; 2National Cancer Institute, Rockville, MD; 3Florida A&M University, Tallahassee, FL; 4UT Health Science Center at Houston, Houston, TX

Introduction: Human papillomavirus (HPV) is responsible for more than 90% of anal and cervical cancers. On the other hand, the current HPV vaccine can prevent 90% of cancers caused by HPV infections. The HPV vaccination coverage in US remains low, and has significant variations among states. Nationally, coverage rates of HPV vaccination have been increasing since its recommendation. Online information and online discussions of HPV-related issues may have a considerable influence on public’s perception and acceptance of HPV vaccination. Thus, the geographic variations may be related to the availability and the quality of online HPV information. Further, the use of social media such as Twitter has dramatically increased over the past decade. Nowadays, social media is one of the most popular ways to get health information and exchange health-related experiences. In this work, we use Twitter data to study the relationship between the state-level variations of HPV vaccination rates and online information.

Methods: First, we collected tweets related to HPV using keywords and their variations such as “hpv”, “human papillomavirus”, and “gardasil”. We first preprocessed the collected data to eliminate tweets that were not written in English. Using our previous geocoding method, we assigned each tweet to a US state based on the location string in the user’s profile, and eliminated those that were outside of US. We used a set of simple rules to categorize these HPV tweets into two groups: 1) online information such as news and expert opinions, and 2) lay people’s discussions and reactions to this online information. Second, we used the TextBlob tool to assess the sentiments (i.e., positive, negative and neutral) of the tweets tagged as lay people discussions. We then aggregated the sentiment analysis results at the state level. Third, we extracted topics from the tweets tagged as online information using the Latent Dirichlet Allocation (LDA) model for topic modeling. Last, we selected several opposite states based on their adolescent HPV vaccination rates (low vs. high), and qualitatively studied the relationship among the vaccination rates, the topics and lay people’s sentiments among these states.

Results: We collected 242,685 tweets from November 2015 to December 2016. After eliminating non-English and non-US tweets, we retained 62,396 tweets for further analysis. Based on a CDC report, we selected 2 states with high vaccination rates (DC, PA), and 2 with low rates (FL, GA). The set of rules (e.g., a tweet is tagged as online information if it contains an URL or from an organization) we used performed reasonably well to categorize the tweets (precision:0.84, recall:0.72) on a manually reviewed sample (~100). We also evaluated the sentiment analysis tool on another manually labeled sample (~100), and obtained good performance (precision: 0.80, recall:0.63). The proportion of positive sentiments is consistently higher than negative sentiments across all states, which reflects the rising trend of HPV vaccination uptakes. Further, we observed geographic variations in terms of HPV vaccination rates and lay people’s sentiments towards HPV. States with high vaccination rates also have high positive to negative sentiment ratios (DC: 3.38; PA: 2.53); while, states with low vaccination rates have low sentiment ratios (FL: 1.57, GA: 1.69). Moreover, using LDA, we extracted topics from online information of two opposite states, DC with a high vaccination rate vs. FL with a low vaccination rate. As shown in Figure 1, there were more negative words in FL than in DC, such as ‘adverse effects’, ‘deadly’, and ‘scam’. While in DC, the words like ‘good’, ‘effective’, ‘safety’ appeared more frequently.

Conclusion: Our study found that the lay people’s opinions towards HPV on social media in a state are associated with the state’s HPV vaccination rate. Promoting positive HPV vaccine discussions on social media, including Twitter, may be a promising intervention tool to increase HPV vaccination and, in turn, cancer prevention.

Effects of Clinical Decision Support Implementation on Clinical Guideline Compliance

Yongkang Zhang, MS, Mark L. Diana, PhD, Allison B. McCoy, PhD

Tulane University School of Public Health and Tropical Medicine, New Orleans, LA

Introduction
Strong evidence indicates that implementation of protocols that standardize practices may reduce the risk of surgical infection. The Surgical Care Improvement Project (SCIP) was created to reduce the rate of surgical complications through increased compliance with infection prevention measures. Prior research has documented wide adoption of clinical decision support (CDS) incorporating clinical guidelines among hospitals. However, few studies have tested the association between CDS adoption and clinical guideline compliance. In this study, we sought to evaluate the effects of CDS implementation on hospitals’ performance on SCIP measures.

Methods
We performed a cross-sectional study of hospital CDS adoption, SCIP measures, and hospital characteristics in 2014. We retrieved hospital characteristics and CDS adoption data from the 2014 American Hospital Association (AHA) Annual Survey and Information Technology Supplement, and SCIP measures from the 2014 Hospital Compare data set; 2,699 hospitals were included in the study. Based on hospitals’ self-reported information, we categorized adoption of CDS with clinical guidelines into three levels: fully implemented across all units, fully implemented in at least one unit, and other (i.e., plan to implement or not considering implementing). SCIP measures included percent of surgical patients who received prophylactic antibiotics within 1 hour prior to surgical incision (INF-1), percent who received recommended prophylactic antibiotics (INF-2), percent whose prophylactic antibiotics were discontinued within 24 hours after surgery end time (INF-3), percent with urinary catheter removed on postoperative day 1 or day 2 (INF-9), percent on beta-blocker therapy prior to admission who received a beta-blocker during the perioperative period (CARD-2), and percent who received appropriate venous thromboembolism (VTE) prophylaxis within 24 hours prior to anesthesia start time to 24 hours after anesthesia end time (VTE-2). Hospital characteristics included ownership, number of staffed beds, teaching status, health care system affiliation, proportion of Medicare patients, proportion of Medicaid patients, and rural/urban location. We used linear regression to test the association between CDS adoption and SCIP measure scores.

Results
Among all hospitals, 1,920 (71.94%) had full implementation of CDS across all units, 426 (15.96%) had full implementation in at least one unit, and 323 (12.10%) had other implementation status. Not-for-profit hospitals, hospitals with health care system affiliations, teaching hospitals, hospitals with more staffed beds, hospitals with lower Medicare and Medicaid shares, and hospitals in urban areas were more likely to fully implement CDS with clinical guidelines. Multivariate analyses indicated that the full implementation of CDS with clinical guidelines across all units was associated with higher scores in CARD-2 (β=1.18, p=0.003) and VTE-2 (β=0.617, p=0.015). No other significant associations were found.

| Table 1. SCIP measure scores (mean and standard deviation) by CDS implementation status |
|---------------------------------|--------------------------------|---------------------------------|------------------|------------------|
| Measure          | Fully implemented across all units | Fully implemented in at least one unit | Other            | Overall          |
| INF-1            | 98.58 (4.39)                  | 97.78 (4.42)                  | 97.84 (4.68)     | 98.40 (4.43)     |
| INF-2            | 98.36 (3.23)                  | 97.62 (4.56)                  | 97.47 (4.30)     | 98.17 (3.58)     |
| INF-3            | 98.04 (3.40)                  | 97.08 (4.80)                  | 97.01 (4.87)     | 97.81 (3.80)     |
| INF-9            | 97.83 (4.16)                  | 96.98 (4.66)                  | 97.28 (4.81)     | 97.66 (4.30)     |
| CARD-2           | 97.88 (4.12) *                | 96.40 (5.36)                  | 96.37 (7.30)     | 97.55 (3.13)     |
| VTE-2            | 99.70 (2.45) *                | 99.12 (5.49)                  | 99.30 (2.90)     | 99.58 (3.13)     |

Conclusion
We found that full implementation of CDS was associated with better compliance with clinical guidelines in two SCIP measures. Further research using longitudinal data and additional measures is warranted and underway to provide more evidence on the effects of CDS implementation on clinical guideline compliance and other quality outcomes.
Evaluating Word Embeddings from Multiple Domains for Symptom Recognition in Psychiatric Notes
Yaoyun Zhang, Ph.D., Hee-Jin Li, Ph.D., Yonghui Wu Ph.D., Hua Xu Ph.D.
School of Biomedical Informatics, The University of Texas Health Science Center at Houston, Houston, TX, USA

Introduction & Background
Recently there is a rapid growth of deep learning (DL) methods and their application in various natural language processing (NLP) tasks, promoted by word embeddings pre-trained from large-scale corpora of multiple domains. However, few NLP studies have used DL methods in the biomedical domain, potentially due to the lack of large amounts of data to generate word embeddings for different sub-domains. The goal of this study is to investigate and exploit word embeddings of external domains for clinical NLP tasks. Specifically, we take the psychiatric symptom recognition task as a typical use case. Psychiatric symptoms consist of subjective descriptions of the patient’s experience, as well as the nature and severity of mental disorders, which are critical for qualitative investigation into mental disorders. However, extracting psychiatric symptoms from clinical text suffers from the data sparseness problem and a low coverage by existing biomedical lexicons, making it challenging to apply traditional named entity recognition methods to this task. We will evaluate the performance of word embeddings from four domains – intensive care, biomedical literature, newswire and social media – to recognize entities of psychiatric symptoms using DL methods. To the best of our knowledge, this is the first work of evaluating multiple word embeddings for psychiatric symptom recognition.

Methods
Datasets: In addition to word embeddings trained from 1,000 psychiatric notes provided by the CEGS N-GRID 2016 challenge, word embeddings pre-trained from corpora of four external domains are investigated, including (1) MIMIC II with clinical text of intensive care units, (2) Medline with abstracts of biomedical literature, (3) Gigaword with newswire from the open domain, and (4) psychiatric forum data from WebMD. Algorithms: Word embeddings are generated by the skip-gram model in the word2vec package by default settings. The recurrent neural network (RNN) algorithm proposed by Lample et al. is employed to build the DL-based symptom recognition model. The pre-trained word embeddings are used to initiate the word embedding vectors in RNN at the beginning of the training process. Evaluation: 400 psychiatric notes are annotated with symptoms and are split into training (60%), development (20%) and test datasets (20%) for experiment. The performance of psychiatric symptom recognition is evaluated using precision (P), recall (R) and F-measure (F1). The result of exact match with the gold standard annotations is reported.

Results & Discussion
As displayed in Table 1, the baseline of using random initiation of RNN without any pre-trained embedding yielded the lowest result, with a F-measure of 68.94%. Surprisingly, the top 2 F-measures of 73.71% and 73.42% were achieved by word embeddings from Gigaword and the Psychiatric Forum respectively, which outperformed the three biomedical corpora, psychiatric notes, MIMIC and MEDLINE. Besides, directly concatenating the five word embeddings gained a median F-measure of 72.71%.

One potential reason of the higher performance obtained using word embeddings from the newswire and social media corpora is due to the essential characteristics of psychiatric symptoms. Psychiatric symptoms consist of words more commonly present in the open domain text, instead of the biomedical terminologies in clinical notes of intensive care and biomedical literature. More complex methods beyond direct concatenation to integrate word embeddings from multiple domains will be explored in the next step.

Detecting Off-label Uses of Prescription Drugs with Meta-Path-Based Mining
Mengnan Zhao¹, Christopher C. Yang¹
¹College of Computing and Informatics, Drexel University, Philadelphia PA 19104

Background
Off-label drug uses are very common in clinical practice. Up to one-fifth prescriptions are off-label¹. To some extent, off-label drug uses provide a pathway for clinical innovation, however, they could cause serious adverse effects due to lacking scientific research and tests. Identifying those off-label uses can provide a clue to the stakeholders to further the investigation on drug use and safety. Therefore, there is the need to develop an automated method to detect off-label drug uses.

Objective
We focus on developing a data mining approach to identify off-label drug uses systematically, rather than relying on human annotations or surveys.

Methods
• Dataset
Large numbers of health consumers exchange health information on online health communities (OHCs); MedHelp, as a pioneer in OHCs, empowers over 12 million people each month to discuss health related issues on the site, which provide huge volumes of valuable information. Considering the fact that many people describe their drug uses in OHCs, we collected data from MedHelp and retrieved more than 70,000 threads.

• Heterogeneous Network Construction and Mining
A heterogeneous network is defined as a graph consisting of nodes connected by links, with at least two types of nodes and at least two types of links, capturing more essential and accurate information about the network. Based on the medical entities we identified from OHC data, we constructed a heterogeneous network that contains three types of nodes (i.e. disease, drug, ADR) and six types of links.

A meta-path is a path defined on the network schema in the form of \( A_1 \rightarrow A_2 \rightarrow \ldots \rightarrow A_{i+1} \), which composes the relations between nodes in the heterogeneous network. Here we exploited meta-path-based networking mining approaches to detect all the possible relationships between the disease and drug\(^*\). \( s(d_i, r_j) \) denotes the relation between nodes \( d_i \) and \( r_j \); \( f(p,d_i,r_j) = 1 \) when there is a meta-path \( p \) connecting \( d_i \) and \( r_j \):

\[
s(d_i, r_j) = \begin{cases} 1, & (\forall p \in P, f(p, d_i, r_j) = 1) \\ 0 & \end{cases}
\]

• Classification
By setting the maximum distance to 3, we defined 13 meta paths in total, and we used the calculated value on each meta path as an input feature for the classifier. There are 2,087 positive disease-drug pairs suggested by Drugbank and PharmGKB and 28,000 generated negative pairs in the dataset. Then we built the binary classification model on Random Forest algorithm and tuned the parameters by applying 10-fold cross validation on the training sets.

Results & Evaluation

Conclusion & Future Plan
This initial research shows the possibility of using OHC data and network mining approaches for off-label drug use detection, as well as the potential of developing an automated detection method. The result confirmed the hypothesis that the connections between medical entities and the network related information are important for detecting off-label drug uses. Therefore, in the future, we plan to extract more network information by using heterogeneous network mining skills or other text mining skills.

HyDeXT: A Hybrid De-identification and Extraction Tool for Health Text

Xinyan Zhao, MSI, V.G.Vinod Vydiswaran, PhD
Department of Learning Health Sciences, University of Michigan, Ann Arbor, MI

Introduction: Identifying Protected Health Information (PHI) from clinical notes is critical to protect the privacy of individuals before their data could be shared publicly. The goal of de-identification is to identify and remove PHI from health records while protecting the integrity of the data as much as possible. In this poster abstract, we present HyDeXT, a Hybrid De-identification and eXtraction tool. HyDeXT combines the labels derived from a machine learning-based sequential tagger and a pattern-based labeler, to effectively de-identify eighteen categories of PHI and outperform existing state-of-the-art approaches.

Methods: The hybrid de-identification and extraction tool, HyDeXT, consists of a text processing pipeline with the following four stages: (i) Data cleaning and pre-processing; where the original text is modified by parsing the raw text format, adding missing whitespace characters, and identifying sentence boundaries and section headers. (ii) Pattern-based and Gazetteer-based labeling; where each labeler performs a high precision pattern-based or list-based matching to generate PHI candidates. (iii) Machine learning-based sequence tagger; which takes in information about section headings and previously identified candidates to derive additional contextual features and learn a sequential tagging model. (iv) The final Combiner; where the labels assigned in stages (ii) and (iii) are combined based on their confidence values to generate the final result.

The machine learning-based sequence tagger is a linear-chain Conditional Random Field (CRF) model defined over five classes of features; namely (a) Word form features: features derived from a word itself such as capitalization or suffixes; (b) Part-of-speech features: the syntactic role of each word in the text string; (c) Neighborhood features: features (a) and (b) derived from words within a contextual window of size 7 for each word; (d) Regex features: pattern-matching based features to capture commonly occurring patterns for certain PHI fields; and (e) IsInX features: features that check if a word matches elements in a list or gazette for certain closed form PHI fields. For example, if a word matches both an organization and a city, then we would activate two features – say, IsInCity and IsInOrganization – and allow the CRF model to assign them appropriate weights based on other contextual features.

Results: The HyDeXT tool was evaluated on the 2016 i2b2 Research Domain Criteria dataset. The dataset contains 1000 psychiatric clinical notes annotated for all instances of PHI fields. Of the thirty different fields annotated in the clinical notes, the tool focuses on the eighteen most frequent fields. The twelve excluded fields are very rare in the dataset and jointly represent only 0.13% (n=46) of all labeled PHI fields.

We compared our system with the current state-of-the-art medical de-identification system, MIST. The micro-averaged accuracy of MIST on the cleaned text version (after stage (i)) is 0.851. HyDeXT achieves an overall accuracy of 0.898, a relative improvement of 5.5% (error reduction of 31.5%)

Discussion and Future Work: The de-identification and extraction tool, HyDeXT, presented in this abstract, contributes from three perspectives: (1) the tool is able to identify eighteen PHI fields using a machine learning-based sequential tagger combined with a pattern-based labeler, which results in a highly efficient and effective PHI de-identification system and improving over a widely used de-identification tool; (2) the individual stages of the proposed pipeline can be utilized separately, in addition to allowing for a plug-and-play architecture to support further improvements; and (3) HyDeXT provides a reliable name recognition and extraction on unseen health data, including social media data. The tool has been used to successfully identify person names and other PHI-like fields from Facebook posts. The HyDeXT tool will be made publicly available for research benchmarking and use. In future, we plan to further develop HyDeXT as a health information extraction tool. Additional work is needed to handle noise common in social media data in terms of limited data and typographic and grammatical errors.

The Use of Natural Language Processing to Identify Tdap Related Local Reaction at Five Health Care Systems in the Vaccine Safety Datalink

Chengyi Zheng, PhD¹, Wei Yu, MS¹, Fagen Xie, PhD¹, Wansu Chen, PhD¹, Cheryl Mercado, MPH¹, Lina S. Sy, MPH¹, Lei Qian, PhD¹, Sungching Glenn, MS¹, Hung Fu Tseng, PhD¹, Jonathan Duffy, MD², Lisa A Jackson, MD³, Matthew F Daley, MD⁴, Brad Crane, MS⁵, Huong McLean, PhD⁶, Steven J Jacobsen, MD PhD¹

Introduction: Local reaction is the most common vaccine related adverse event.¹ Although local reaction is generally mild, patients may seek medical attention for more severe manifestations of local reactions.² There is no specific diagnosis code for local reaction due to vaccine. Previous vaccine safety studies³ used a mixture of non-specific diagnosis codes to identify potential local reaction cases and confirmed the cases through chart review. However, due to the high incidence, manual chart review of all suspected local reaction cases would require significant resources. In this study, a Natural Language Processing (NLP) algorithm was developed and implemented to identify medically attended local reaction associated with tetanus-diphtheria-acellular pertussis (Tdap) vaccine at five integrated health care systems in the Vaccine Safety Datalink.

Methods: Presumptive cases of local reactions were identified among members ≥ 11 years of age using ICD-9 codes in outpatient, urgent care, emergency and inpatient settings in the 1-6 days following a Tdap vaccination between 2012 and 2014. The NLP system was developed at the lead study site, Kaiser Permanente Southern California (KPSC), based on NLTK, pyConText/NegEx, and Stanford NLP. The algorithm was developed based on 250 chart reviewed training cases from KPSC, and implemented at all five participating sites. A stratified validation sample of 500 patients (250 at KPSC and 250 at other sites) was randomly selected and manually chart reviewed at each site. Chart review, which served as the reference standard, was performed according to a chart abstraction manual. A quality assurance plan was implemented to ensure abstraction quality. Keywords and phrases were compiled based on published case definitions, other ontologies such as SNOMED and MedDRA, and enriched by the training data. The clinical notes containing the keywords were searched for signs and symptoms consistent with local reaction. Information on the timing and the location of a sign or symptom was also extracted to help determine whether or not the sign or symptom was vaccine related. Reactions triggered by causes other than Tdap vaccination were excluded. A confirmed case satisfied the following criteria: local reaction symptom location matched the Tdap injection site, symptom onset was not prior to vaccination, and there were no other possible causes for the symptom.

Results: There were 7,123 vaccinated patients identified with the presumptive ICD-9 codes. Only 26.8% of cases identified by ICD-9 codes were confirmed by chart review. The clinical notes generated on days 1-6 following a Tdap vaccination were processed. The NLP algorithm achieved an overall sensitivity of 86.6%, specificity of 92.3%, positive predictive value (PPV) of 80.6% and negative predictive value (NPV) of 94.9%. Compared to KPSC, lower PPV at two other KP sites and lower sensitivity at two non-KP sites were observed. Based on the error analysis of the 18 false negative and 28 false positive cases, we identified three major types of errors: data sources (11), abstraction (10), and NLP (25).

Discussion: These results suggest that NLP can reduce the efforts of manual chart review in vaccine safety studies. However, they also suggest that further refinement of the NLP algorithm should be done when applying an NLP system developed at one site to other sites. Medically attended local reaction leads to an unscheduled clinical visit which adds burden to both patients and the healthcare system. Studying vaccine related local reaction can help clinicians provide better instructions to patients regarding possible vaccine adverse events.

Heart on FHIR: Integrating Patient Generated Data into Clinical Care to Reduce 30 Day Heart Failure Readmissions (Extended Abstract)

Timothy Bergquist¹, Ronald W Buie, MTCM¹, Kevin Li¹, Pascal Brandt, MSc¹

¹University of Washington, Seattle, WA

Problem Definition

30-day readmissions are extremely costly for hospitals (fig. 1¹). Heart failure (HF) patients are particularly vulnerable following an exacerbation event, and so need to be tracked closely following discharge. However, data tend to be siloed, the patient may fail to retain or accurately interpret home care instructions, and the self-management plan may not be fully communicated to the patient. Additionally, data collected by the patient may not be accurately reported, and are often collected on paper, which makes interpretation during the clinical encounter difficult. Finally, the receipt of patient generated data often occurs through oral history taken during the clinical encounter, requiring substantial time on the part of the provider. Patient follow-up is conducted on a predefined schedule, limiting opportunities for providers to identify failure, and adjust treatment protocols.

Design Process

Starting in March 2017, our design process started with a series of team meetings to isolate the target problem. Over the next 4 months, we went through a series of common design procedures to develop a digital solution to our defined problem (fig. 17). To start our design process, we interviewed a number of cardiologists and nurses to gain a deeper understanding of the challenges that caring for heart failure patients brings. Through interviews and literature surveys we developed representative personas for whom we optimized our proposal: the patient, Mr. Liang, the home care assistant and daughter, Mrs. Liang, the patient’s doctor, Dr. Wyatt, and the cardiology nurse, Karen (fig. 2-5). A diagram is provided to better understand how these personas interact (fig. 12). Since we are developing digital technology with user interfaces, we built interface mockups to visualize how each persona would interact with the technology (fig. 6-9). Along with these mockups, we developed storyboards to develop a deeper picture of how users would interact with the application in a longitudinal fashion (fig. 13-16).

Description of the proposed solution

To address the challenges defined above, we propose the development of an integrated patient generated data (PGD) data collection platform, and an application embedded in the EHR using the FHIR and SMART technologies. An intuitive interface allows providers to select the clinically meaningful data to be collected, and to view annotated reports integrating clinical data with the collected PGD within the EHR before meeting the patient. Data collected outside of the point of care will be gathered through telematics and survey/log records. Patients will receive feedback to improve compliance and motivation and be able to view longitudinal summaries of the collected data and health events. In the following sections, we present the major components of our proposed design, including patient enrollment, data collection, communication and the various user interfaces. We also include a brief discussion of the technology choices we considered while designing Heart on FHIR. We present our designs organized by feature.

Enrollment

At discharge from the hospital, patients are given their home care instructions in the form of verbal description, paper packets with information, and medication prescription orders. Application enrollment would occur during this period so as to minimize disruption of established workflow. Instead of packets of information, the patient would be instructed on the application and how to use it, since Heart on FHIR includes care plan details. This would also

¹ All figures in supplemental materials.
facilitate enrollment at the earliest possible time, allowing for close monitoring in the crucial early days post discharge.

In order to begin using the system, a patient must complete the enrollment process. This process is initiated by the provider at the time of discharge after hospitalization resulting from an HF exacerbation event. When this happens, an account is created for the patient on the Heart on FHIR servers. Simple demographic data will be pulled from the EHR to avoid duplicate data entry. The patient will then receive an email or text message with an activation link they can use to enroll and complete the creation of their account. This enables shared decision making and empowers the patient to choose whether or not they would like to enroll in the system.

**Patient Data Collection**

At University of Washington Medical Center (UWMC), Microsoft Excel is the primary patient data collection system. It is used when a patient takes initiative to collect their own data and visualize it themselves. Most of the time, patients either don’t track their own health progress or write all their data onto paper and present this during their clinical consult. Though useful, data presented this way is very difficult to interpret. Most heart failure patients are told to track similar data, however, providers need to have the ability to customize which data is important for each individual to collect, and at what frequency. During our interviews, when asked about what data would be useful for care, a common answer from physicians was, “It depends.” It became apparent through our interviews that the concept of precision medicine applies to the collection of PGD. By allowing the provider to tailor the data collection of the application to only the clinically necessary data elements specific to the patient, the patient data collection burden and the provider information overload are both reduced.

The Chief Technology Officer of Wellpepper² reported in our interview with him that continued engagement can be driven by the personal desire for tracking/monitoring improvements. Their experience showed that patients like to visualize their own data, and as a result input it regularly. In this design, we visualize the PGD to help encourage care plan adherence. In our application, data that the patient is to collect is assigned by the physician. There are many data collection options that the application will facilitate. Only selected modules will be displayed to the patient, and will include instructional materials, customized alerts set by the doctor, and forms for data input (fig. 6).

**Data collection options**

Daily diet, blood pressure, heart rate, step count/activity, and weight directly logged into the app

- Medication compliance measured through a daily reminder/question of whether the patient took their medication. Since the app would know the medication schedule of the patient which it pulls from the host EHR, it could be setup to alert the patient when their next round of medications is supposed to be taken. Although the effectiveness of these reminders will be hard to evaluate, we hope that these reminders will simply make the patient more aware of their medication compliance.

- Survey questions and frequency are chosen by the physician to match patient needs. The provider will be able to customize their own questions, but default questions will include common health assessment questions like “Do you ever feel short of breath?”; “When do you feel short of breath?”; or “Were you able to take your medications today?”

- Health literacy assessment surveys will be implemented early in the home care process. These include questions like, “Why is tracking your weight important?”; “Do you know how to perform a six minute walk test?”; or “Do you know how to measure your heart rate?”

All data collected will be visualized as trend lines to allow the patient to have a view of their health history.

**Patient Care Team Communication**

It takes a team to care for a heart failure patient, and this team, which includes the patient, needs to communicate. Based on our stakeholder interviews, we found that this communication happens in a number of ways. The primary

---

² Wellpepper ([wellpepper.com](http://wellpepper.com)) is a commercial patient engagement platform.
way is synchronous communication in phone calls and clinic visits which is supplemented by asynchronous secure messaging via the patient portal.

The first communication event happens during enrollment, when the care plan is discussed between the care team members and made available on the patient interface. During execution of the care plan, the team communicates through a built-in secure messaging feature, which allows all team members to send direct, private messages, as well engage in group conversation. This type of communication supplements phone calls and clinic visits, and improves upon patient portal messaging by sending push notifications on new messages, as well as by supporting group chats.

**Provider Interface**

One of the main themes that we found in our interviews with cardiologists and nurses is that large amounts of time are spent on prying information from patients about their health. Physicians often described using 20 minutes of a 30 minute consults collecting and validating data from the patient. Often patients who did log their information, did it on paper, limiting the usefulness of the information due to lack of interpretability at the point of care. Inaccuracies in reported prescription adherence or symptom reporting further reduced information quality. These inefficiencies slow down the assessment by the physician. Misinformation can inhibit the ability of the physician to make an informed and effective decision about the patient’s health.

In the interviews, a theme that appeared was the need for the physician to customize what data patients collected. Not only is every bit of information not universally useful, but it may cause stress in some patients to have to collect a lot of daily information. Our clinician interface design facilitates this customization.

The provider interface would be built using SMART, a health application standard that uses FHIR (Fast Healthcare Interoperability Resources) for data access. This would allow the application to directly interact with the EHR, and the physician to open the application in the EHR window. They would be presented with a screen like figure 6, allowing them to select any patient enrolled in the system. Our application is modular, with each module managing a different data collection feature. For instance, adding the weight module will activate the weight data collection module on the patient interface, sending a reminder, at the physician defined frequency, to the patient to log their weight using the intuitive weight data entry form. Each data type can be added or removed from the patient profile as the physician sees fit.

After the patient has input data, the physician can pull up their data and trends at any time. The application would take all the input data and visualize it into a clean and easily digestible format (Fig. 6). Ideally, this would be used during a scheduled appointment and would allow the clinician to have a snapshot view of the health status fluctuations between visits. This could allow the physician to spend less of that original 20 minutes fishing for information and instead give them more time to listen to and educate the patient.

**Patient Interface**

Patients are the most important member of the care team. Given the appropriate care plan, even if the care team do their job perfectly, it’s ultimately the behaviors of the patient that determine their health. In the care of HF, these behaviors are well understood, and include medication adherence, proper diet and collecting the data requested by the provider. Monitoring this data can help catch problems early, and inform adjustments to the care plan. Our tool will enable patients to remain engaged with their care by simplifying data collection, keeping them in touch with their care team, and ensuring they understand their condition and what is required of them.

The patient’s interface into the system is via a mobile application (fig. 6a), or in the absence of a smartphone, a web interface with the same design. Since most of the HF patients are older adults, the interface should be adjustable based on user comfort level (fig. 6b). The application contains all the details of the care plan, and serves as a point of reference for the patient. The reminders and alert escalation scheme are configured in collaboration with the provider at the time of enrollment and are unobtrusive in order to avoid alert fatigue. Data entry is extremely simple, and the patient is able to monitor their own trends inside the application (fig. 6), which helps drive engagement, according to numerous stakeholders.
In addition to medication, appointment and exercise reminders, the patient will occasionally be prompted to answer questions relating to their care. This is to assess their understanding, and if necessary, they will be provided with education materials (e.g. videos) to improve their understanding. Finally, the patient will be able to communicate with the care team using the messaging feature.

**Care Partner Interface**

In many cases, patients have someone to help them manage their condition. This person could be a spouse or family member, or professional home care provider. These individuals sometimes enter data for the patient, but at least need to be able to monitor trends and be alerted when something goes wrong. The care partner also needs to be able to communicate with the care team (fig. 8). The care partner interface is essentially identical to the patient interface. The care partner is able to enter and review patient data, as well as interact with the rest of the care team using the secure messaging feature. The primary difference between the care partner interface and the patient interface is the alerting. Care partners will receive different alerts than the patient, according to the alert escalation configuration set up by the provider.

**Nurse/Care Coordinator Interface**

Nurses at the UWMC HF clinic have a high case load. Among many other things, they are responsible for scheduling appointments, making sure patients understand their care plan, and remote monitoring during the 30 days following discharge. They are also responsible for answering questions from the patient and their care partner. The current process to perform these tasks is to pull up individual patient records in the EHR, and call patients if necessary.

The nurse home screen (fig. 9) is a dashboard of the panel of patients they are responsible for, which is embedded in the EHR using SMART on FHIR to minimize workflow disruption. The screen gives an overview of the status of all patients, along with any triggered alerts and questions submitted via the messaging feature. From this screen, the nurse is able to click on any patient and view the same detail available to the cardiologist. More importantly though, they are immediately able to respond to alerts or messages without navigating away from the dashboard screen, which will decrease the amount of time it takes to complete a round of remote monitoring. The nurse will also be able to use the messaging feature to contact all members of the care team.

**Technology**

There are a number of technical factors that we considered when designing Heart on FHIR. EHRs are not designed to capture patient generated data, and therefore our solution uses the HIPAA compliant Microsoft HealthVault cloud infrastructure. This gives us the additional benefit of being able to iteratively implement application logic rapidly, without being constrained by the lack of extensibility of the Epic implementation at UWMC. However, we want to integrate as tightly as possible into existing provider workflow to minimize disruption. The SMART on FHIR (SoF) standard allows us to do exactly this, by exposing a custom web application (hosted anywhere) as a new screen within a conformant EHR. When viewed inside the EHR, the SoF specification allows the application access to data both on our servers, as well as in the EHR. Alternative approaches considered include a completely separate standalone application, as well as an Epic customization. The former would disrupt workflow and require special access to FHIR APIs, while the latter would require development resources and timelines beyond our control, and the developed solution would not be translatable to other settings.

HIPAA compliance is always a concern when dealing with patient data, and in order to ensure security and privacy, Heart on FHIR application servers will be hosted using the HIPAA approved Microsoft Azure cloud infrastructure, and use industry standard transport layer security for all API requests. Additionally, any data access will require a secure password, and full audit trails will be maintained.
Implementation

From a technical perspective, to enable adoption of Heart on FHIR at scale, it would be necessary to publish the application in vendor SoF app stores, like Epic’s App Orchard\(^3\). This would allow “one click” installation analogous to installing an app on a smartphone. It may be necessary to charge a fee or subscription for the application to cover cloud infrastructure costs. From an organizational perspective, to gain acceptance from hospital executives and IT departments, we would be required to demonstrate HIPAA compliance by providing our Azure HIPAA compliance certification, as well as our documented standard operating procedures. Acceptance by clinical staff would be gained by having a well designed application that does not disrupt workflow and provides value by having a positive impact on clinical care. We have collaborated with clinical staff during our design phases to achieve these goals.

Alternative Solutions

One-size-fits-all

A more basic data visualization tool that does not accept physician configuration. Essentially an extension of the EHR, this simplifies use by the provider, but does not necessarily fit the customized approach of each care plan. We decided we could design a simplified interface and avoid this route.

Machine learned feedback and plan generation

The data we collect has the potential to be automatically matched to care plans based on protocol, effectively automating the assignment and variation of the care plan without provider input. After some discussion with providers, it was clear that buy in would not be universal, and proofing such a system would require its own project.

Research and Evaluation

Our evaluation plan attempts to address the following questions:

1. In what ways does the actual workflow of our users vary from expected workflows?
2. Does our intervention reduce encounter times?
3. Is use of our intervention associated with a difference in 30 day readmission compared to usual care?
4. How does our intervention impact satisfaction experienced by clinical staff managing HF patients?
5. How does our intervention impact satisfaction experienced by HF patients?
6. What are the barriers to technology acceptance by our users?

The first question will be addressed in qualitative interviews with each member of the care team. These structured interviews will ask participants to recount their actual usage along many scenarios, which will then be compared to the intended workflow. In order to address the second question, we will survey cardiologists who manage HF patients at the UWMCH before and after the intervention.

Our 3rd research question can be tested by comparing outcomes in our intervention and control groups, controlling for provider and severity of the condition. Although it would be best to randomize both patients and providers, this may not be possible at UWMCH due to HF clinic staffing and operations. Our 4th and 5th aims will be addressed by a pre and post intervention survey. The instrument will attempt to assess success as defined in the DeLone and McLean Information System (IS) Success Model (fig. 10). This model attempts to capture the relationship between the quality of the IS and its information, and the user’s satisfaction and capacity to realize benefit. Our 6th aim can be assessed during the same surveys as the prior two aims. However, questions will be based on the technology acceptance model (fig. 11), and focused on capturing both technical and experiential barriers to acceptance and use of the IS. Taken together, our evaluation should provide insight for future design iterations, as well as preliminary approaches for studying effectiveness and efficacy in reducing 30 day readmissions and, ultimately, the efficiency and accuracy in tracking heart failure patients throughout the course of illness.

Abstract:
Unplanned surgical readmissions pose a challenging problem for the American healthcare system. We propose to combine consumer electronic voice recognition technology with the FHIR standard to create a post-surgical discharge monitoring app to identify and alert physicians to a patient’s deteriorating status.

Introduction:
Of the nearly 50 Million patients that receive surgical care every year, almost one in five of them will have an unplanned readmission to the hospital[1]. Despite many of these readmissions being preventable, these events cost the American health system over $17 Billion in the Medicare population alone[2]. In addition to these high costs, surgical readmissions have been previously investigated by federal regulators as a potential quality metric for reimbursement[3]. As the healthcare system attempts to realign with these changing reimbursement models that emphasize health outcomes, hospitals have struggled with implementing strategies to reduce these preventable readmissions. Previous work has shown that additional nurse follow-up and monitoring improves surgical outcomes and prevent unplanned readmission in prostatectomy, total joint, and cardiac surgeries[4-6]. While these solutions have shown promising results, the care model requires a specialized nursing staff, limiting the scalability of these care units across multiple service lines. In response to these limitations, health researchers have recently investigated the potential to utilize patient generated data (PGD) to extend care monitoring in the post-surgical care setting[7].
Despite an acute need for PGD to be integrated into the electronic healthcare record (EHR), interoperability and secure authentication methodologies remain an active area of design and research[8]. Specifically, Mandel, et al. highlighted these challenges in the development of the pivotal SMART on FHIR (Fast Healthcare Interoperability Resource) framework which brought standardized authentication methods to FHIR specifications[9]. However, to date there has been scant utilization of these resources to bridge the digital divide between patient home care and the EHR.

Despite comprising only 13% of the overall population, an estimated third of the aggregate national health care spending is concentrated among the elderly. It is therefore imperative for patient-focused devices that enable PGD EHR integration to consider that a significant proportion of users may not be as technologically adept to newer technologies. Previously, detailed user interviews have highlighted the potential benefits of using voice-enabled frameworks to interface with this population.

Given the goal of reducing unplanned surgical readmission, we propose a voice enabled framework to monitor these patients in the post-discharge setting using consumer internet connected smart home devices. Using the FHIR based standards, we aim to provide EHR connectivity to structured patient interviews performed by the smart home device, prompting clinician in potential medical crises.

METHODS:

Colorectal surgery was identified by the collaborating surgical residents as a primary clinical use case given the high degree of post-surgical intervention for this patient population. User screening questions and potential question responses were developed. These were then compiled into a dialogue tree, which was used to inform the application state machine design. Additional clinical applications could be added with unique dialogue trees to reflect the heterogeneity of surgical complications.

We considered all major consumer-grade home voice-command assistive device platforms including Apple Siri, Google Home, Microsoft Cortana, and Amazon Alexa. Given the strong market share and wide range of developer tools necessary for rapid prototyping, the Amazon Alexa (and associated Voice Skills application framework) was chosen[10]. This framework provides developer specified intents (invocation programming triggers) and utterances (mapping to user dialogue), which are mapped together in the server application. Incoming intents trigger the Amazon Voice Service server to send a JSON
POST request to the application server. Using the flask-ask extension for the flask python microframework (https://github.com/johnwheeler/flask-ask), these intents are mapped to state dependent functionality, providing context aware and seemingly ‘intelligent’ communication abilities.

FHIR was chosen given its conformance to modern REST-like messaging standards and providing HTTP verb functionality such as ‘GET’ and ‘POST’. With an appropriately authorized oauth token, secure and interoperable transmission of patient information to the application server is enabled.

Results:

The proposed schematic is displays the technical and interactive details using this framework (Supplemental materials). (Step 1) When a patient is being discharged, the surgeon would select a relevant surgical indication that would specify the type of questions the framework would ask. (Step 2) Upon the patient’s activation of the Amazon Alexa app, he would be prompted to login through their patient portal credentials. This would create a session level oauth token allowing the patient server to request their medical information from a FHIR enabled server. Using the Encounter FHIR resource specifying the patient’s surgery from an appropriate ‘GET’ request search, surgery-specific screening questions are then mapped to the current session

(Step 3) The application then confirms that this application is okay to proceed, and asks birth date information to further verify the identity of the patient. Failure to appropriately authorized would result in quitting of the application and deauthorization of the token. After each question is answered, it is similarly saved to the application until the final question is answered. The patient is then asked to confirm any abnormalities that were found during the screening session before alerting the clinician. (Step 4) The screening application then structures all recorded answers as a FHIR’s ‘QuestionnaireResponse’ resource, and ‘POSTS’ these data to the hospital’s FHIR enabled server. (Step 5) Once these data are integrated into the hospital’s EHR, the attending surgeon’s email would receive a starred alert message contained structured results of the patient interaction, prompting the doctor to follow up with a clinical care team to further investigate the patient.
Source Code for the alpha prototype is available from https://github.com/KBlansit/Alexa-Discharge-Monitoring/tree/master. The video describing the patient interaction is located at https://youtu.be/05MgJHWA-ns.

Conclusions:

Developing new modalities to extend care monitoring to the home is a current and active area of research. In this project, we elected to utilize a consumer home assistant device. While using this platform permitted the focus of development on the underlying server application logic, it limited the scope and capabilities of the project to curated interactions, which may not fully cover the landscape of potential medical needs from patients. Since this platform uses both consumer technology and interoperable health web standards, there is high potential for scalability of this framework to reduce unplanned surgical readmissions. Future efforts should seek to formally evaluate the potential of this framework to aid in reducing unplanned surgical admissions and increase patient recovery self-efficacy. Partnership with a surgical department to pilot these efforts would be necessary to aid in the study coordination. Further considerations must be given the integration into each medical site’s EHR as robust APIs from vendors do not come standardized.

Home Behavior Monitoring Module in OpenEMR: Use of home sensors as Patient-Generated Data (PGD) for elderly care

Regina A Casanova-Perez, BSc1, Pierre G Padilla-Huamanitnco, BSc1, Catharine I De Freitas-Vidal, MBBS1, Yong K Choi, MPH2

1Biomedical Informatics in Global Health Research Unit, School of Public Health and Administration, Universidad Peruana Cayetano Heredia, Lima, Peru; 2Department of Biomedical Informatics and Medical Education, School of Medicine, University of Washington, Seattle, WA, USA

Definition of the selected challenge related to leveraging of patient-generated data for improving patient care grounded in deep understanding of an identified health problem

People older than 60 years old represent the twelve percent of world population, and the treatment of elder-related diseases represents an important percentage of health expenditure. The amount of older adults is growing every year due the better quality of life and the advancement in medical technologies. This phenomenon occurs on high and low-and-middle income countries predicting that, by 2030, elder population will be more than 25 percent of North American population, and 17 percent of Latin America and the Caribbean people.

Many diseases, such as type 2 diabetes mellitus, high blood pressure, coronary artery disease and neurologic disorders are prevalent among older adults, and, for many of them, physical activity (PA) is a cornerstone in their management and prevention. PA has shown to diminish mortality and improve quality of life in older adults with such diseases. By its own, a great amount of low level energy expenditure activities during the day, increases the mortality up to 20% according to a systematic review.

Assessing physical activity in an older adult is challenging due to several factors. First, defining how active an older adult is will depend on the comorbidities that an older adult may have such as musculoskeletal or neurological impairment. Additionally, self-reports of physical activity rely on how well they can recall, which is also influenced by their older age. Studies have shown that older adults tend to report less sitting time compared to sitting time measured objectively. Despite the importance of the measurement of the level of physical activity and sedentary behaviors, patient-generated data (PGD) related to physical activity has not yet been integrated to the patients’ Electronic Health Record (EHR).

The rapid development and proliferation of digital devices, apps, and services made it possible to capture and record different parameters that are relevant to human health. The advances in data processing and storage, communication infrastructures and networks, and the increased capacity of batteries allowed for continuous tracking and monitoring of various parameters regarding people’s health and illness. The use of smart home sensors to detect and record individuals’ activities and behavior patterns is one such example. In addition, we can also track environmental factors such as temperature, humidity and luminosity reports, or on/off control data for the lamp. The information from these home-based sensor technologies make it possible to learn about different patterns associated with a particular behavior and the health status of people.

Home-based sensors have been implemented in several previous projects. However, the previous efforts have focused on producing and displaying the sensor measurements to patients and have not looked into how this information should be reported to the health providers. Therefore, we propose to implement a new module into an EHR that will allow the follow up of the home environment and the physical activity in older adults through home-based sensors. This module will let health providers know in an objective way the characteristics of home behavior of patients ranging from home characteristics to indoor physical activity.
Description of the proposed solution

Our solution concentrates on the system OpenEMR (http://www.open-emr.org/) which is an open source Electronic Health Record (EHR) for international use. As the team is composed of 4 graduate students, 3 living and studying in Peru and 1 living and studying in the US, we wanted to focus on a possible solution that can be used in both countries. In Peru the EHR is not yet used because the regulations are not yet finished, but its implementation is imminent for the future, so we are getting ahead with this proposal showing how an EHR could integrate the Patient-Generated Data (PGD); and in the US case, we are showing just an improvement of the EHR with a new Module.

For our proposal, we plan to collect data generated by the user in their home environment using the home-based sensors specifically that can track movement, open/close signal from door and windows, humidity, temperature and luminosity. With the use of these sensors we plan to know the behavior patterns of an older adult, so that timely interventions can be given when a sudden or peculiar change in pattern have been detected. The data could also be used to identify slow, gradual changes of their habits by making comparisons with the historical data generated longitudinally.

In this solution, we show the PGD in a new tab inside each patient record, specifically we added one option just below the patient’s name called ‘Patient Data’ where the physician would find easy-to-read charts about the patient’s motion around their house, the luminosity, humidity and temperature of their house and the data about when the doors and windows have been opened or closed. With this information, the physician can make a medical decision regarding the patient’s health with the use of this charts. For example, if one patient has a lung condition, decreasing or rising the humidity or temperature can help to improve the patient’s lifestyle. Or a patient that has been through orthopedic surgery need to decrease their activity levels within their house so that it can heal properly. All those small and non-intrusive sensors can help physicians keep track of their older patients, so that they can have better quality of life. For the part of showing the charts, we provided three different solutions of how the information would be arranged within the EHR. Also, a summary of the main data would be available for every patient, this would help the physician to make decisions about whether they need to review the data from each sensor or if the older adults continues taking care of their health as before. For this part, only has one solution and it would be shown as the home page of the ‘Patient Data’ tab.

When the patient arrives to the doctor’s office, the doctor would look up the summary report of the ‘Patient Data’ tab, in this report we tried to generate some interpretations of possible health indicators that may be of interest to the physicians, this indicators will show the amount of time the patient is currently sleeping at night, the average time that they are spending outdoors and how much time they are spending doing low level energy expenditure activities, such as reading or watching tv. With these indicators, the physician can have a rough idea of how well the patient is doing regarding their mobility; even so, physicians will be able to look at the specific charts if they need more information before giving any recommendation. We expect that, by looking at the summary, physicians will be able to obtain objective measure of patient’s home behavior, making the interaction go more fluid and giving the physician more time to concentrate on other useful questions. With this information, we expect that both, physician and patient, will agree on the best and realistic PA goal based on accurate measurement of the patient’s activity patterns.

Discussion of alternative solutions considered

The evolution of mobile technology has changed different aspects of our lives. Data and knowledge are more affordable and manageable. It happens because digital technology allows us not only to carry or place devices but also wear them. Wearable technology has potential applications in healthcare, especially in patient monitoring. Some reports say that this technology would make health systems more efficient and responsive than the current ones17. Unfortunately, these devices are a challenge for elder people. If the wearable device presents a complexity in attachments or management (e.g., limited battery life), older patients may be unable to carry it continuously during their daily lives18. Some studies show that the interventions with wearable technologies work fine under supervision because it is hard for elder people to understand the user interfaces19.
Another solution considered was a hand-written activity journal where patients can log their daily activities such as how many hours they have slept or how many hours they have gone out. This type of journal relies heavily on the patients’ memory and their responsibility to log the activities in timely manner before they forget. This solution is not so much different from the feedback the patients give to their doctors during their appointments. As we are trying to objectively measure the patients’ activity levels and the environmental characteristics of where they live, the manual activity logging would not be an ideal solution.

**Discussion of the strengths and weakness of the chosen solution as compared to the alternatives.**

Our proposal seeks to integrate into the Electronic Health Record (EHR) new information from sensors installed in patients’ homes. These sensors make the elder people a data source and follow the approach of Internet of Things (IoT). We decided to integrate this information because patients produce many data day by day, and the IoT revolution is redefining modern healthcare. Sensors can track and monitor people 24/7 in any environment. It allows that any information related to healthcare (logistics, diagnosis, therapy, recovery, medication, administration, finance and daily activity) can be stored, managed and shared. Getting the maximum benefits from this data means having a better understanding of people’s health. We just need to use it properly and distribute it efficiently.

Setting up smart homes solutions is not usually affordable, the cost is the main reason. Many people would live at smart homes if the transformation of their environments were not expensive. Open source solutions become more relevant to face this challenge while they promote the integration of new data for healthcare. Our solution will use OpenEMR an open source EHR platform because we plan to implement it in a high-income country (US) and LMIC country (Peru). The main advantages of open source are accessibility, flexibility, and documentation. Open source solutions are gaining more traction in the scientific community by the evidence of superior technical levels and less expensive than proprietary solutions.

**Proposed implementation and dissemination plan**

For implementation, previously we need to identify and involve the principal actors from the health system in both countries. Companies like Google and its Health service failed because they wanted to implement the service without providing added values to the stakeholders of the US health system. Then, we must select intervention sites like patient homes and health centers. The selected institutions should already have OpenEMR. The proposal does not pretend to create a new workflow or modify the existing IT infrastructure. In the case of patients, they have to be older adults who live alone in their homes. Patients should have agreed to be installed a set of sensors before the implementation. They will receive an informed consent where we mention the study protocol, the privacy, and potential security risks of using the sensor devices to collect the PGD. The acquisition and implementation should be assigned to IT area from health centers. The information about installation and local providers would be available on a Wiki page. We will ensure the providers give a special discount to health centers if they want to start with a pilot. The project will offer training in home sensors installation.

**Implementation and Integration of New Module**

With this implementation, three stakeholders of the medical system would benefit. The care providers would benefit because they would make better medical decisions with better understanding of the patient’s health, without having to rely only on the patient’s self-report of their physical activity. The hospitals or clinics would benefit as a result of the better medical decisions that the doctors would make, making the management easier because the resources and equipment won’t be used in an inadequate way. Finally, the patients would benefit because it would be easier for them to identify their patterns in their daily lives by seeing the charts and won’t need to stress about remembering about their habits. This add-on to the OpenEMR system would be easy to install and won’t need nothing more than an update, all the data collected by the sensors, would be daily updated to the servers via internet connection so the doctors would have updated data.
Home Sensors Description

The set of sensors selected is from Arduino IoT platform. Arduino IoT guides anyone who wants to get started tinkering with the Internet of Things. The sensors will measure parameters like movement, temperature, humidity, luminosity, and open/close doors and windows. These devices must have strategic positions if patients have pets or frequent guests. Interoperability plays a major role in ensuring a better adoption. Our proposal follows recommendations from the Continua Health Alliance (CHA), a major standardization body working on device level interoperability, which has recommended to use standards like the Bluetooth Health Device Profiles and USB Personal Healthcare Device Profile. These formats have been specified by the ISO/IEEE 11073 family.

Dissemination plan

Open source lets people replicate, modify and upgrade different technologies. Our purpose focus on creating a community in Public Health and more institutions can add new data for giving patients a better service. The project keeps the same license from OpenEMR, the documentation and a tutorial will be available on the Wiki page. The team will ensure these instructions may be read by someone whose expertise is different from engineering. Github will host the code and firmware required to implement the project. Also, a publicity campaign would be used both in hospitals and in residential homes where elderly patients are known to live alone, this would help us recruit the subjects to install the sensor in their homes.

Proposed evaluation plan

After the implementation, we will conduct a usability study with the participant physicians. Physicians that will receive the implementation of the module will be those in charge of patients that already have sensors deployed within the home, which may vary depending on preference of the patient.

All the physicians involved in the implementation will be invited to participate in the usability study. It will consist of semi-structured interviews asking participants to give feedback on the presented designs and to comment on which sensor data visualization was considered more useful, and to generate ideas for new alternatives to the visualization.

Once subjects have agreed to participate in the study and have signed the consent form, we will collect socio-demographic data such as age, gender and time of experience. Then, we will conduct an interview with the participant that will take 30-45 minutes, addressing the following questions:

- We would like to hear about your general thoughts on the new module of the EHR.
- How do you think the new module in the EHR plays a role in your clinical practice, if at all?
  - What are some benefits that you might find in using the new module in your clinical practice?
  - What are some drawbacks that you might have with using the new module in your clinical practice?
- Here we have some of the charts that you have been working with in the new module. What are your thoughts on the way they are displayed?
  - What do you find interesting about the displays?
  - What do you find confusing about the displays?
  - How might you use these displays, if at all?
  - What indicators would you like as feedback on the visual display?
  - How useful were the indicators presented to you in the new module, if at all? What kind of clinical recommendation did you give based on the information reported in the new module, if at all?
  - What suggestions would you have for improving the displays?
  - Are there alternative ways in which you would like the sensor information to be presented?
  - How frequently did you look at this information in your clinical practice?
- Is there anything else that you would like to add regarding the new module?
References

Abstract

Cardiovascular disease and diabetes are epidemic in the United States, and efforts to shift this trend have been largely ineffective. The greatest challenge that health care practitioners face is inspiring the lifestyle changes necessary to prevent or reverse these conditions. New evidence suggests that minimal activity, such as simply standing up periodically and moving around can reduce biomarkers of cardiovascular disease and diabetes. Given the challenge and temporary nature of inspiring habitually sedentary individuals to take on intensive exercise routines, this is an exciting prospect. With this new information, the question becomes: “How do we inspire individuals and populations to get up and move?” Dr. Matthew Buman and his group at Arizona State University are addressing this question through researching methods to inspire individuals and groups to stand and move at work. In support of Dr. Buman’s work, we have leveraged subject generated postural data gathered by his group to create a pipeline that processes and analyzes the patterns of subject movement with the prompts they received in order to identify the most effective prompt that elicits standing and moving behavior. The pipeline helps researchers in his group visualize their data in an interactive way and to help inform statistical analyses. In future directions, this pipeline structure can be adopted by various aspects of clinical work such as diagnosis, selection of treatment options, monitoring for changes in a patient’s conditions over time, evaluating efficacy of different treatment options, and promoting shared decision-making between providers and patients. They can range from novel ways to visualize PGD to help clinicians and patients identify important and actionable trends, to novel computational solutions, to using these data together with the traditional EHR data to provide clinical decision support that may or may not include visual presentations. Importantly, in this challenge, our focus is on integrating PGD with EHR to improve care within the clinical context, rather than on using these data outside of traditional care settings to promote health and wellness.

Introduction

According to the American Heart Association, cardiovascular disease (CVD) is the leading cause of death for both men and women in the United States (1), and there is ample evidence to support a link between CVD and diabetes (2). At least 68 percent of people age 65 or older with diabetes die from some form of CVD, and adults with diabetes are two to four times more likely to die from heart disease than adults without diabetes. This major health crisis can be linked, in great part, to an increasingly sedentary lifestyle in the US population (3).

Moderate-to-vigorous physical activities are effective in reducing biomarkers of CVD (4), but it is very difficult to inspire habitually sedentary individuals to take on a regular practice of moderate to vigorous physical activity. Matthew Buman et al., 2014, found that for sedentary individuals, periodically replacing sedentary activity with light-intensity activity such as standing up and moving around significantly lowered biomarkers of CVD and diabetes (5,6). Subsequently, Dr. Buman and his group set out to create a mechanism by which they could encourage large groups of individuals who are sedentary (sitting) during the work day to stand or stand and move at periodic intervals.

Using patient generated data (PGD) gathered by Dr. Buman and his team, we created “Stand and Move at Work” (the name given to the project by Dr. Buman’s group), a pipeline that analyzes PGD from a device that detects sitting behavior, standing behavior, and stepping behavior, and establishes which of several prompts most effectively inspires individuals and groups to stand and move at intervals during their work day. Our pipeline includes visualization tools for postural data for individuals and selected groups that can be linked to an electronic health record to assist researchers and practitioners in a variety of fields such as occupational health, wellness, and nutrition.

Design Process
Dr. Buman’s group provided us with files containing postural data collected over a four-week period on subjects working in the transportation department at Arizona State University (ASU). All subjects were given a sit/stand desk a few weeks prior to the start of the data collection. Their postural information was collected using an activePAL™ device which is a proprietary instrument worn on a subject’s 18 subjects during the work-week during the time frame of the study. We were also given a file containing prompts that were sent to subjects by email each hour throughout the work day. The prompts were divided into three assessment groups: prompts that tell individuals to stand vs prompts that tell individuals to move, prompts that contain an authoritative tone vs those that do not, and prompts that include a goal vs those that do not.

**Problem Clarification:** Dr. Buman’s group is hoping to use this data to determine if sending subjects prompts over email will encourage them to stand and move at work. Further, they want to know which prompts were most effective. Our job was to create a reproducible pipeline that uses the data we were given to determine which subset of prompts most effectively influenced the subjects to stand and/or move.

We carried out three meetings over Skype with the ASU group. Our first meeting was designed to clarify their study design and pinpoint the portion of the study we were to address. During our second meeting we clarified some data cleaning issues and they gave us more information on the type of data visualization and analyses they needed in order to help them understand the data and outcomes. During our third meeting we discussed ways in which we could extend our pipeline to include more analyses.

**Pipeline Design:** Our pipeline was created using the R statistical programming language. We also used the R package, “Shiny”, which is a platform used to translate R to HTML code in order for users to interact with the data visualizations through a web interface. This method is especially important when there is a high volume of data because it makes it faster and easier for researchers to view the data. The Shiny application is launched through a local server at OHSU. We uploaded the activPal™ events files provided to us by the ASU group. These files contain information about changes in postural position (sitting, standing, or moving) associated with the dates and times that these changes occurred. We also uploaded a prompts file containing a list of prompts, such as “Try to stand for the next 5 minutes”, which were queued every hour during the workday for the length of the study, 50% of which were emailed to subjects and 50% percent were not emailed (this allowed for a comparison between activity following a prompt and activity with no prompt). There were a total of eight different prompts. The prompts file also noted which subject the prompts were sent to, and what date and time they were opened. Our pipeline merges these files together resulting in a dataset that allows us to calculate the time interval between when a prompt was opened by a subject and when a positive action (standing to standing, or standing to moving) took place.

Our pipeline performs a non-parametric test, the Kruskal-Wallis rank sum test, on log transformed data to assess whether there are significant differences in the time interval described above relative to each of the eight prompts. We also used a Chi-squared test to determine whether significant differences existed in the proportion of subjects that responded positively to each prompt. There are various normalization methods available in the Shiny app.

We conducted a secondary analysis that observed the subject’s sitting and standing behavior within the first half hour each prompt was sent. From this data, we computed statistical analyses to see whether the average time spent standing or moving was significantly higher in prompt versus no prompt events, goal versus no goal prompts, authoritative versus non-authoritative, and stand versus move prompts. We found the average time of standing was significantly higher when subjects received a prompt compared to when subjects did not receive a prompt (p-value=0.03).

**Alternative Solutions Considered**

We considered the possibility of creating an application that would ring or chime periodically throughout the day to remind subjects that they should get up and move. After discussing this idea with Dr. Buman, we learned that these kinds of applications had been tested previously and found to be ineffective.

**Results:**

Our pipeline determined that there was no statistical difference between the interval of time it took the subjects to positively respond to each of the eight prompts.
Figure 1. Image of the first tab of the data visualization app showing the summary by week and by day for each subject across the study. Users can select specific starting and end dates and download this data as a .csv file in order to flag specific days.

Figure 2. Image of activePAL™ events file data visualization page from our Shiny application showing the percentage of time each subject spent in each of the three postural activities detected by the activPAL™ device.

Use Case:

Shared provider-patient Decision Making and Novel Data Visualization

Mr. Smith works in the transportation department of local university and spends most of his work day sitting for long periods of time. He is overweight and has developed diabetes. He is here for routine follow-up in your primary care clinic. He tells you he has participated in an employer sponsored project that looks at workplace interventions that could improve his diabetes control. He brings in data from an activity tracker that he has been wearing. He explains that based on preliminary results evaluated for him the nurse running this employer-sponsored project, he was assigned to receive an email alert that said “Try to stand for the next 5 minutes” every hour during his work day. He proudly shows you his data that indicates he had increased his standing/moving time at work by 45 minutes. You bring up the HgA1C he had drawn before his clinic visit and find it has decreased significantly, but it is still slightly elevated. Together, you review his latest HgA1C and activity data and suggest increasing his daytime activity by another 20 minutes. He goes back to his employer sponsored project and requests that they increase the frequency of his reminder to stand/move alerts.

Feedback and Evaluation Plan:

We created a survey that was distributed to Dr. Buman and the researchers who are working on this project. Our questions were focused on the usability of our application within an electronic health record in a clinical/patient care setting and in an occupational/employee wellness setting. The overarching response was that being able to visualize an individual’s physical activity and sedentary behavior is a valuable tool for providers which will allow them to co-create personalized interventions that are geared toward disease prevention and health promotion.

Our survey also included a question regarding what could be added to the visualization to support shared decision making for providers and patients or employees. One suggestion for future application of this tool would be to have it provide a recommendation for health improvement based on the individual’s current level of activity and health promotion goals.
We plan to further our evaluation by using our survey to gain feedback from providers in the health care and occupational health settings. We would also like to test our pipeline and visualization on a new set of data provided by a group in a different occupational setting.

Summary:

We have created a pipeline that we believe can be adapted for use by any group interested in using activePAL™ events data to examine intervals between interventions and positive changes in postural behavior. This data can be incorporated into both occupational and individual electronic health records, and can be used in partnership with patients to determine the best interventions to improve their health. More broadly, this data can also be used to guide employer health programs.

Special thanks to graduate student Lawrence Hsu for initial input and support for this project.

Visualizing the Patient-Reported Outcomes Measurement Information System (PROMIS) Measures for Clinicians and Patients

Lisa V. Grossman1,2*, Elliot G. Mitchell1*

Abstract

Congruent with the nationwide movement toward patient-centered healthcare, an increasing number of organizations collect and assess patient-reported outcomes (PROs). The standardized NIH PROMIS measures represent one of the most widely used PRO questionnaires, but organizations still face challenges with conveying PROMIS outcomes to clinicians in clinically relevant ways. Our proposed solution, the ProVis application, uses visualizations to engage heart failure patients with PROMIS questionnaires in the waiting room, and conveys PROMIS data to clinicians through longitudinal visualizations in iNYP, our institution's electronic health record (EHR) interface. Here, we discuss the design and development of ProVis, the alternative strategies we considered, the strengths and weaknesses of ProVis, and our future dissemination and evaluation plans.

Background and Definition of the Challenge

Patient-reported outcomes (PROs) constitute an important subset of patient-generated health data. When collecting PROs, healthcare organizations use standardized survey questions to understand patient's experiences, and the data may inform each patient's care plan individually. Recently, the National Institutes of Health (NIH) created the Patient-Reported Outcomes Measurement Information System (PROMIS) measures.1,2 PROMIS is a validated and standardized set of PRO measures applicable to a range of chronic conditions. The PROMIS scales map directly to PRO measures such as the PHQ-9 depression questionnaire. As such, PROMIS measures occupy an important position at the center of national "Meaningful Use" efforts to incorporate PROs into patient care. Epic Systems now offers PROMIS measures through the MyChart patient portal, and the NIH's EASI-PRO initiative promotes integration of PROMIS into major electronic health records systems, including Epic and Cerner.

Despite PROMIS's success, challenges remain. An ideal PRO measure is efficient (minimizes the number of items without compromising reliability) and precise (minimizes error in estimate).2 Despite efforts to maximize efficiency of individual scales, clinically useful combinations of PROMIS scales may take too long (>10 minutes) for older patients and patients with low technology literacy. Despite rigorous effort to increase precision, patients with a lower literacy level may demonstrate lower precision.3 Such limitations may decrease clinician's confidence in PROMIS outcomes, especially clinicians who work with disadvantaged populations. One untested solution is to visualize each PROMIS item's answer choices to help patients select answers more precisely and efficiently.

Another challenge is defining appropriate cutoff points for clinical action based on PROs. Indicating the patient-reported symptom's severity is necessary, but insufficient. Clinician-facing systems must also report changes in each symptom's severity. For example, a patient with longstanding severe depression known to a psychiatrist is less clinically concerning than a patient with newly-reported depression that requires a psychiatric consult. Currently, physicians use clinical notes to track symptom changes over time, a practice that presents challenges due to copy-paste conventions and the time needed to re-read the note. Overcoming these challenges will require better presentation of longitudinal PROs in the EHR to support clinical decision making.

In collaboration with the Columbia University Center for Advanced Cardiac Care at NewYork-Presbyterian Hospital (NYP), our proposed solution is to 1) visualize PROMIS answer choices for heart failure patients to increase PROMIS's precision and efficiency, especially in disadvantaged populations, 2) incorporate these visualizations into an application, ProVis, for heart failure patients to report PROMIS measures from the waiting room, and 3) visualize ProVis data for cardiologists in the EHR, in a manner that predicates clinical action and facilitates longitudinal symptom tracking. We use the heart failure population to demonstrate our application's utility for multiple reasons.
Heart failure affects more than 5.7 million Americans and is the leading cause of 30-day hospital readmissions in the United States.4 Ineffective symptom recognition and management is the primary cause of repeated hospital readmissions in heart failure.5 Clinicians typically spend the majority of the outpatient visit discussing symptoms, although time constraints may prevent the full elucidation of clinically relevant symptoms. As such, PROMIS measures hold great potential to transform clinical decision making in heart failure care.

**Proposed Solution**

At this time, the patient-facing component of ProVis is fully developed and communicates with the EHR, and the interface for the clinician-facing component is designed. During the design process for ProVis, we applied techniques from biomedical informatics (see Integration with the EHR section), human-computer interaction (see Patient-Facing Interface section), and information visualization (see Clinician-Facing Interface section) to enhance usefulness and usability. To integrate clinical expertise, we conducted participatory design sessions with two clinicians to ensure each visualization's clinical relevance, including card sorting to discover clinicians' mental models of heart failure symptoms. To integrate patient expertise, we refined the application after usability testing with 6 hospitalized patients (poster accepted to 2017 AMIA proceedings).

**Conceptual Framework:** We used the updated technology acceptance model (TAM) to guide the development of the patient-facing interface.6 TAM is a validated model that considers how users come to accept and use technology. Figure 1 displays the TAM, and indicates which factors the 4 patient-facing features of ProVis specifically support.

![Figure 1. Technology Acceptance Factors](image)

**Use Case Scenario:** When the heart failure patient arrives, the receptionist enters the patient's MRN into the ProVis application, installed on an iPad (see video demonstration). The MRN triggers ProVis to display the patient's identifying information. The receptionist hands the iPad to the patient, and the patient verifies their identifying information. Then, the patient completes the PROMIS measures and views their summary visualization on ProVis while in the waiting room. When the patient presses the "submit" button, the application prompts the patient to return the iPad to the receptionist. Then, provider and patient review the PROMIS outcomes together, in conjunction with medication data, through the EHR interface, during the actual clinic visit.

**Innovation:** As the use case scenario describes, the proposed solution: (1) integrates PROMIS measures into the EHR with medication data to inform clinical decision making, (2) presents PROMIS outcomes to patients and clinicians using novel visualizations, (3) applies PROs to a population, heart failure, where symptom management is critical, and (4) facilitates communication between the patient and provider during the clinic visit.

**Patient-Facing Design Process:** We applied material design to create an industry-standard interface for use in populations with low technology literacy (see Supplementary Materials). Launched in 2014, Google's material design is among the most widely accepted design frameworks. Advantages over previously popular minimalist frameworks include three-dimensional layering effects which enhance system usability for older users, as well as updated design patterns. A design pattern is a highly-tested solution to a commonly occurring problem in interface design. ProVis uses a responsive mobile-first framework, Bootstrap 3, for viewing on various screen sizes, including both the vertical and horizontal iPad orientations. To improve the interface's learnability and memorability for older adults, we use clearly identifiable buttons, progress bars, consistent linear navigation, large font, colorful icons, high contrast, and system response times tailored to older users. To increase precision and efficiency, we coupled previously published infographics tested in low health literacy populations with PROMIS answer choices.7 Additionally, we created visualizations to summarize PROMIS outcomes for the patient directly after survey completion. In creating patient-facing summary visualizations, we provide immediate feedback to patients, engage them in their care, and highlight the survey's usefulness to them. Within the summary visualization, we used locally developed materials to educate patients about their symptoms and enhance their situational awareness.
Integration with the EHR: The NewYork-Presbyterian (NYP) hospital enterprise uses multiple EHR vendors, including Epic, Cerner, Athena, and Allscripts. Instead of working with each vendor separately, we will integrate our clinician-facing visualizations into iNYP, an EHR-viewing system interoperable across multiple commercial EHRs within NYP. 12,000 physicians use the iNYP daily to view 4.5 million patient records. iNYP uses "clinical dashboards" to summarize and synthesize patient information for the provider. Our department oversees the development and maintenance of the dashboards. To prepopulate patient demographics in the ProVis interface, a back-end programmer integrated it with iNYP using Microsoft's .Net. To integrate patient-reported data into the dashboard, iNYP will query the ProVis database server (see Hardware section) for the patient's MRN.

Clinician-Facing Design Process: Clinicians view PROs within discrete packets of information, termed "cards," within the iNYP clinical dashboard. The cards separate data into portions and support one particular clinical action each, to prevent information overload. One card summarizes recommended clinical actions for the provider based on the novelty and severity of each symptom. Because heart failure symptoms differ dramatically between individuals, and clinicians may wish to track different symptoms in different patients, we offer clinicians the ability to customize cards to individual patients. We anticipate that customization will increase utilization of PROs in the EHR. We used visualization techniques for time-oriented data to visualize PROs longitudinally in cards. For example, we visualize how patients' symptoms scores vary according to medication dose and type (see Supplementary Materials).

Training: The Patient-Centered Outcomes Research Institute (PCORI) user's guide on integrating PROs in EHRs recommends training administrators and clinicians prior to implementing PROs to prevent non-use. To help clinicians understand how to manipulate provider-facing visualizations and discuss them with patients, we will offer training at monthly cardiology team meetings. Additionally, we will train the clinic receptionists to engage patients in ProVis and provider user support. We will provide a phone number to report hardware problems.

Hardware: ProVis will be accessed using iPads located in cardiac clinic waiting rooms. The iPads access secure WiFi through an existing hospital network. To protect the iPads, the hospital uses rubberized cases and installs theft-deterrent software. The information systems, including the ProVis application itself and the databases housing patient-reported data from ProVis, use secure, encrypted, HIPAA-compliant servers. Physical access to the servers requires keycard authentication, and we secure electronic access via the Secure Shell (SSH) protocol.

Alternative Solutions, Strengths, and Weaknesses

We choose to implement ProVis in the waiting room for five key reasons. First, although our institution offers an online patient portal, monthly use for patients with access lies below 2%, consistent with the low adoption of portals across the US. Second, physicians can immediately act on information collected in the waiting room, decreasing legal liability. For example, if the patient screens positive for depression in the waiting room, the physician can immediately place them on an antidepressant trial. Third, because every patient the provider sees reports PROs from the waiting room, the provider can integrate PROs into their standard clinic workflow, which may increase PRO utilization. As such, we do not need to prompt providers with notifications to view PROs, and this may prevent alert fatigue. Fourth, the clinic receptionist can assist patients with the application in the waiting room, potentially increasing reliability and therefore clinician's trust in the patient-reported information. Fifth, restricting the frequency of PRO collection to clinic visits reduces the burden of reporting on patients. Although collecting PROs in the waiting room demonstrates many strengths, one weakness is the inability to monitor symptoms between visits.

We chose to use an external, or "wraparound," system for PRO collection, rather than collecting PROs using an application within the EHR system itself. External systems offer several strengths over internal systems, including the easy customization necessary to create our visualizations. However, external systems also demonstrate several weaknesses. First, although our system does not require any username or password, the clinical receptionist must links the external system directly to the EHR using the patient's MRN. Second, our external system uses a unique protocol to communicate with iNYP, which is not easily generalizable to other EHR systems.

We chose to normalize patient-reported symptoms relative to the population distribution in only one clinician-facing visualization. In participatory design sessions, our clinician participants described population-level data as irrelevant to the heart failure clinic, which sees primarily vulnerable populations. Clinician participants placed more emphasis on patient perceptions of severity and changes to severity over time, so we emphasized that instead. Furthermore, the current version of ProVis does not normalize to the population distribution in patient-facing visualizations. This
is a weakness, since seeing their information relative to the population may motivate behavior change in some patients. However, it is also a strength, since participants in usability testing worried that population information may prompt complacency ("I'm where everyone else is") or despair ("I'll never be able to fix this").

Implementation and Dissemination Plan

Prior to implementation and dissemination, we will demonstrate the usability and usefulness of our visualizations to patients and clinicians, as well as their impact on PROMIS's precision and efficiency (see Evaluation Plan section). As discussed above, we will work with the Center for Advanced Cardiac Care to integrate ProVis into electronic intake systems in our hospital's heart failure clinics. Going forward, the iNYP clinical dashboard team at Columbia University Department of Biomedical Informatics will govern the cardiology PRO system in collaboration with the Center for Advanced Cardiac Care. Independent of implementation of the ProVis application, the visualizations hold potential for adaptation and use in any system incorporating PROMIS measures. Ideally, we would translate our visualizations to other systems through close collaboration with institutions participating in the NIH EASI-PRO initiative. We will share all of the tested visualizations and interfaces on GitHub.

Dissemination beyond the clinic to hospital administrators and policy makers is an important consideration. For example, Franklin and colleagues recently demonstrated that incorporating PRO data dramatically improved their readmission risk prediction model (c-statistic of 0.86 vs 0.65). Hospitals use readmission risk prediction models to distribute resources, and the Centers for Medicare and Medicaid Services uses such models to standardize readmission rates between hospitals. Making PRO data available to administrators and policy makers may improve readmission risk prediction, among other pursuits.

Evaluation Plan

In addition to the evaluations our team already conducted (see first paragraph of the Proposed Solution section), we plan to complete the evaluations described below.

Further Usability Testing with Patients: We will recruit 20 patient users from the heart failure clinic for laboratory-based usability testing. The research coordinator will guide the end-users through an IRB-approved usability assessment protocol. The users will complete goal-oriented tasks such as reporting specific symptoms. The coordinator will video-record the screen during each interview using QuickTime Player and ask predetermined questions to encourage concurrent think-aloud. After each task, the coordinator will assess satisfaction, ease-of-use, and confidence with retrospective probing techniques. Quantitative measurements will include time to task completion (approximating efficiency) and the task error rate (approximating precision).

According to the ISO / IEC 9126-9 quality model, usability involves 4 dimensions: (1) understandability, (2) operability, (3) learnability, and (4) attractiveness. Only 32% of usability-related publications focused on mobile health applications assessed all 4 dimensions. However, assessing all dimensions is critical. For example, attractiveness, the least assessed dimension, plays the greatest role in a user's decision to being using an application. To ensure we assess all dimensions, we will administer a field-based usefulness, ease-of-use, and ease-of-learning questionnaire to 20 randomly-selected patients after their clinic visit.

Validation of PROMIS Visualizations: We will conduct a two-arm randomized trial to evaluate the impact of visualizing answer choices on PROMIS's precision and efficiency. A 20 person pilot study prior to the trial will generate parameters to estimate effect sizes in an a priori power analysis. General medicine patients will be block randomized to complete PROMIS measures with visualizations or without visualizations. For the gold standard, all patients will complete "legacy" questionnaires (well-validated and widely-used measures of the same concepts). At baseline, both arms will complete a survey to assess demographics, health literacy, and prior technology use. The primary outcome will be efficiency (time to completion) and precision in comparison with the gold standard.

Semi-Structured Interviews with Clinicians: We will conduct semi-structured interviews with clinicians to assess the predisposing factors (attitudes towards use), enabling factors (skills and support required for use), and reinforcing factors (perception that use makes a difference) for use of clinician-facing PRO visualizations in the EHR. We will analyze the interviews in multiple steps using a qualitative descriptive approach to uncover common themes. First, 2 researchers with training in qualitative methods will independently read each transcript, and define codes in a
We will conduct 1 round of inter-coder comparison queries. The coders will meet to review, discuss, and arrive at consensus for the content coding. To enhance rigor, a third researcher with extensive experience in qualitative research will conduct an audit trail of the coding processes. To enhance confirmability, we will use “member checks” and peer debriefing among the data collection team. We will share summaries of the coded data with 3 clinicians and ask for their confirmation or revisions to interpretation.

**Conclusion**

Our proposed solution, ProVis, uses visualizations to display PROMIS measures and outcomes to heart failure patients in the waiting room, and display PROMIS outcomes to clinicians in the EHR. We believe ProVis will impact heart failure symptom management and prevent readmissions, as well as increase PRO utilization.

Sensi-steps: Using Patient-Generated Data to Prevent Post-stroke Falls

Angela Smith, MS, Ada Ng, Eleanor R. Burgess, MSc,
Noah Weingarten, MA, Jennifer A. Pacheco
Northwestern University, Chicago, IL, USA

Abstract

We present Sensi-steps, an application using patient-generated data (PGD) to prevent falls for geriatric and especially post-stroke patients. The Sensi-steps tool incorporates a wearable wrist device, pedometer, pressure and proximity sensors, and tablet. PGD collection occurs through Timed Up and Go (TUG) tests and collection of physiological data, which is integrated into the EHR. Fall risk factor active tracking encourages new ways of shared decision-making between patients, caregivers, and practitioners. PGD will be managed at the primary care nurse or Care Manager level (see 3-tier PGD service proposal), presenting a novel way to incorporate PGD into clinical decision-support systems. We expect our solution to be easier to use routinely by the patient at home than other fall risk tracking solutions. Sensi-steps has the potential to improve patient care, help patients make informed decisions, and help clinicians understand patient-generated, environmental, and lifestyle information to deliver personalized, preventative healthcare.

Background

Problem Definition Patient falls are a major health concern in geriatric care and rehabilitation. In several geriatric populations, approximately 80% to 90% of patient injuries are caused by falls. The risk of falls is abnormally high among stroke patients, and falling is one of the most common recurrent complications among stroke patients in rehabilitation. Stroke patients are susceptible to falls due to several factors: reduced efficacy of postural responses, diminished sensory acuity, impaired musculoskeletal, neuromuscular, and/or cardiopulmonary systems, deconditioning associated with inactivity, depression and low balance self-efficacy, polypharmacy and a host of environmental factors. Clinicians assess for the presence of these factors by: asking questions about medical history (e.g., do you remember falling in the last 6 months?), obtaining self-report measures (e.g., fear of falling scales), and administering performance based tests (e.g., Timed Up and Go test and ambulation speed). Clinicians synthesize this information to identify specific causes of fall risk that can be addressed.

The “Timed Up and Go” (TUG) test provides a reliable and valid assessment of functional mobility in the population at large. It has been specifically validated as a predictor of fall risk in community-dwelling older adults and patients with stroke. A fall is an event in which a patient unintentionally comes to rest on the ground or other lower supporting surface, unrelated to a medical incident or to an overwhelming external physical force. Since falls are common in stroke rehabilitation, a major challenge is to reduce the number of falls and injuries without limiting patients’ physical activity. Many falls are caused by intrinsic mechanisms and occur during transfers and changes in position -- and in most cases by the patient acting against given instructions. Consequently, a major goal of stroke rehabilitation is to improve postural stability, motor performance, and the patient’s self-perception and awareness of the risk of falls. Achieving these goals enables patients to ambulate more safely. This project seeks to collect ongoing patient-generated data from stroke patients to identify those at risk to implement appropriate preventative measures and therapies in place and decrease complications.

The AMIA Challenge Our team presents the Sensi-steps application designed to decrease fall risk in patients recovering from strokes by collecting patient-generated data (PGD) predictive of fall risk. PGD reports are shared with patients and clinicians in a user-friendly format. The app displays data in both the EHR and the app itself in a way that establishes common ground between patients and clinicians, supporting shared decision making. Our application satisfies clinicians and patients alike by collecting and displaying the following PGD: patient TUG score, ambulation speed, and basic physiological data relevant to stroke rehabilitation. This data can be collected automatically or manually through a series of tools: pressure/load and proximity sensors, Alvita Wireless Activity Tracker (pedometer), and the Omron Heartvue wearable wrist device. Sensi-steps rewards patient’s test compliance with a virtual garden, a type of performance feedback that provides a motivating context for therapy. The Sensi-steps physiological data displays in corresponding fields in the electronic health record (EHR) and high-risk TUG scores are sent as an EHR note to primary care nurses and Care Managers. Patients’ information is logged in the Sensi-steps application for trend and progress overview. Sensi-steps integrates into the patient’s EHR where clinicians can see clinical, evidence-based information related to predicted fall analysis and imbalance, with the aim of improving clinical interpretability.
Solution Design and Development

Design Process Overview: Our user-centered design process focused on understanding and building PGD solutions for the needs of stroke patients and their team of providers. Our initial point of contact was Dr. Chen Lin, a practicing neurologist and Stroke Research Fellow at Northwestern University who researches technological initiatives for improving stroke recovery. He detailed what he saw as the major needs and challenges for patients in stroke recovery. This foundational knowledge allowed our team to plan our design process in three phases: (I) needs analysis, (II) design, and (III) iterative human-centered evaluation.

(I) Needs Analysis: First we carried out a literature and current technology solutions review, and then we conducted interviews with multiple relevant stakeholders. Our initial literature and technology research delved into existing tools that supported common stroke recovery symptoms such as aphasia, cognitive and motor functionality decrease, mood and anxiety disorders, as well as overall decreased quality of life. Information gleaned from our literature review guided our semi-structured interview protocol with clinicians and patients. For a list of questions and general themes asked, please refer to the Interview Protocol in Appendix A. In total, we interviewed eight practitioners, including two primary care physicians (PCP), one physical therapist (PT), one speech-language pathologist (SLP), one occupational health physician, and three neurology fellows at a teaching hospital in a large Midwestern city. We, additionally, interviewed with a number of patients with and without their caregivers to aid in this design process.

The patients’ needs analysis findings identified the following concerns and suggestions: 1) discerning what PGD and patient concerns warrant seeking immediate/emergency medical care; 2) simplifying technology usage; 3) general reminders to slow down. Similarly, our clinicians noted the following issues during our phase 1 assessment: 1) biological trends in relation to prescription regimens; 2) various risk management factors (glucose, blood pressure, heart rate, cognition, exercise, etc.); 3) data that provides an actionable outcome (and that the alerts themselves be actionable with pre-formatted buttons enabling quick decision-to-action pathways); 4) desire to have primary care nurses or Care Managers manage PGD reports; 5) the legal reality that ongoing PGD must be managed at the primary care level.

(II) Design: Our tool was developed to fulfill the identified needs of our participants and reflects overall needs assessment insights. Our interviews indicated a lack of general knowledge about stroke recovery rehabilitation among specialists and PCPs. Day-to-day stroke rehabilitation management is left in the purview of primary care physicians, yet those to whom we spoke explain that they are largely unfamiliar with how to meet the specific needs of stroke patients. Here, we present our design of the Sensi-steps a) novel technology and b) novel tiered PGD and EHR management process for primary care support staff.

a) Novel Technology: Our proposed solution, Sensi-steps, is a tablet-based application bundle designed to decrease fall risk in patients recovering from stroke. The tool has four main technological components comprised of currently available market technologies: (1) an ambulation speed calculator, (2) a TUG performance tool, (3) a patient portal add-in for medical adherence and notes to the clinician, and (4) practitioner-facing PGD EHR data visualizations. We focus on ambulation speed and the common clinical Timed Up and Go test because the time taken to complete this test is strongly correlated to the patient’s level of functional mobility, (i.e. the more time taken, the more the patient is likely to be dependent for daily living activities). Older adults who take longer than 12 seconds to complete the TUG have a high risk for falls. 

(1) The Sensi-steps ambulation speed calculator utilizes a combination of either a) the Omron Heartvue, a wearable wrist device that accurately captures blood pressure and tracks other heart health data, such as sleep patterns, together with the Alvita Wireless Activity Tracker (pedometer) or b) three household sensors placed within the patient’s home. One is a pressure sensor located in the patient’s seat and the other two are proximity sensors mounted on the wall in corridor (see Appendix E for household sensor setup). (2) The Timed-up-and-go (TUG) performance tool responds to the Omron Heartvue or the proximity and load sensors via Bluetooth connectivity. The Omron Heartvue TUG, hereby known as the “manual TUG”, begins when the seated user taps the ‘Start’ button on the watch application and ends when the user has risen from his chair, walked 10 feet, returned to his seat, and tapped the application’s ‘End’ button. Upon completion, the user is presented with a new seedling, which is planted in the virtual garden, the application’s background. The user has choice to use the pedometer as well, which will provide more accuracy and allow capture and calculation of the ambulation speed. Upon continuous usage, the seedlings continue to grow and the user’s garden expands. The sensor option, hereby referred to as “automated TUG”, tracks every time the patient rises from the chair configured with a load sensor (Sensor A). As the patient begins to rise from the chair, Sensor A detects a negative change in pressure and starts the TUG timer. The test is
logged in the Sensi-steps application when the Omron Heartvue connects via Bluetooth to the wall-mounted sensor (Sensor B) and the chair’s pressure is returned to zero, indicating that the patient has sat down again. The test will time out at 30 seconds. If the test times out before final pressure is returned to the chair, the tool will prompt the user with a dialogue window providing the option to call for support if the user has fallen. Upon clicking the app, the user is prompted with a disclaimer: “For your safety, caregiver supervision is highly recommended while you take this assessment.” If a patient opts out of sensor integration in their home, ambulation speed can only be calculated using the manual TUG test. Sensi-steps also incorporates (3) medical prescription compliance and messages to the clinician through the patient portal. Our interviews with clinicians identified prescription compliance as a point of action, and we incorporated this into automated data. The use of algorithms will populate automated trend information below the user’s graphic display, e.g. improved performance with continued use of Drug A or measurements at certain times of day (See Appendix D, p. 10 and Appendix D-3, p. 16). (4) Lastly, information visualizations for patients and for clinicians showing physiological data, ambulation speed, and TUG trends. This directly integrates actionable information for clinicians. The main Sensi-steps dashboard provides an array of this information (see Appendix D, p. 9). The Fall Risk Score is visualized on a spectrum from 0 to 6 and is calculated with an algorithm that incorporates TUG time and ambulation speed. Left of the score display are five metrics, all of which are synced passively from the Omron Heartvue and sensory data, blood pressure, heart rate, step count, distance travelled, and last TUG. Clicking an individual metric provides a graphical screen illustrating the specific metrics trend over time. The banner across the top of the screen allows the patient to view and share information from the tethered personal health record (PHR) or patient portal view and write specific notes that will be linked to relevant EHR information.

Because approximately 70% of the one million stroke patients discharged annually from United States hospitals continue living in their homes15, we envision our solution being used in-home as: a routine part of physical therapy, a shared information delivery system, and a tool for primary prevention of falls, for patients aged 60 to 101 years. A longitudinal study was performed using the TUG tool at a patient’s 1st week to 3 months, 3 to 6 months, and 6 to 12 months after discharge. Research shows that the TUG is a responsive test for capturing improvements in mobility during the first three months after stroke16. Responsiveness was established in relation to statistically significant changes in mobility.

b) Novel Service Provision: Key to ongoing management of PGD is to identify which members of the healthcare system are most able to closely track ongoing PGD “red flags.” We present a three-tiered system for PGD management to ensure long-term sustainability of not just Sensi-steps, but also the many other future PGD applications. Tier 1 is for information or actions that a Medical Administrative Assistant could accomplish, such as rescheduling a patient meeting. Tier 2, the main PGD ongoing management tier, is for information or actions that could be under the purview of a primary care nurse or Care Manager. In the attached appendix, the Sensi-steps PGD notification would be sent to the primary care nurse or Care Manager. Tier 3 is for high-priority notifications and sign-offs at the level of the primary care physician.

(III) Iterative Evaluation Once an initial wireframe was developed, we conducted a more formal needs assessment (phase 2) with additional provider types and researchers at multiple institutions and with potential patients. We asked for feedback on our initial wireframes (see Appendix B and Appendix C for the list of questions asked as well as the initial wireframes). For example, for the wireframe provider-side EHR message, we conducted three iterations based on clinician feedback. This process showcased the importance of including the PGD data graph together with decision pathway buttons. We also interviewed patients prior to our initial design, which guided our development from the initial wires to the prototype design. We presented Sensi-steps, our newly developed prototype, to aid fall prevention in stroke recovery patients to PCPs and various patients to gauge their conceptual understanding, usability, and sustained usage.

Alternative Solutions and Solutions Comparison

During outpatient sessions, physical therapists provide stabilization exercises and monitor patient progress utilizing validated indexes and tools, such as Berg’s balance scale, the Barthel Index, and the SitBAT assessment tool. SitBAT is not considered a clinical tool, so we have not included it within the strengths and weaknesses assessment. Sensi-steps and its use of the timed up and go assessment succeeds because the previous tools lack global interpretability, acceptability, and feasibility. There are no common standards for the interpretation of these scores despite the establishment of a minimum score for balance impairment and a lack of standardization across individuals. The rating scales associated with each item, while numerically identical, have different operational definitions for each number or score. For example, a score of 2 in one item is defined differently and has a different
associated level of difficulty when compared to a score of 2 in another item. Use of an overall score that adds ratings with different meanings having no common reference point may not be appropriate as interpretation is difficult and very little functional information is provided about the individual patient. Table 1 summarizes the alternative solutions as well as their strengths and weaknesses.

Table 1. Comparison of risk tools for fall prediction and imbalance.

**Implementation and Dissemination**

We have spent over three months iteratively developing our current prototype with input and feedback from provider and patient stakeholders. We will continue to iteratively improve our tool based on further needs assessments and feedback and add additional features, such as educational resources and community support connections. Our next version will be ready by November 6, 2017, and will include changes and improvements resulting from usability testing, including visualization of risks for providers/patients/caregivers (e.g. infographics, dashboards), and context-sensitive links or InfoButtons directing patients to clinical guidelines and knowledge resources (e.g. American Stroke Association resources). Future versions of Sensi-steps will integrate: users’ assistive devices into their Fall Risk score, TUG test extensions to incorporate cognitive and manual tasks such as counting backwards or pouring a glass of water, and assessments reported by patients and caregivers. These iterations will help demonstrate that Sensi-steps can be generalizable to other measures of function, health risk, and quality of life and applicable to other conditions, which increases the impact of our solution.

To disseminate our application to others, we will collaborate with stakeholder groups such as Dr. Chen Lin and his clinic, and the associated clinical and research community. We strive to solve a problem that not only satisfies the goals of the AMIA Design Challenge, but also aligns with Dr. Lin’s focus to develop app-based recovery tools to improve outcomes in post-stroke patients. After pilot trials at Northwestern University (NU) we will capitalize on NU’s partnerships with other hospitals and rehabilitation clinics. We may also partner with the Omron company to integrate our successfully trialed Sensi-steps application within all Heartvue devices. Additionally, we will leverage organizations such as the American Stroke Association, the National Stroke Association, and the American Stroke Foundation to promote and gather feedback on our tool. The shared mission of these organizations is to empower survivors and their families to overcome the challenges of life after stroke. Our tool promotes this mission by actively engaging stroke patients and their caregivers in the complex decision making and self-management required during the stroke rehabilitation process.

**Evaluation**

The proposed Sensi-steps tool will be evaluated through usability testing, and comparative effectiveness evaluation of similar balance and fall risk tools. Usability testing has been recommended as an important part of the evaluation of health risk communications, and is a recognized method to achieve user-centered improvements in health information, and research-based improvement in web information resources[^8]. Usability testing will follow recognized methodologies, and allow us to observe actual users and evaluate if Sensi-steps meets user needs. Results will enable identification of potential usability problems, and inform redesign and / or improvement of the fall prevention tool.

**Conclusion**

Falls are common and potentially debilitating for patients who have had strokes and for the geriatric population, at large. There is growing demand for patient-focused preventative efforts. There is also a great need for tools that help clinicians parse through and handle the complexity of clinical and biomedical “Big Data”. Sensi-steps has the
potential to improve patient care, help patients make informed decisions, and help clinicians understand patient-generated, environmental, and lifestyle information to deliver personalized, preventative healthcare to improve patient and population health.

Quantifying and Visualizing Medication Adherence in Patients Following Acute Myocardial Infarction

Jane Wang, B.S.1, Shannon Wongvibulsin, B.S.1, Katharine Henry, B.S.2, Saki Fujita2
1 Johns Hopkins University School of Medicine, Baltimore, MD, 2 Johns Hopkins University, Baltimore, MD

Abstract
Medication adherence is a critical component for recovery following acute myocardial infarction (AMI). Currently, numerous smartphone applications are capable of tracking medication adherence through patient-generated data (PGD), but few are integrated with the electronic health record (EHR). Integration of medication adherence PGD into the EHR can give both healthcare providers and patients increased insight into patterns of missed doses, effects on vital signs, and correlation with side effect symptomology to inform healthcare decisions. We propose the generation of a medication adherence “vital sign”, a score calculated based upon the patient’s reported doses taken collected through a smartphone application and streamed into the EHR on a daily basis. We also propose the creation of Patient Health Reports that incorporate relevant patient history, information from previous visits, and the medication adherence scores to give providers a comprehensive view of patients’ health prior to clinic visits. These features are intended to incorporate PGD into clinical care to inform decision making in ways that streamlines patient visits, reduces healthcare costs, and improves health outcomes.

Introduction
Medication non-adherence has been reported in over 60% of patients with cardiovascular disease (CVD), the leading cause of morbidity and mortality worldwide,1, 2 and in approximately 50% of patients with chronic diseases.3 Typical medication regimens for CVD are complex and involve drugs from multiple classes that may require intake at numerous different time points4. Medication non-adherence contributes to poor achievement of treatment goals, increased patient morbidity and mortality, and an estimated $300 billion annually in U.S. healthcare expenditures.5 Verification of proper patient usage of prescribed medications is important for assessing treatment efficacy. In most outpatient settings, clinicians rely upon the patient’s self-report through recall.6 However, studies have shown that the patient’s recall for medical information may be poor, and patients generally over-report adherence.7 Suboptimal assessment of patient adherence leads to medication errors, such as over-prescription and dosing errors.

With the growth of health information technology, the Electronic Health Record (EHR) has become central to the practice of medicine. According to the Office of the National Coordinator for Health IT (ONC), approximately 74% of physicians have adopted certified EHR systems.8 However, approximately 51% of physicians are only using basic EHR functionalities, such as inputting patient demographic information.8 EHRs also introduce work-flow disruptions for clinical staff that have been shown to lead to productivity losses of up to 20% in internal medicine clinics within the first month of implementation.9,10 These studies illustrate that EHRs are not yet being used to their greatest potential.

Recent developments in smartphone applications and wearable technologies have led to the concept of patient-generated data (PGD), which are health metrics captured by the patient outside of the context of formal clinical care.11 The integration of PGD into the EHR has been suggested as a method of allowing providers to monitor patient health behaviors and key health metrics, enabling them to make more informed decisions on patient care.11 However, incorporating PGD into the EHR is hindered by numerous challenges including the following: the capacity to handle large volumes of data in a manner that neither overwhelms the EHR11,12 nor the providers,12,13 and the presentation of PGD in a way that is easily interpretable and relevant to clinical decision making.

Proposed Solution
A. Medication Adherence “Vital Sign”
A group of clinicians, engineers, and hospital administrators have developed the first Apple CareKit smartphone-based cardiology application, Corrie, to reduce hospital readmission rates following acute myocardial infarction (AMI).14 Corrie aggregates all components of follow-up care surrounding AMI, including medication trackers, vital
sign intake, care team contacts, and educational modules into a single mobile application. Corrie’s current platform enables patients to log their adherence to each prescription on the basis of dose and time.

We propose the creation of a medication adherence score and corresponding graph to be streamed into the EHR daily as a “vital sign”. The medication adherence score will be calculated for each medication as (#doses taken)/(#doses prescribed) *100. The visualization will be generated based upon the patient’s medication tracker that captures the patient’s adherence to each medication, temporal and prescription-specific patterns of adherence, and medication side effects (Figure 1). This feature will also have the capacity to generate visualizations that highlight time points throughout which the patient has not been adherent to specific medications (Supplemental Materials). Clinicians may hover over the plot in order to see precise data specific to time, day, and medication. The medication adherence “vital sign” will be incorporated into the EHR as a streaming data set that can be accessed for any day in the patient’s history, and as a cumulative report that summarizes the information into an adherence score for a specified window of time. Additionally, to evaluate whether the current medication regimen requires titration adjustments, adherence to medications targeted at outcomes such as blood pressure (BP) and heart rate (HR) can be viewed alongside the recordings of BP, HR, and other vital signs as well as reports of side effects or symptoms to determine trends between adherence and outcomes (Figure 2). Clinicians who are concerned about patient compliance to medications and the consequences on health outcomes may check on patient medication adherence and directly contact the patient through the mobile application’s secure platform. These visualizations will also be available to patients to increase patient engagement and empowerment, which has been shown to be linked to patient satisfaction and compliance, which in turn can lead to improved health outcomes.

Figure 1: Medication adherence plot emphasizing completed doses

Figure 2: Medication adherence plot (bottom panel) with corresponding daily changes in vital signs, mood, and steps (top panel)
B. Patient Health Reports

To streamline clinical workflow, we furthermore propose the creation of a Patient Health Report (Figure 3) that clinicians may generate and view before a clinical encounter. Clinicians may specify the timeframe of interest (e.g., since the last clinical encounter) for the Patient Health Report, which will include key components of every patient’s medical record such as past medical history, current medication regimen, concerns raised during the previous clinical encounter, a longitudinal graph of the patient’s medication adherence, and the overall medication adherence score for each medication. Since many clinicians prepare for patient visits by refreshing their knowledge of their patients’ medical history, needs, and active problems the night before or the morning of a clinical visit, we propose the health report to expedite pre-encounter preparation by providing clinicians with information that will inform the clinical encounter. In a process mapping study conducted by the Veteran’s Health Association, physicians agreed that reviewing recent patient information prior to a patient encounter helped to 1) build trust and rapport to establish a basis of familiarity and knowledgeability about the patient, 2) determine whether pre-visit tests or consultations are required, 3) remind clinicians about care plans from previous visits. By incorporating the Patient Health Report with the medication adherence information into the workflow that many clinicians already use, we hope to enhance the clinical workflow experience through the centralization of relevant information and the addition of the medication adherence vital sign. An example of the Patient Health Report can be accessed here: https://kathen.shinyapps.io/amia_visual3/. Further details may be found in the Supplemental Materials.

Figure 3: Sample Patient Health Report with pertinent patient demographics, history, and medication adherence
Alternative Solutions Considered

A. Data collection methods for medication adherence: As an alternative to using the medication logging functionality of the Corrie app, we considered using data collected from smart pill bottles17 or smart pills with digestible circuits18 that can automatically keep a record of the patient’s medication adherence.

B. Medication adherence visualization: As an alternative to the heat map of medication adherence, we considered presenting the visualizations as longitudinal bar graphs or line graphs to display the trajectory of the adherence score over time.

C. Medication adherence “vital sign” and comprehensive summary: As an alternative to the medication adherence score and Patient Health Report summary, we considered presenting the adherence information in a separate tab in the EHR where the clinicians can view the adherence history.

Strengths and Weakness

A. Medication adherence data collection through Corrie mobile health app: Corrie already incorporates a comprehensive recovery plan for AMI patients, so logging their medication intake through this app will facilitate ease of use and centralize the patients’ self-care tasks to a single app. Using a smart pill bottle and smart pills with digestible circuits would add another level of unnecessary complexity to the data collection process. Additionally, using smart pills could limit which medications we could track. Nevertheless, smart pill bottle and smart pills could help address the issue of the validity of PGD from self-reported loggings of medication adherence through the Corrie mobile app. Yet, if patients intend to falsify their adherence, they could also manipulate the records from smart pill bottles (by simply opening the pill bottle but not taking the medication) and smart pills (by dissolving the pill rather than taking the medication).

B. Medication adherence visualization: Presenting the adherence score as a heat map allows clinicians to easily visualize the general patterns of medication adherence. Visualizations as longitudinal bar graphs or line graphs would allow for exact values to be plotted and displayed over time. However, with patients commonly on dozens of medications, presenting the scores as bar or line graphs in different colors for different medications can become complex and challenging to interpret. In our proposed solution, clinicians may hover over each box in the heat map to see the actual value of the adherence score and how it was calculated.

C. Medication adherence “vital sign” and comprehensive summary: Incorporating the adherence score as a vital sign stresses that medication adherence is an essential component of medical care that must be considered frequently. One weakness of including the medication adherence as a vital sign is that this requires the adherence of all the medications to be summarized into a single value. To overcome this limitation, we have also included the options for clinicians to view the adherence score for each medication separately under the medications list section of the EHR. Our proposed solution would be more helpful clinically than presenting the adherence information in a separate tab in the EHR since our method integrates the medication adherence information into a clinical workflow that clinicians are already accustomed to.

Implementation and Dissemination Plan

Implementation: Our implementation plan includes feasibility and usability studies as the initial step. We propose to pilot our proposed solution in the cardiology clinic, specifically with Corrie patients and providers. The feasibility and usability studies will begin with clinician training of the new EHR features and patient education on medication adherence and the medication logging function on Corrie. Then, the patients and clinicians will be surveyed (additional details are provided in the Evaluation Plan section below).

Dissemination: To disseminate our proposed solution, we will develop open-source software that is modular, scalable, and easily adapted to a variety of EHR systems. Additionally, we propose to publish the results of our small-scale implementation and feasibility-usability studies to inform future large-scale implementations across various institutions and EHR systems. The Shiny app demonstration of the implementation as well as videos with step-by-step user instructions for patients and providers will help facilitate the dissemination and adoption of this proposed solution at a large scale. The code will also be published on GitHub, so individuals interested in adapting it to their systems can easily access and modify the code for implementation at their institutions.

Evaluation Plan

The efficacy of our proposed solution may be evaluated through the following methods:

1. User satisfaction and feasibility-usability surveys: These surveys will be incorporated into the Corrie application and administered at 1 month intervals to patients; providers will receive monthly surveys via email; they will evaluate the frequency of Corrie use, ease of use, medication compliance following Corrie use, and efficiency of use during clinical encounters.
2. Comparison of medication adherence rates of CVD drugs (e.g. aspirin, clopidogrel, simvastatin, etc.), hospital readmission rates, and blood pressure and heart rate control within a target range between Corrie users and the national average at the time points of 1 month, 3 months, and 6 months.

3. Comparison of medication adherence rates of CVD drugs, hospital readmission rates, and blood pressure and heart rate control within a target range between high-frequency Corrie users (log at least 5 medications/week) and low-frequency Corrie users (log 4 or fewer medications/week) at the time points of 1 month, 3 months, and 6 months.

Conclusion
Medication adherence is one of the most frequently cited causes of hospital readmissions following AMI. We propose streaming recorded medication compliance PGD from the Corrie application directly into the EHR that can be visualized and assessed in the same capacity as a vital sign. Providers and patients may monitor and conduct early modifications to the medication regimen. We furthermore propose the creation of a Patient Health Report that streamlines clinical encounters by incorporating all relevant information (including the medication adherence score) that providers may need to prepare for patient visits. The integration of medication adherence PGD has widespread implications in CVD management and can be easily translated to other disease entities. We hope that our proposed solution will improve medication adherence rates and ultimately, long-term patient health outcomes at reduced healthcare costs.

The National Institutes of Health (NIH) has made an unprecedented investment in biomedical data science through its Big Data to Knowledge (BD2K) initiative (datascience.nih.gov). Through a series of K01 career development awards, T32/T15 institutional training awards, R25 data science training research awards, as well as the training components of fifteen U54 BD2K Centers of Excellence, the NIH has placed a premium on the development of a new generation of biomedical data science professionals¹. These efforts are systematically producing unique training materials which seek to introduce everything from the basics of data science to in-depth examinations of applied biomedical analytics in the investigation of health as well as disease. In addition to these BD2K training resources, a large number of high-quality data science educational resources are available online, such as massive open online courses and video lectures. Consequently, the BD2K Training Coordinating Center (TCC) is developing a data science educational resource discovery index (ERuDIte) and an online education platform with the capability to automatically discover, describe, organize, and personalize training materials for the varied learning objectives of its users.

In this system demonstration, we will first provide a tour of the core functionality of the BD2K TCC web portal (http://www.bigdatau.org), including the exploration, search, and recommendation of learning resources tailored to a user’s learning goal. Figures 1–3 show three key site features: the Concept Map, the Faceted Search Interface, and the Educational Plan Interface. The system is already available for beta testing. Second, we will describe how we use data science techniques to build the ERuDIte index that powers the web portal. This system demonstration aims to inform the audience on the educational value of http://www.bigdatau.org for the medical informatics community, while also showing the generality and extensibility of the education platform to other domains.

Systems Demonstration: NIH Common Data Elements Repository

Liz Amos, MLIS, Christophe Ludet, MS, Lisa Lang, MPP and Vojtech Huser, MD, PhD
U.S. National Library of Medicine, National Institutes of Health, Bethesda, MD

Description of purpose: Ability to share and re-analyze data from clinical trials is a well-recognized challenge in Clinical Research Informatics (CRI). Similarly, aggregation of corresponding data across several trials can facilitate larger meta-analyses that may lead to new discoveries. To facilitate data aggregation, research relevant Common Data Elements (CDEs) have been defined by number of initiatives1. The National Library of Medicine (NLM), with initial funding from an HHS Patient Centered Outcome Research Trust Fund, launched a beta version of the NIH Common Data Element Repository in January 2015 and has been involved in active pilot projects throughout 2015-2016.

The NIH Common Data Elements Repository has been designed to provide access to structured human and machine-readable definitions of data elements that have been recommended or required by NIH Institutes and Centers and other organizations for use in research and for other purposes. Each NIH Institute or Center (IC) classifies their CDEs in collections or sets belonging to specific clinical domains. The process of developing CDEs varies from initiative to initiative, but generally, a designated working group—or other set of subject matter experts—collectively decides the core variables or measures that should be recommended for researchers studying in that domain or disease area. The finished set is sent back to the IC and there is a period of public review and commentary. Once vetting is complete, the IC returns its data elements and classifies per the IC’s internal policies and formatting. The most established of these initiatives developed their own access portals and formats. While large repositories exist (most notable, NCI), the ability to search across all NIH CDEs, and to link clinical research to clinical data standards in active use in EHRs, seemed critical. For examples of current collections of CDEs from NIH ICs, see the NIH CDE Portal2.

CDEs have many benefits for research: facilitating cross-study comparisons of results, aggregation of data, speeding study start time by selecting existing measures, improving data quality via use of validated measures, and improving replication and reproducibility3. Perhaps most pressing, though, is the increase in language from NIH funding announcements which encourages or recommends the use of CDEs: “NIH encourages the use of common data elements in basic, clinical, and applied research, patient registries and other human subject research to facilitate broader and more effective use of data and advance research across studies...[and] investigators are encouraged to consult the Portal and describe in their applications any use they will make of NIH-supported CDEs in their projects”3.

A demonstration of the tooling and functionality will highlight the ability to search across all collections from initiatives in a centralized place, annotate with clinical terminology(ies), and variety of form creation and export capabilities. A brief discussion of the pilot projects will incorporate feedback from working groups and feature improvements based usage. The demonstration will also describe challenges and future steps for development and implementation.

Degree of deployment: The repository has been deployed and available since 2015 with new web-based functionality added regularly. It contains a total of 42,123 data elements and 1724 forms from 12 different initiatives (e.g., PhenX, PROMIS, National Eye Institute or AHRQ). For full export functionality (JSON, ODM/XML, Structured Data Capture/XML, REDCap), users must use/obtain a free Unified Medical Language System (UMLS) license.

Acknowledgements: This work is supported by the Intramural Research program of the U.S. National Library of Medicine.

CKMS – An Integrated System for Managing Institutional Clinical Knowledge Assets

Dominik Aronsky¹, MD, PhD, Dirk Wenke¹, MS, Priyaranjan Tokachichu², MD, MS, Christopher J. Vitale², PharmD, Margarita Sordo², MSc, PhD, Saverio M. Maviglia², MD, MSc, Roberto A. Rocha², MD, PhD

Abstract

Many healthcare institutions maintain a large quantity of clinical knowledge assets, such as rules, pathways, order sets, templates, and dictionaries, frequently within multiple proprietary clinical applications, resulting in “knowledge silos.” A central, dedicated and independent repository of knowledge assets with systematic lifecycle processes for managing institutional knowledge often does not exist. Knowledge silos result in inconsistent and error-prone workflows, requiring the wasteful application of specialized resources to update and maintain redundant knowledge assets. This demonstration showcases a novel clinical knowledge management system that enables a structured and systematic knowledge curation process, based on a strict semantic validation framework that ensures the integrity of assets at different lifecycle stages.

System Description and Functionality

The clinical knowledge management system (CKMS) provides a flexible and scalable framework for creating various types of knowledge assets, including detailed semantic linkages, while also guaranteeing the referential integrity of each asset through validation processes with a rule-based semantic reasoning engine. The external knowledge assets can be imported, extended, and linked to other assets within and across different namespaces. An authoring workbench supports a strict curation lifecycle and enables knowledge and terminology engineers to create, revise, clone, extend, validate, publish, audit, or retire knowledge assets. During the authoring and maintenance process, the participation of subject matter experts is supported by a collaboration workbench, which facilitates the communication and documentation required for the definition and maintenance of knowledge assets. An end user, such as a clinician, can search and view assets using faceted queries available via a read-only portal. Knowledge assets can also be displayed in a customizable, asset type specific view. Multiple import and export options support the need to embed and connect to clinical systems. These integration options allow standard terminologies, content from knowledge providers, and locally maintained assets to be consistently curated, including the effective management of dependencies across successive revisions (Figure). Knowledge-driven applications, such as an Infobutton Manager, can utilize CKMS as a backend system.

CKMS is the result of a multiyear collaboration between Partners and Semedy. The system is a web-based application using standard technologies (Java, JDBC, Apache Wicket, HTML, JavaScript, JQuery, jQueryUI, XML) and stores data in a MS SQL server database. IRIS™ serves as the reasoning engine. User authorization occurs via LDAP and a fine-grained role permission system governs asset control. REST-like web services provide access for external applications, enabling seamless integration with other systems. The presentation will provide in-depth information about the system’s architecture, structure, knowledge modeling approaches, etc. CKMS has been deployed at Partners for more than 24 months, and more recently at another large academic medical center. The system is currently being used to catalog and preserve legacy knowledge assets, as well as to catalog and manage assets used by a commercially available EHR. The system also includes curated versions of standard terminologies, such as SNOMED CT, ICD-10-CM, LOINC. The CKMS repository at Partners includes over 11 million discrete knowledge assets, corresponding to 138 distinct asset types.
Vicinity Exploration: Enabling User-Driven Visual Search of Multiple Machine Learning Models for Precision Medicine

Suresh K. Bhavnani PhD1, Archana Ayyaswamy MS1, Tianlong Chen BS2, Shyam Visweswaran MD PhD3, Gowtham Bellala PhD4, Kevin E. Bassler PhD2

1Institute for Translational Sciences, University of Texas Medical Branch, Galveston, TX; 2Department of Physics, University of Houston, Houston, TX; 3Department of Biomedical Informatics, University of Pittsburgh, Pittsburgh, PA; 4C3 IoT, Redwood City, CA

Abstract

Although machine learning methods (e.g., cluster analysis) are increasingly being integrated into visual analytical applications for identifying complex patterns (e.g., patient subgroups) in large data sets, such approaches typically generate a single best model based on optimizing an objective function. However, comparison of models in the vicinity of the optimal model can enable analysts to explore tradeoffs among key model parameters, important when exploring large datasets. Here we describe the user interface features critical for vicinity exploration, and demonstrate its efficacy in the use of a network layout algorithm to explore a large dataset related to precision medicine.

Introduction

Machine learning (ML) methods such as cluster analysis and feature selection are increasingly being integrated into visual analytical applications to enable the rapid identification and comprehension of patterns in large datasets. However, such methods typically output a single best model determined by optimizing an objective function. For example, the ExplodeLayout algorithm attempts to enhance the comprehension of networks that have significant but highly overlapped clusters (Fig. 1A). The algorithm takes as input a network layout (e.g., generated from a layout algorithm such as Fruchterman Reingold), and node clusters (e.g., generated by a modularity algorithm), and maps each cluster’s centroid onto equidistant points on an imaginary circle. The algorithm searches for a circle radius such that the ratio of the total non-overlapped area among the clusters, and the total space required for the entire network layout is maximized, resulting in an optimal cluster separation within a compact area (Fig. 1B). Here we describe the user interface (UI) design features and utility of vicinity exploration, an interaction approach that enables users to explore multiple ML models in the vicinity of the optimal model such as that generated by ExplodeLayout, to better comprehend complex patterns in large datasets.

Method and Results

As shown in Fig. 1, we designed five UI features for enabling vicinity exploration of an optimal model generated by ML algorithms such as ExplodeLayout: (i) vicinity graph implemented as a line graph of how the objective function changes with respect to the circle radius, (ii) optimal model indicator implemented as a dotted line on the graph to help recall the circle radius of the optimal model, (iii) single model viewer implemented as a scroll bar to select a circle radius and display a high resolution image of the corresponding exploded network, (iv) model significance implemented as progressive analysis and display of significance of vicinity models to address the high computation time in large datasets, and (v) multiple model viewer implemented as side-by-side views of user-selected models in the vicinity of the optimal model to reduce working memory loads during model comparisons. The above features were used by a geriatrician to comprehend patient subgroups within all 30-day readmitted hip fracture patients (n=6150), extracted from the 2010 Medicare database that had at least one of the 8 significant comorbidities shown. The optimal layout (Fig. 1B, radius=0.5) revealed 2 levels of heterogeneity in each of 7 patient subgroups: patients with one comorbidity on the outer side, and patients with more than one comorbidity on the inner side of each cluster. A higher separation of the clusters (Fig. 1C, radius=1), while not optimal based on the objective function and with lower resolution of the clusters, enabled the comprehension of inter-cluster edges showing how patients shared comorbidities across clusters. This led to hypotheses of how renal disease and diabetes interacted with other comorbidities precipitating hospital readmission in each patient subgroup. Future research will test the generality and usability of the above features in other ML-integrated visual analytical applications.

RxMix – Use of NLM drug APIs by non-programmers

Olivier Bodenreider, M.D., PhD, M.S., Lee Peters, M.S.
National Library of Medicine, National Institutes of Health, Bethesda, Maryland, USA

Contact information: RXNAVINFO@LIST.NIH.GOV

Motivation

Subject matter experts, including pharmacists, pharmacy benefit managers, health researchers and health data analytics specialists, are generally knowledgeable in drug resources, such as RxNorm, and have developed interesting use cases for it. However, processing datasets often requires programming skills, e.g., making calls to a service, such as the RxNorm Application Programming Interface (API). To enable users who do not have programming skills to leverage National Library of Medicine (NLM) drug APIs, we developed RxMix, a web application designed for non-programmers to create queries for complex use cases and execute batch queries against our APIs.

NLM drug Application Programming Interfaces (APIs) available through RxMix

Over the past decade, NLM has developed a variety of publicly available drug APIs to expose some of its resources through SOAP and RESTful web services for users to integrate into applications (https://rxnav.nlm.nih.gov/). API usage reached 1 billion queries in 2015. We also make these APIs available through RxMix.

- The RxNorm API enables users to access RxNorm drug names and codes. The most common use is for mapping drug identifiers (e.g., NDC codes) to RxNorm. It can also be used to map drug names from local formularies to RxNorm using normalization and approximate matching. The APIs is useful for traversing the rich graph of relations among drug entities provided by RxNorm. Recently developed functions help access historical drug codes for analytics purposes.
- The RxClass API enables users to access drug classes and drug members for a number of different drug class types, including ATC, DailyMed and NDF-RT. It can be used to find the classes for a particular RxNorm generic or brand name drug, or can list the ingredient members of a specified drug class.
- The Interaction API enables users to find drug-drug interaction (DDI) information for a specified drug or find the interactions from a list of drugs. Sources of DDI include DrugBank and the ONC high-priority list of DDIs.
- The RxTerms API provides access to the physician-friendly display names for clinical and branded drugs in e-prescribing applications.
- The NDF-RT API enables users to access clinically-oriented information associating drugs with their pharmacologic classes and other properties (e.g., mechanism of action and physiologic effect).
- The DailyMed API provides access to drug information from the FDA Structured Product Labels.
- The RxImageAccess API provides access to pill images as well as their related properties.

RxMix – Complex queries and batch processing

Using the RxMix graphical interface (https://mor.nlm.nih.gov/RxMix/), users can select an API function apply it in batch mode to a list of input values. For example, a list of identifiers from the National Drug Code found in a claims database can easily be mapped to RxNorm identifiers using the function RxNorm:findRxceByld. The batch query is executed on NLM servers and the results are returned to the users after completion.

Users can also create complex workflows (i.e., sequences of API functions) for specific use cases. RxMix “knows” which functions are interoperable and helps guide users in workflow development. Users can also select existing workflows from a library and save their own workflows for future use. Use cases suggested by users include mapping drug codes found in observational datasets to drug classes for analytics purposes and identifying non-opioid analgesics in a list of analgesics that includes multi-ingredient drug products.

All queries and workflows can be tested interactively in RxMix, which makes it a powerful educational resource. RxMix receives 150-200 batch queries and 1800 interactive queries each month on average.
NLM3D: an Open-Source Library of Medical-Imaging-derived 3D Polygonal Models for Use in Public Health, Medical and STEM Applications

Kristen Browne, MSc¹, Anne Altemus, MA²
¹,²Audiovisual Program Development Branch, Lister Hill National Center for Biomedical Communications, National Library of Medicine, Bethesda, MD, USA

System Description:

The NLM3D: Anatomy site has been developed to address multiple health and science issues. First, while a wealth of 3D data is being generated by imaging professionals in the medical and research communities, distribution is often limited to either 2D renderings of 3D objects or to a selection of images from large image stacks; this leaves a gap between the audience’s ability to interpret these images and the true meaning of the data. A library of optimized 3D scientific models derived from raw data can bridge these communication gaps, especially if they are delivered in conjunction with educational information explaining the imaging technology and how to use 3D models in practice. As a starting point, our library is focused on human anatomy derived from medical imaging data.

It is currently difficult to find accurate and high quality 3D scientific models. This can significantly delay the production of health and science communication resources. To address this issue, our base models are derived from segmentations of medical imaging data, then optimized to industry standards using professional digital sculpting and retopology software. To date, we have a nearly complete Visible Human Male, as well as a significant portion of the Visible Human Female. Future imaging sets could include the NCI Cancer Imaging Archive, the Visible Korean, and embryonic development series such as the Carnegie Embryology Collection ¹,²,³,⁴.

Models are uploaded to a MS SQL database that is managed with a Drupal content management system. A custom user interface requires inclusion of all model information (including structural modifications) as well as relations to custom anatomical vocabularies and imaging collection details. The UI also requires creation of ALT tags for all media including images and models to improve resource accessibility. All included metadata are autocomplete keyword searchable using an Apache Solr powered engine. Faceted and hierarchical searching are also available using the vocabularies and other metadata as filters.

NLM3D strives to provide the educational resources necessary for both communications professionals and the general public to utilize our assets. This includes relevant material describing the types of medical imaging used to create our models, how to process imaging data into 3D models, and how to use these assets in gaming, illustration, and animation environments. We also provide fully functional example projects, such as 3D printer-ready model sets, and interactive gaming environments.

NLM3D is a primary effort to create scientifically accurate and industry standard 3D models for public use, deployed through an engaging interface with interactive tools. This fills a different niche that other initiatives which are community-driven, where the quantity of models available can be high, but the quality control is more difficult to implement. All modeling and site development work has thus far been completed with a staff of one research fellow and one summer student per year. We therefore project that with the addition of 1-2 qualified medical illustrators we will continue to grow and maintain NLM3D with minimal resources. NLM3D is therefore well-poised to become a sustainable and trusted source of assets to populate novel health systems, treatment and training applications, and educational resources well into the future.

References:

Statement of Deployment:

As of June 15th, 2017 NLM3D anatomy exists as a functional prototype with most resources described above; educational content is still under development. We hope to have a complete prototype (with all NLM Visible Human Male and Female Models) in mid-2018.
Person-Centric vs. Problem-Centric: Data-driven Heuristics for using Machine Learning to Improve Health Outcomes

John B. Coles, Ph.D.¹, Brett F. Cropp¹, Jacob M. Ekstrum¹, Jacob T. Fijas¹, Michael D. Moskal¹ CUBRC Inc. Information Fusion Group, Buffalo, NY, USA

Abstract
In the world of big data, health outcome and personalized medicine research is in the process of shifting from a hypothesis, problem-centric approach to a data-driven, person-centric approach. In this talk we highlight how data-driven approaches to developing predictive models can open the door to improving health outcomes with cross-sector collaboration and data fusion, leveraging a diverse set of datasets and measures for model development and validation. Specifically, we will discuss how multi-variate heuristic filtering and semi-automated machine learning techniques can be used to select the right subset of variables and hyperparameters when developing predictive models. We will demonstrate the capability of the Heartwood Analytics™ Software, with a focus on the Machine Learning (ML) AutoPilot system, to rapidly develop new predictive models across a range of problems from open datasets, highlighting the breadth of data that can be rapidly assessed when developing new predictive models.

Introduction
This presentation will build on ongoing work addressing problems in outpatient treatment and case management, with the goal of providing guidance to stakeholders through prediction of intervention efficacy including short-term and long-term outcomes¹. Here we will build on promising results in clinical outcome prediction using Neural Nets, with advanced methods for temporal data². The Heartwood Analytics™ Software (Figure 1) was developed using open source software packages such as Apache Kafka, Storm, NiFi, and Fuseki RDF store. Heartwood’s semi-supervised machine learning component, ML AutoPilot, was built using Google’s TensorFlow Library to automatically identify driving variables based on heuristic filtering, combine a myriad of machine learning models, and automatically tune each model’s hyperparameters using Bayesian Optimization³. Finally, ML AutoPilot exports self-contained, problem-specific models that can be deployed as a web application via Flask.

Figure 1. Fusion of data with semantic enhancement and predictive modeling.

Current Deployments: The current system is in its Beta phase and is deployed on AWS and in internal cloud for secure customer data analytics. Additionally, it has been installed at multiple partner sites for evaluation and feedback for retrospective and prospective analysis to support clinicians and case managers in understanding and engaging challenging populations. We will highlight current work including the impact for customers while comparing and contrasting existing systems with Heartwood Analytics™ for capability, flexibility, and ease of integration.

Improving the Care of Women through Health Information Technology

Caitlin M. Cusack, MD MPH FACOG

1 Contract Physician Informaticist, Offices of Informatics & Information Governance and Women’s Health Services, Veteran’s Health Administration, Silver Spring MD

Abstract

The Veterans Health Administration has undertaken two projects to improve the documentation and tracking of care for Women Veterans: The Teratogenic Drugs project and the System for Mammography Results Tracking (SMART). These projects improve the ability to record and store discretely a woman’s ability to conceive, and pregnancy and lactation status. Refinement of order checks and alerts around known or potentially unsafe medication or imaging use in reproductive aged or breast feeding women increases the clinical relevancy and mitigates alert fatigue. Clinical reminders are used to increase conversations around family planning, preconception planning, and contraception use. SMART introduces the ability to track the management of a mammogram from the point of ordering, through additional testing and treatment, to a return to routine age-based mammogram screening. In combination, these projects will improve the efficiency in documenting care to women Veterans, as well as improve the quality and safety of that care. This system demonstration will highlight features of these projects.

Introduction

Many electronic health records have taken a gender-neutral approach to clinical decision support tools and documentation of care. An inability to capture reproductive data elements as structured data results in clinical reminders, order checks, and alerts that are indiscriminate and frequently clinically irrelevant, risking alert fatigue. One evaluation showed that drug-pregnancy alerts had the lowest acceptance rates of all drug alerts presented to clinicians. Across all genders, delayed follow up of abnormal results, immature tracking systems of preventive health care. Journal of the American Medical Informatics Association. 2006 Jan 1;13(1):5-11. Women’s Health Services, Veteran’s Health Administration, Silver Spring MD

AMICUS: A Metasystem for Interoperation and Combination of UIMA Systems

Gregory P. Finley, PhD¹, Benjamin C. Knoll¹, Reed McEwan, MS, MSSE¹, Genevieve B. Melton, MD, PhD¹, Hongfang Liu, PhD², Hua Xu, PhD³, Serguei V.S. Pakhomov, PhD¹
¹Institute for Health Informatics, University of Minnesota, Minneapolis, MN; ²Mayo Clinic, Rochester, MN; ³University of Texas Health Science Center at Houston, TX

Introduction

There are many publicly available systems for natural language processing (NLP) of biomedical and clinical text to facilitate data mining, information retrieval, and natural language understanding. These systems have their respective strengths and unique capabilities, and in some cases it is desirable to combine annotations from different systems, or even to chain together these systems’ components. A practical and reproducible means of doing so has remained elusive, however, due to differences in type systems—i.e., what types of NLP annotations are available in each system and how they are defined.

Many of these systems are built around the Unstructured Information Management Architecture (UIMA) or have UIMA wrappers available. Though UIMA does not define a standardized type system, it does provide a robust and mature framework for working with annotations of any arbitrary type. We introduce AMICUS, an open-source “metasystem” that facilitates working with any number of UIMA-based NLP systems. AMICUS takes annotations from other systems and can inspect, compare, translate, and combine them according to flexible, user-defined configurations. (We previously released NLP-TAB, a tool for visually browsing UIMA annotations¹; together, NLP-TAB and AMICUS constitute a natural workflow to identify and operate on annotations of interest.)

AMICUS is unique in that it works across systems without relying upon or demanding standardization of types—indeed, part of its design philosophy is to celebrate the strengths of other systems and give end users a simple yet powerful framework to make use of the best options available for any NLP task.

System details

AMICUS itself does not perform NLP, but rather imports annotations from other systems’ outputs into its own analysis pipeline. A wide variety of pipelines can be designed from a small set of configurable and repeatable modules, where each module is designed for a specific task, such as: filtering annotations or changing their values, converting annotations to other types, combining annotations across systems, and exporting annotation values to CSV and other formats. Everything can be configured in a single text file—no programming experience is required.

The AMICUS distribution includes a “cookbook” of example pipelines for numerous applications. Users can apply these recipes to their own data, draw upon them for inspiration, or write their own from scratch. Examples of tasks that can be accomplished using a single pipeline include: converting annotations between type systems to enable serial processing by multiple other systems; filtering annotations based upon their values and/or the values of others; pooling annotations across several systems, possibly according to various voting schemes; generating statistics of annotation values; and measuring precision and recall of annotations against a manually annotated standard.

AMICUS is an open-source, cross-platform application that includes a documented Java API for developers to extend the functionality of analysis components. Additionally, all modules are implemented with uimaFIT and can be instantiated independently of the pipeline in other applications.

Development status

A public beta release is available at https://github.com/gpfinley/amicus. We have published experiments demonstrating the utility of merging disparate annotations from three different clinical NLP systems for an abbreviation disambiguation task² (the cookbook includes a recipe to repeat these experiments).

All work was supported by the National Institute of General Medical Sciences (GM102282).

mCerebrum and Cerebral Cortex: A Real-time Collection, Analytic, and Intervention Platform for High-frequency Mobile Sensor Data

Timothy Hnat, PhD; Syed Hossain, PhD; Nasir Ali, PhD; Simona Carini, MA; Tyson Condie, PhD; Ida Sim, MD, PhD; Mani Srivastava, PhD; Santosh Kumar, PhD

1University of Memphis, Memphis, TN; 2University of California, San Francisco, San Francisco, CA; 3University of California, Los Angeles, Los Angeles, CA

mCerebrum and Cerebral Cortex

The Center of Excellence for Mobile Sensor Data to Knowledge (MD2K) has developed two open-source software platforms (for mobile phones and the cloud) that enables the collection of high-frequency raw sensor data (at 800+ Hz for 70+ million samples/day), curation, analytics, storage (2GB/day) and secure uploads to a cloud. mCerebrum supports concurrent collection of streaming data from multiple devices (including wearables: Microsoft Band, research-grade MotionSenseHRV, EasySense, and AutoSense), phone sensors (e.g., GPS), Omron scale and blood pressure monitors and a smart toothbrush. mCerebrum continuously assesses data quality to detect issues of sensor detachment or placement on the body so they can be addressed. Data science research conducted by MD2K has resulted in 10 mHealth biomarkers: stress likelihood, smoking via hand gestures, nicotine craving, eating, lung congestion, heart motion, location, physical activity, driving, and drug use. Several of these biomarkers are computed in real-time on the phone to support biomarker-triggered Just-in-Time Adaptive Interventions (JITAI).

Cerebral Cortex is the big data companion of mCerebrum designed to support population-scale data analysis, visualization, and model development. It currently supports thousands of concurrent mCerebrum instances and provides machine-learning model development capabilities on population-scale data sets. Cerebral Cortex supports the same mHealth biomarkers that our phone platform computes, but does so on the entire dataset by using an Apache Spark powered abstraction that is designed for batch-mode computations as well as near real-time analysis via a data science dashboard. The MD2K platform uses Open mHealth mobile data exchange standards that are being harmonized with FHIR for EHR data exchange. All MD2K software is available under the BSD 2-Clause license.

By collecting and storing high-frequency raw sensor data, our approach enables external validation of computed biomarkers as well as computation of new biomarkers in the future. This benefit is akin to how biomedical studies archive biospecimens in biobanks so that they can be reprocessed to take advantage of future improvements in assays and support discoveries not possible at the time of data collection. Our platform addresses the challenges of high frequency, large volume, rapid variability and battery life limitations to enable long-lasting digital biobanks or digibanks as research utilities for mobile-driven translational research.

This demonstration will showcase data collection and visualization from multiple wearable sensor platforms and just-in-time user engagement will demonstrate how the platform can react in real-time to biomarker events. The demonstration will show how Cerebral Cortex’s capabilities for near real-time visualization of mCerebrum data are currently utilized to manage multiple concurrent clinical study participants at several sites across the United States. Finally, we will explore the interactive data science interface and showcase biomarker generation and model evaluation.

Study Deployment and Ongoing Activity

mCerebrum and Cerebral Cortex are currently deployed in ten studies at sites worldwide. These studies will result in a total of 106,806 person-days (1.3 million usable hours) of high-frequency sensor data from 2,251 unique participants. We estimate that the net data generated, processed, stored, and transmitted will be at least 150TB, consisting of more than 4.7 trillion data points.

Enterprise Level Data Restructuring in the Military Health System – Building the Foundation for Optimization and Advanced Analytic Capability

Andrew J. Holdaway, MD, Chris Nichols, MSN, Eric A. Shry, MD
1Madigan Army Medical Center, Tacoma, WA; 2Defense Health Agency, Falls Church, VA

Introduction

The Military Health System (MHS) has historically provided data services within silos defined by branch affiliation (Army, Air Force, Navy), as well as by differing customer business requirements. This has resulted in redundancy and limited crossover of capabilities. In order to increase efficiency of medical services in the MHS, a joint directorate named the Defense Health Agency (DHA) was launched in 2012. From the outset one of the DHA’s key roles has been to standardize the collection, aggregation, storage and application of clinical and business data generated by the MHS. One of the key challenges has been to provide accurate, timely, meaningful data and business intelligence solutions. These solutions must be flexible enough to meet a variety of business, clinical and tactical needs, all while remaining standardized enough for broad implementation across a large integrated health system.

The consolidation of data services is far from complete, and adoption of a new commercial EHR is proving to be a forcing function in modernizing the data architecture. As presently constructed, the data schema for the MHS is an amalgamation of products designed to meet niche requirements derived from both clinical and operational circumstances. Specifically, the current data infrastructure is driven by 23 source systems which feed 52 distinct data domains. These systems at the source layer are joined to an integration layer by over 450 interfaces to 5 largely independent data repositories. Much of the data processing for the reporting layer is still done by manual extraction and manipulation. This in turn limits the capacity to employ meaningful real-time analytic capability.

Project Description

To address these issues, a recent project was launched within DHA to streamline these products and services. The goal is to organize these disparate data collection methods into a streamlined schema that will systematically collect, process and analyze data in near real time. The organization is informed by the concept of a layered approach to data collection, storage, aggregation and reporting. The end-state will allow for modern predictive capabilities at the application layer. This will allow leaders at all levels to access up-to-date information in near real-time. Ultimately, the desired end-state is to move the entire enterprise closer to becoming a learning healthcare system.

Demonstration Aims

This project has practical implications beyond the MHS. In the setting of hospital acquisitions and health system mergers, the challenge of migrating, integrating, and optimizing data acquisition and use is a considerable challenge. If not executed in the context of a principled framework, usability of data, and ultimately the ability to monitor and manage is diminished. In order to discuss the MHS data modernization in context, the panel will present data consolidation and management principles driven by academic reports and industry best-practices.

Specifically, this demonstration panel proposes to:

1) Describe the framework and requirements of a modern data architecture that is capable of delivering actionable data at the analytics layer for multiple customers with unique requirements.
2) Summarize the current state of the data schema of the MHS.
3) Describe the proposed MHS data modernization project in the context of industry best practices, with a focus on the potential for cost savings and enhanced reporting and analytic capabilities.

As of proposal submission, the project is in the development/planning stage with proposed execution within 3-6 months. At the time of presentation, early results will be available for discussion.
SMART on FHIR Apps from the University of Utah Interoperable Apps and Services (IAPPS) Initiative: Extending the EHR to Optimize Patient Care

Kensaku Kawamoto, MD, PhD, MHS¹, Guilherme Del Fiol, MD, PhD¹, Benjamin Brooke, MD, PhD², Charlene R. Weir, PhD, RN¹

¹Department of Biomedical Informatics, University of Utah, Salt Lake City, UT
²Department of Surgery, University of Utah, Salt Lake City, UT

Abstract

The SMART on FHIR interoperability framework enables healthcare organizations to extend the functionality of electronic health record (EHR) systems such as Epic and Cerner to improve patient care and enhance the provider experience. At the University of Utah, which uses the Epic EHR platform, a multi-stakeholder effort known as the Interoperable Apps and Services (IAPPS) initiative is developing a variety of SMART on FHIR applications to improve patient care in an interoperable, scalable manner. In this demonstration, leaders in the IAPPS initiative will demonstrate various SMART on FHIR applications that have been developed, including a neonatal bilirubin management application that has received several awards through the HHS/ONC Provider User Experience Challenge, as well as a surgical referral and communication dashboard that is being developed through the ONC High Impact Pilot program. Both the bilirubin management application and the surgical referral dashboard are available for free under an open-source license. We will also demonstrate additional SMART on FHIR applications that complement and extend the EHR through data aggregation, data visualization and clinical decision support.

Description

The mission of the University of Utah IAPPS initiative is to extend the Epic EHR to optimize patient care and the provider experience, with the additional objective of using a standards-based, interoperable approach that can be scaled to other healthcare institutions and EHR platforms. This demonstration will showcase selected applications that illustrate this approach, including a neonatal bilirubin management application, a surgical referral dashboard and several other SMART on FHIR applications designed to improve care in specific clinical areas. The neonatal bilirubin management application has won several awards.¹ Its purpose is to enable efficient and effective management of neonatal hyperbilirubinemia (Figure). Prior work by our group identified knowledge gaps in goals of care shared by primary care physicians (PCPs) and surgeons managing complex patients during the referral and follow-up period after surgery. This led to the design of a surgical referral dashboard, which facilitates bidirectional communication to support closed-looped referrals between PCPs and surgeons and improvements in patient care. The bilirubin management app is in production clinical use, and the surgical referral dashboard is under active development, with a plan for pilot use starting in the summer of 2017. Additional applications that we plan to demonstrate include a diabetes management dashboard that uses predictive modeling to guide pharmacotherapy (1.0 system completed and undergoing Epic integration), an enhanced growth chart application (physician-requested enhancements completed and undergoing Epic integration), and various other applications for data aggregation, data visualization and clinical decision support.

Interoperable Web Services for Research Data Repositories
Nationwide, hospital systems’ clinical data are becoming available to researchers for comparative effectiveness research. Various national initiatives are engaging IT departments to consolidate clinical data sources into institution-wide data warehouses using one of several emerging standard data formats, such as PCORNet’s Common Data Model (CDM) and the Observational Medical Outcomes Partnership (OMOP) CDM. Use of a CDM format is critical for efficient data exchange across organizations. Both PCORnet and OMOP CDMs are coded using standard terminologies and support common data elements in observational medical data. Unfortunately, there is still significant difference between each data model, in that they favor different standard terminologies and have a somewhat different set of supported data fields. Moreover, each model has its own suite of analytical programs, incompatible with the other models.

Informatics for Integrating Biology and the Bedside (i2b2), an open-source clinical data warehousing and analytics platform developed for the past decade and in use at presently over at over 100 institutions nationwide, provides a flexible web services layer which runs on top of its data model and abstracts the actual database structure into clinically meaningful XML objects, such as the Patient Data Object (PDO). These XML objects are agnostic to the underlying data model and can provide information on any data that can be modeled in i2b2’s “ontology” structure. We have previously described how this structure can be used to represent a generic Information Model to express a wide variety of data representations. [1] Therefore, i2b2 has the theoretical capability to query a variety of data models through the common i2b2 web services.

Reusable Apps Running on i2b2
The Fast Healthcare Interoperability Resources (FHIR) data format is an increasingly popular standardized messaging language for encapsulating patient data. It has added traction because it is an HL7 standard, and their official FHIR wiki presently lists 50 organizations interested in using FHIR. Electronic Health Record (EHR) systems are being outfitted with FHIR interfaces, and apps are being written to understand FHIR. Such apps will run interoperably on any FHIR interface. The SMART (Substitutable Apps, Reusable Technology) app platform, which is spearheading this approach, features, at the time of writing, twenty-five functional apps in their gallery: https://gallery.smarthealthit.org/.

We have developed a component (called a “cell”) for i2b2 which translates its XML data objects into FHIR format. [2] These can then be consumed by apps that would like to interface to the data warehouse. This interface allows apps to be developed directly on the data warehouse layer, enabling apps for research. Additionally, it serves an important use case in developing clinical apps, because it can frequently be difficult to gain access to the EHR FHIR interface, especially during app development.

Description of System
We made small changes to i2b2 to allow it to query other data models, configurable through the existing ontology system. We next adapted a previously-developed PCORnet CDM ontology to interface directly with the PCORnet data model tables. [1] We also developed an OMOP ontology which implements a subset of the OMOP data model (drug exposure, conditions, and procedures), and we also modified this to interface directly with the OMOP data model. At the time of this writing, we are able to query our OMOP and PCORnet data models directly through i2b2. We are now testing the i2b2-FHIR cell for executing SMART apps on these data models.

This enables a suite of interoperable apps to engage popular research data models without requiring institutions to transform their data. Our demonstration will feature SMART on FHIR apps running against OMOP and PCORnet via i2b2 web services. All tools used in this demo will be made available open-source.

CDS Connect: A New National Repository for Clinical Decision Support Knowledge Artifacts

Edwin A. Lomotan, M.D.1, Robert McCready, M.S.2, Steven Bernstein1

1Agency for Healthcare Research and Quality, Rockville, MD; 2The MITRE Corporation, Bedford, MA

Background
Clinical decision support (CDS), as a component of quality improvement and when properly implemented, has the potential to accelerate the movement of evidence into practice. This process may be further expedited by tools and infrastructure that facilitate sharing of CDS among developers, implementers, and target audiences such as patients, clinicians, health care organizations, and other stakeholders dedicated to improving health care quality. In 2016, the Agency for Healthcare Research and Quality (AHRQ) launched an ambitious multi-component initiative, focused on patient-centered CDS, with two primary aims: 1) to accelerate the movement of evidence into practice through CDS and 2) to bring CDS closer to becoming a shareable, standards-based, and publicly-available resource.

Description of Demonstration
One of the initiative’s components, known as “CDS Connect”, is a contractual effort through the MITRE Corporation to build prototype infrastructure for CDS authoring, sharing, and dissemination. CDS Connect is a combination of web-based infrastructure and software, including a repository of CDS knowledge artifacts and a CDS authoring tool. This system demonstration will feature use of both.

The CDS repository stores and makes available for sharing CDS knowledge artifacts developed by AHRQ and others. CDS knowledge artifacts can range considerably in scope, purpose, and format. They include computer-interpretable, formal logic statements derived from clinical practice guidelines to results of CDS testing, implementation guides, links to primary research evidence, and other resources designed to leverage CDS as a means for quality improvement. Attendees will learn how to access the repository and the CDS artifacts that are available. Since user feedback and interaction with the CDS community are key drivers for improving CDS Connect, attendees will also learn how to contribute feedback and participate with ongoing development efforts.

The CDS authoring tool enables the design of standards-based CDS artifacts that can be more easily shared among disparate electronic health record platforms and other technologies. The CDS authoring tool leverages the Clinical Quality Language (CQL), a Draft Standard for Trial Use under HL7. CQL is the expression language that harmonizes specifications for electronic clinical quality measures (eCQMs) and CDS. When working together, eCQMS and CDS can be powerful tools to address gaps in care and improve health care processes. Attendees will learn how to access the CDS authoring tool and will view a demonstration of its use.

CDS Connect also includes application programming interfaces (APIs) that allow for more automated interaction with the CDS repository, the CDS authoring tool, and other software sources designed to produce and consume CDS artifacts. Attendees will also learn how MITRE developed CDS for cholesterol management as part of the AHRQ initiative, piloted the CDS in a live clinical setting, and made CDS artifacts publicly-available as a proof-of-concept. Finally, attendees will learn how CDS Connect relates to other, existing platforms and about plans for maintenance of the CDS, governance, and sustainability of the infrastructure.

Author Statement
CDS Connect has been available since early March 2017. The CDS repository is undergoing constant improvement, with a more formal second release scheduled for September 2017. The CDS authoring tool is currently being built and is scheduled for its first release in September 2017. The initial design of the CDS for cholesterol management is complete, with formal piloting and refinement to occur from the spring through summer 2017. Information about the AHRQ initiative, including access to CDS Connect, can be found at http://cds.ahrq.gov.
CANARY: An Information Extraction Platform for Clinical Researchers

Shervin Malmasi, PhD¹, Nicolae L. Sandor, DM, PhD², Naoshi Hosomura, DDS, DMS²¹, Matt Goldberg³, Stephen Skentzos, MA⁴, Alexander Turchin, MD, MS, FACMI¹

¹Brigham and Women's Hospital, Boston, MA; ²Boston University, Boston, MA; ³Harvard University, Boston, MA; ⁴Kiip, Inc., San Francisco, CA

Abstract

Information extraction is a key Natural Language Processing (NLP) task for discovering and mining critical knowledge buried in unstructured clinical data. Nevertheless, widespread adoption of NLP has yet to materialize; the technical skills required for the development or use of such software present a major barrier for medical researchers wishing to employ these methods. In particular, no free NLP software geared towards biomedical researchers with little technical expertise has been made available. To address this issue we have developed CANARY, a free and open source solution designed for users without NLP, software development or engineering experience. The software allows users to model their target information using lexicons and detection criteria, ranging from simple to complex. It was designed to be fast and work out of the box via a user-friendly graphical interface.

Introduction

Unstructured, free-text documents contain vital clinical data and this has led to the development of computational methods to process and mine them for information of interest, a key task in clinical research. Despite the task’s prevalence, no readily usable tools for biomedical researchers are available. Ideally, such tools should be easy to use for researchers, even those without any NLP or software development experience. However, no such free or open source solution exists. This need prompted the development of CANARY, an NLP-based information extraction platform designed to meet these criteria. It has been developed (using Perl and Microsoft .NET) for processing clinical documents to support the extraction of text snippets via user-defined knowledge discovery criteria and lexicons.

Demonstration Description

We first outline the software’s motivation and design process. The components forming the NLP pipeline and information identification mechanism for identification of concepts of interest will be described. Next, we present an end-to-end demo covering: (1) installation; (2) a tour of the graphical user interface; (3) data acquisition; (4) text normalization & preprocessing; (5) ontology definition; (6) information discovery parameter definition; (7) structured value extraction; (8) model testing and empirical evaluation; (9) data filtering; and (10) scaling up to process big data.

This functionality will be interactively demonstrated using complex, real-world models designed by members of our research team without technical expertise. The models process large-scale (Gigabytes) datasets focusing on drug side effect discovery, medication adherence, surgical procedures, and radiology report processing, amongst others. The models have been used to publish numerous studies and we cover how the structured output generated by our software can be analyzed to obtain study results ranging from prevalence statistics to temporal analysis of patient outcomes.

Sync for Science (S4S): Helping patients share EHR data with research

Joshua C. Mandel, MD\textsuperscript{1,2}, David A. Kreda, BA\textsuperscript{1}

\textsuperscript{1}Harvard Medical School, Boston, MA \textsuperscript{2}Verily, Cambridge MA

Abstract: Sync for Science (S4S) is a new form of patient-mediated digital workflow that enables donating electronic health record (EHR) data to research projects such as the Precision Medicine Initiative's All of Us Research Program. S4S offers a streamlined, ecommerce-like user experience for donating data from any EHR system by making use of HL7 FHIR\textsuperscript{®} to represent clinical data and OAuth 2.0 for authorization. S4S leverages the HIPAA requirement that patients must be able to access their own EHR data, and the Meaningful Use Stage 3 and 2015 EHR Certification programs that require patients be able to share a Common Clinical Data Set with software apps of their choice. S4S design incorporates input from the National Institutes of Health (NIH), the Office of the National Coordinator, and the Office for Civil Rights to be sure it satisfies rigorous technical, operational, ethical, and legal requirements for patient to release their personally identifiable health information to research studies.

Purpose: Using Sync for Science (S4S) technology, research participants can donate their EHR data to research projects by executing a simple workflow between a participant-facing mobile (or web) app and a healthcare provider's patient portal (see Figure). This is particularly useful when participants are recruited from outside of traditional institutional settings, where collection of EHR data is otherwise hard to automate. To create this patient-mediated solution, our NIH-funded team worked with partner teams from several major EHR vendors to implement S4S technology consistently into their individual patient portal products.\textsuperscript{1} Each EHR's patient portal represents data using Argonaut-profiled FHIR resources including patient demographics, allergies and intolerances, immunizations, lab results, medications, documents, problems, procedures, vital signs, and smoking status.\textsuperscript{2} Each app is registered with provider systems ahead of time. Subsequently, a patient's in-portal approval causes the provider EHR to generate an access token that the app uses to retrieve clinical data. The app issues requests to retrieve historical patient data, and periodic requests for updates during a patient-determined time interval. See http://synfor.science for details.

Deployment Status: Real-world testing of S4S-enabled patient portals will be performed at twelve healthcare sites. In accordance with the All of Us Research Program IRB protocol, as many as 2,000 participants will be invited to join by using the All of Us research app to self-enroll, to consent the use of their EHR data, and, using the portal-based S4S workflow, to instruct their healthcare provider to share EHR data with the research app.

Genome Dashboard: An Interactive Tool for the Exploration of Human Genomic Variants and Phenotypic Associations

Katherine Miller, PhD1, Rajeswari Swaminathan, MS1, Soheil Moosavinasab, MS1, Robert Strouse, MFA1, Matthew Bailey, BA1, Yungui Huang, PhD1, Simon Lin, MD1

1The Research Institute at Nationwide Children’s Hospital, Columbus, Ohio

Introduction

Whole genome and exome sequencing (WGS/WES) are increasingly being utilized to establish the genetic basis of disease in patients. Typically, extensive bioinformatics experience is required to use complex tools to sort through thousands of sequence variants and identify potentially disease-causing variants, thus preventing many clinicians/researchers from exploring sequence variant interpretation on their own in light of new symptoms or in light of new information on genotype-phenotype associations that are constantly being discovered and curated in public databases. We developed an interactive, easy-to-use web application Genome Dashboard (GD) that enables users to easily explore sequence variant interpretation.

System Description

GD is designed as a search engine to uncover known disease-gene associations using phenotype keyword(s) search to match with entries in public knowledgebases against uploaded genome sequencing data (variant call format; VCF). We integrated knowledge from public archives of gene-phenotype relationships (Online Mendelian Inheritance in Man [OMIM], ClinVar, NCBI GeneRIFs, and Mouse & Rat Genome Database). We implemented various filters (e.g., for location in gene, molecular consequence, and variant allele frequency using gnomAD1 database) to help users refine and narrow their search. Elasticsearch is used to index annotated VCF files (via ANNOVAR2).

System Evaluation

We tested Genome Dashboard using WES data set from CLARITY 1 Challenge3 (Figure 1). We input phenotype terms (“cardiac conduction defects” and “familial heart block”) from the patient of interest. Additional filtering for location in gene (exonic) and minor allele frequency <1% identified the same variant in the TRPM4 gene reported by 13/23 groups as disease-causing in CLARITY 1 challenge1.

System Deployment

The system was developed and tested internally at Nationwide Children’s Hospital (NCH). GD has been demonstrated internally to researchers in the NCH Institute for Genomic Medicine and to physician-scientists in the Center for Cardiovascular Research at NCH. Next steps include beta-testing to genetic counselors and medical geneticists in central Ohio.

Conclusion

Genome Dashboard will give clinicians/researchers opportunity to dive through sequencing data and explore clinically relevant variants, which may help lead to diagnosis, assessment on recurrence risk, insight to prognosis, medical surveillance for suspected complications, and/or tailored approaches to clinical management. We will provide a URL during our demonstration for a public version of Genome Dashboard.

Systems Demonstration: Fall Prevention and Fire Departments

Andrew Muth, MD\(^1\), Christopher Hollweg, MD, MPH\(^1\), Pamela Garcia-Filion, PhD\(^1\), Michael Smith, RN\(^2\), Hamed Abbaspazegan, MD, MBA\(^2\)

\(^1\)University of Arizona College of Medicine, Phoenix, Arizona; \(^2\)Phoenix VA Healthcare System, Phoenix, Arizona

Problem
Accidental falls continue to be a leading cause of injury among the elderly population and a common reason to activate the 911 system.\(^1\) Fall screening is not routinely done, and interventions are not tailored to patients’ specific needs. There is a gap in access to standard preventative care, and the unintentional fall rate in the elderly is rising. Coupled with this is the significant associated morbidity and mortality.

Purpose
The Clinical Informatics Department at the Phoenix VA had previously established successful partnerships with both the City of Tempe Fire Department’s and the City of Chandler Fire Health & Medical’s Community Paramedic (CP) programs to identify chronically ill Veterans in need of interim care and intervene. With this project, we sought to expand the target cohort by identifying Veterans at high risk of falling or adverse outcomes from a fall. To mitigate fall risk, our objective was to intervene and connect Veterans to services for Occupational Therapy (OT) and Physical Therapy (PT).

Description
Using a novel, weighted sum model, Veterans living in the municipalities of Chandler or Tempe are identified as high risk of falling and/or adverse outcomes based on pre-defined criteria. These criteria include: a history of fall, high Morse Fall Scale score (>45), certain diagnoses (e.g. stroke, blindness), problems with ambulation, taking certain medications from Beers list (e.g. benzodiazepines, antipsychotics), recent ED visit/hospitalization, and Care Assessment Needs (CAN) score, a VA tool predicting high utilization of the system.\(^2\) Points are assigned to each criterion, with a higher value given to a more significant factor, and then summed. Patients with high scores are then scheduled via CP programs for a telehealth visit with a Nurse Practitioner. The use of telehealth allows qualified providers to assess the patient, as well as his/her environment, perform a thorough medication reconciliation, and manage the patient within the VA system in real-time.

Degree of Service Deployment
Barriers to the implementation included the coordination of a multidisciplinary team and the complexity of risk factors involved. Furthermore, many Veterans that likely would have benefited from visits declined them. Regardless, at the time of presentation, the project will have been running for almost 2 years: 1 year based solely on CAN score, and since 2017 with the current modified model. During this time, we have been able to successfully identify Veterans needing fall preventative services. The post-fall initiative cohort was much more likely to have an abnormal gait and history of fall, and the number of orders placed for all categories increased, most notably for labs, imaging, and prescriptions (half of which were fall related). More orders were also written for mobility aids and PT/OT consults. Additionally, subjective experiences from both patients and providers continue to be positive. As medicine is becoming more focused on preventative care, we anticipate this care delivery model to continue and even expand to other areas. For example, identifying patients with risk factors for myocardial infarction (eg obesity, high blood pressure, diabetes, tobacco use) would allow for interventions like lifestyle counseling, medication reconciliation/adherence, and closer monitoring of chronic conditions.

Applications of the Ontology Abstraction Framework

Christopher Ochs, PhD¹, James Geller, PhD¹, Yehoshua Perl, PhD¹
New Jersey Institute of Technology, Newark, NJ¹

Abstract

Biomedical ontologies are large and complex knowledge representation systems. We have developed a software system called the Ontology Abstraction Framework (OAF) to create, visualize, and explore summaries of ontologies called abstraction networks. We have used abstraction networks to support comprehension of ontology structure, ontology quality assurance, and ontology change analysis. The OAF is composed of several modules and supports ontologies in various formats. We will demonstrate several applications of ontology summarization using the OAF. Several components of the OAF, such as the Visual Semantic Delta (VSD), which identifies and summarizes the effects of editorial efforts applied to SNOMED CT, and Live Abstraction Networks (LAbNs), which are structural summaries created “on the fly” as a user edits an ontology in Protégé, will be presented.

Introduction

Ontologies often contain many thousands of concepts and tens of thousands of semantic relationships; too much information to display on a single screen. Understanding the overall structure of an ontology, and how that structure changes, is important for ontology maintenance, development, and use. We have created a software system called the Ontology Abstraction Framework (OAF) [1] to derive, visualize, and explore ontology summaries called abstraction networks. An abstraction network provides a compact view of an ontology’s content and structure. The OAF can create different types of abstraction networks for ontologies in OWL, OBO format, and SNOMED CT’s RF2 format.

The OAF is currently available for download as a free and open source software (the current version, and its associated source code, are available for download at https://njitsaboc.github.io/). The OAF is released as standalone software tools for OWL or SNOMED CT and as an OAF plugin for the Protégé ontology editor.

Different OAF modules enable the summarization of a different aspect of an ontology’s structure. We will demonstrate how the different types of ontology summaries created by the OAF can support various applications, including ontology development. An overview of the architecture of the OAF system and three recently completed modules of the OAF will be presented. Illustrative examples from prior and on-going research studies will be presented using the OAF tool.

- **Visual Semantic Delta (VSD) module:** In a recent study [2] we introduced the visual semantic delta for identifying and summarizing changes in SNOMED CT. The VSD identifies editing operations that were applied to a selected subhierarchy of concepts. Editing operations reverse engineer the editorial processes applied to a given concept, based on the delta files provided with each SNOMED CT release. The VSD provides a visual summary of major structural changes, starting from which a user can investigate a selected subset of concepts, to review their individual changes. Examples from SNOMED CT’s Bacterial infectious disease subhierarchy will be shown.

- **Live Abstraction Network (LAbN) module:** Many biomedical ontologies have been developed using Protégé. We will demonstrate how LAbNs create dynamically changing summary views of an ontology’s structure as a user is editing the ontology in Protégé. We will demonstrate how LAbNs can be used to support ontology development.

- **Aggregate Abstraction Network (AAbN) module:** Aggregate abstraction networks were designed to enable comprehension of an ontology’s content in a visual way. The overall purpose of an aggregate abstraction network is to capture the “big picture” of an ontology in a scalable, flexible manner. Aggregate abstraction networks allow a user to control the granularity of summarization of an ontology.

A Scalable Approach to Federating Distributed Data: The Avec® Platform

Philip R.O. Payne, PhD1,2; Mark Vance1; Peter J. Embi, MD, MS1,3
1Signet Accel, Columbus, OH; 2Washington University in St. Louis School of Medicine, St. Louis, MO; 3Regenstrief Institute, Indianapolis, IN

Abstract
Researchers, clinicians, and organizational leaders recognize that the use of advanced data analytics can improve the quality, safety, outcomes, and cost of both biomedical research and healthcare delivery. However, achieving such a vision of a data-driven ecosystem requires surmounting substantive challenges related to the collection, storage, management, analysis, and dissemination of data assets that are often distributed across multiple systems, locations, and organizational boundaries. In response to this critical need, we have designed and delivered Avec®, a data federation platform that achieves the promise of truly interoperable healthcare data across and between traditional geographic, temporal, policy, and technical boundaries. In this systems demonstration, the creators of Avec® will provide real-world examples of use cases in which Avec® can be used to facilitate hypothesis-generating research, the creation of large-scale patient-focused registries, and the use of data federation technologies to create virtual integrative data repositories at an institutional level.

Introduction
Avec® provides organizations with a scalable, flexible, and resource-efficient solution to their data sharing and integration needs. In doing so, Avec® allows organizations to put their existing data assets and technology investment to work in new and innovative ways—generating demonstrable value, all while addressing critical data security, workflow, and human-computer interaction needs.

Key Platform Characteristics
The ability of the Avec® platform to enable such capabilities reflects a number of characteristics, including:

1. **Lightweight technology deployment**: Requires minimal infrastructure investment, and can be deployed on premise using a virtual appliance model and/or using cloud computing resources;
2. **Scalable distributed query execution**: Scales and evolves gracefully to support constantly changing biomedical big data standards, types, and models in a source data platform independent manner
3. **Compatibility with diverse technology**: Offers proprietary structural mapping compatible with a substantial cross-section of standard vocabularies;
4. **Faster/easier query building**: Enables end users to build and reuse complex queries that are executed in a distributed environment across multiple data sources; and
5. **Robust data security**: Delivers security mechanisms that enable data stewards/owners to maintain control over their data and determine how it is shared and for what purpose, addressing ownership, stewardship, and valuation concerns, as well as comprehensive authentication, access control, and auditing functionality.

Conclusion
Building upon the preceding capabilities, Avec® provides organizations with an efficient, scalable, and trustworthy technology infrastructure that can meet the demands of today’s challenging data security environment and simultaneously create value through enabling data sharing and liquidity.
The All of Us Research Program Researcher Portal:
Innovative access to Unprecedented Data

Andrea H. Ramirez, MD, MS; Anthony A. Philippakis, MD, PhD; Gonçalo Abecasis, PhD; Paul A. Harris, PhD; Joshua C. Denny, MD, MS

1Vanderbilt University Medical Center, Nashville, TN; 2Broad Institute, Cambridge, MA; 3University of Michigan, Ann Arbor, MI

Abstract

The Precision Medicine Initiative All of Us Research Program\(^1\) is a national effort to recruit and engage at least one million participants who consent to provide health information (including data from health surveys, electronic health records, and baseline physical measures), biospecimens, and to be recontactable in the future. The Data and Research Center (DRC) sits at the confluence of all these varied data and, in collaboration with the many All of Us partners, has been creating a framework to shape and support biomedical research in the future. This systems demonstration will present the Researcher Portal developed to bring diverse researchers to the data for hypothesis testing and experimentation in a cloud computing environment. The Researcher Portal integrates single authentication with access to raw data and advanced methodology including notebook based programming and statistics capability, tools to identify participants of interest within the larger group, and innovative data visualization techniques. This demonstration is a key part of efforts to engage world-class researchers including the AMIA community in testing and development of this intentionally dynamic framework.

Description

The All of Us Research Program Researcher Portal serves to fulfill the intent of the Precision Medicine Initiative (PMI) to bring traditional and nontraditional researchers to the wealth of data collected on diverse longitudinal participants. The PMI broadly aims to advance generation of knowledge supporting implementation of both disease treatment and health maintenance strategies aimed at an individual, by gathering an unprecedented depth and scope of data and providing broad access to diverse researchers while maintaining the highest standards of security and privacy. The Researcher Portal will serve as a catalyst to identify areas for improvement in medical research as state of the art informatics tools enable appropriate protection and analytics support so such valuable data may facilitate innovative methodology and solutions to health threats facing our population. The individual components of this system include adaptation of the Broad Institute’s FireCloud platform to enable hosting of Jupyter notebooks with capability for collaboration during a project and supporting efforts at reproducibility with shared documentation. Cohort builder tools querying structured data democratizes access to researchers of various backgrounds and sets a standard for interoperability challenges facing medical research and clinical care. The Researcher Portal will enable hosting of external data for analysis and visualization enabling genotype and phenotype correlations between populations. This platform will be a dynamic tool growing as research uses and needs are identified with active feedback mechanisms and training forums.

Statement

As of March 9, 2017, the Researcher Portal has been conceptualized including policy and architecture framework and testing of individual components and interoperability is underway. Ensuing development will include integration of tools to a unified platform with simulated data ahead of federal Authorization to Operate approval when All of Us participant data will be hosted.

\(^1\)Precision Medicine Initiative, PMI, All of Us, the All of Us logo, and The Future of Health Begins With You are service marks of the U.S. Department of Health and Human Services.
DocUBuild: A Collaborative System to Enhance Dissemination and Discovery of Genomic Clinical Content

Luke V. Rasmussen, MS¹, Casey L. Overby, PhD²,³
¹Northwestern University Feinberg School of Medicine, Chicago, IL; ²Johns Hopkins University, Baltimore, MD; ³Geisinger Health System, Danville, PA

System Description

As genomic medicine programs continue to expand, there is also a growing need to deliver sufficient and high quality information resources to aid patients and healthcare providers in their comprehension and decision-making. As part of the NHGRI-funded electronic Medical Records and Genomics (eMERGE) network (a national consortium developing methods and best practices for using the EHR for genomic medicine and research), we have created the DocUBuild system to support developing and sharing genomic medicine information that is accessible through context-sensitive links in the medical record (“infobuttons”).

A recent survey of sites involved with the eMERGE network and Clinical Sequencing Exploratory Research (CSER) consortium indicated that institutions continue to rely on locally-authored content (synthesized from external resources), and that similar content may need to be delivered as multiple modalities (e.g., printed handout, website, e-mail, printed along with an after visit summary)¹. In addition, some content may require local customizations (e.g., site-specific contact information, institutional branding), which precludes the reuse of existing content by others. While many document management and content management systems exist that allow rich editing and collaborative environments, many challenges to managing genomic information resources have not yet been addressed. A recent survey, for example, found that some genomic medicine resources only support keyword searching and for those that do allow searching, typically only use a single standard terminology (e.g., OMIM)². This highlights an opportunity to increase the amount of relevant metadata associated with individual resources (e.g., the use of other relevant terminologies to enable more robust searching). Furthermore, we believe there is a need to streamline sharing and rebranding of content for use across institutions, and a need to enable quick and easy deployment of content to multiple endpoints.

To address these gaps, we have developed DocUBuild (https://docubuild.fsm.northwestern.edu/) as part of the electronic health record (EHR) integration efforts within the eMERGE network. DocUBuild provides infrastructure to support: a) authoring content using structured templates, b) making content discoverable through the annotation of documents and individual sections with context elements according to the HL7 infobutton standard, c) sharing content and discovering content authored by other institutions, and d) deploying content in multiple formats in order to meet individual needs.

This system demonstration will show how DocUBuild may be used in different content authoring workflows, and how the output of DocUBuild can facilitate information retrieval. A particularly novel aspect to be shown is the ability to quickly and easily annotate an article with infobutton context elements, including the use of structured templates where infobutton context is already applied. Furthermore, we will demonstrate the ability to push or pull information resources to a variety of external systems, including OpenInfobutton⁵, and how this may reduce duplication and burden of keeping content in sync in disparate systems.

Deployment Status

The base DocUBuild system has been made publicly accessible as of the time of submission. Certain features are currently in the development phase and are not yet publicly accessible (OpenInfobutton responder integration), but will be prior to the system demonstration.

Creating a Cluster of Preclinical Science Lessons Using Pharmacogenomic-Focused Patient Case Presentations

Blaine Takesue, MD1,2, Maureen Harrington, PhD1, Bradley Allen, MD, PhD1, Debra Litzelman, MD1,2, Paul Dexter, MD1,2

1Indiana University School of Medicine, Indianapolis, IN; 2Regenstrief Institute, Indianapolis, State, IN

Introduction
Genetic testing and the use of genetic tests results in clinical decision making have become more prevalent over the past decade. Despite these advances, many physicians acknowledge their pharmacogenomic knowledge base is not adequate to take full advantage of genomics-based information in medication ordering.1 To address the gap between the state of the art pharmacogenomics knowledge and provider needs we created patient care vignettes through which students could learn pharmacogenomics principles.

The Indiana University School of Medicine (IUSOM) is home to the INGENIOUS (INdiana GENomics Implementation: an Opportunity for the UnderServed) trial.2 This NIH-funded study is investigating the implementation issues around pharmacogenomics recommendations in an urban hospital. As part of this study, the INGENIOUS team created pharmacogenomics clinical decision support (CDS) rules for the production Regenstrief Gopher computerized provider order entry system (CPOE). The team created 87 rules covering 28 medications and 97 medical problems (Figure 1).

In 2013, the Regenstrief Institute created a teaching electronic health record (tEHR). The tEHR is a branch of the production Regenstrief Gopher CPOE. As opposed to the clinical role of the Gopher, the tEHR is designed to support health professions education. The tEHR is a stand-alone application that uses anonymized, real patient data. The system allows students to provide virtually care for patients in a safe and realistic environment.

We imported the pharmacogenomic CDS rules from the Gopher to the tEHR). In the tEHR, we propose that alerts created by the CDS will prompt discussions of pharmacogenomic principles and the role of informatics in presenting pharmacogenomic data. Extending this model, we plan to use these vignettes to link pharmacogenomic patient cases to topics in biochemistry, genetics, pharmacology, and physiology.

System Demonstration
After discussing the design principles behind pharmacogenomics-focused patient vignettes, we propose to demonstrate a learner’s experience by working through a pharmacogenomics-focused case. In the demonstration, we will show 1) how background case information is delivered through the tEHR, 2) how orders trigger alerts based on the patient’s genomic data and medication selected 3) how educational alerts create opportunities for teaching and learning biochemical, genetic, pharmacologic, and physiologic content.

Relevance/Impact
There is a gap between the pharmacogenomic knowledge base and the knowledge base of many practicing providers. This podium presentation/demonstration will attract educators who are interested in pharmacogenomics training methods for providers early in their professional career. The presentation will also interest those who are contemplating the use of electronic health records and specifically the tEHR, as an instructional tool.

System deployment status
As of the submission date, the Regenstrief tEHR is deployed to 8 health professions colleges/schools.

CLAMP – A User-Centric Clinical Natural Language Processing Toolkit

Hua Xu, PhD, Ergin Soysal, MD, PhD, Jingqi Wang, Min Jiang, Yonghui Wu
School of Biomedical Informatics, University of Texas Health Science Center at Houston, Houston, TX

Abstract
In this demonstration session, we will introduce a new clinical natural language processing (NLP) system called CLAMP (Clinical language annotation, modeling, and processing) to the medical informatics community. Similar to cTAKES and MetaMap, CLAMP is another comprehensive, general-purpose clinical NLP system, representing a significant amount of development effort by the NLP team at UTHealth. The motivation for developing CLAMP is to support non-technical end users to take advantage of the power of the state-of-the-art machine learning/hybrid approaches in clinical NLP, by implementing novel algorithms and designing user-friendly interfaces. CLAMP builds on a set of high performance NLP components that were proven in previous clinical NLP shared tasks such as i2b2, SHARE/CLEF, and SemEVAL challenges. In addition to the default Apache UIMA interfaces for system development, we developed graphical user interfaces that allow end users to easily manage their projects by annotating clinical text and managing clinical corpora, training machine learning modules for different components such as named entity recognition (NER), and building customized pipelines with different components. Currently, CLAMP version 1.0 is being used in both UTHealth and MD Anderson Cancer Center, and it is already downloaded and used by 80 users in more than 30 research institutes.

Motivations for developing CLAMP
Currently, there are many text processing tools specialized to clinical narratives, e.g., MetaMap, cTAKES, etc. Despite the great contribution and success of these existing tools, they generally require certain level of programming skills if a user wants to customize an NLP system for his/her specific tasks. For example, our experience showed that a machine learning-based smoking status detection system needed to be retrained in order to achieve desirable performance in a different institute; however, it requires knowledge and skills on machine learning technologies, which many end users may not have. Therefore, the goal of CLAMP is to enable non-technical users to utilize the state-of-the-art algorithms to build customized NLP systems for their applications.

Features of CLAMP
Highlighted features of CLAMP include:
2. **Annotation and corpora management**: Users can import clinical text corpora into the CLAMP workspace and annotate files using the built-in annotation tool. Then, this annotated corpus can be utilized by CLAMP projects, both for development as train and test data for a model, or in production running with the complete pipeline.
3. **Machine learning and hybrid approaches**: Depending on the task, users can train their own model for machine learning based components. CLAMP serves required functionality to train and evaluate custom models using a custom corpus for that component. Results can be evaluated by n-fold cross validation within CLAMP.
4. **Customized pipelines**: CLAMP offers all common components, like named entity recognition, assertion, and UMLS encoder to build an NLP pipeline. For some tasks, CLAMP may provide variations of a component that may utilize rule based methods, or machine learning algorithms such as Brown clustering, SVM, and CRF.
5. **Knowledge sources and sample clinical text**: All knowledge resources required by CLAMP components – e.g. dictionaries, section header list or medical abbreviation list – are also provided, in addition to a corpus with 400 annotated notes derived from MTSamples. So, user can start to develop and test NLP pipelines, immediately.
6. **Interoperability and Scalability**: CLAMP was built on the UIMA framework, so that it is compatible with other systems such as cTAKES. Moreover, it adopts cTAKES’ type system for lower linguistic level annotations, to increase interoperability. We also plan to develop a Hadoop version of CLAMP in next release to support distributed computing for big datasets.

Current Development Status
Developing general-purpose clinical NLP systems such as MetaMap and cTAKES requires substantial amounts of efforts and resources. Three programmers in our team have worked on CLAMP for almost two years. Prototypes of CLAMP have been used in various projects in UTHealth, as well as MD Anderson Cancer Center since 2013. Now we released CLAMP 1.2.1 to the public, with a specialized version for Cancer. A manuscript of this new tool is in preparation and will be submitted to JAMIA. We believe such a user-centric clinical NLP tool will greatly benefit the end users, thus facilitating clinical research and healthcare practice.
