Welcome Message for the AMIA 2017 Annual Symposium Scientific Program Committee Chair

On behalf of the Vice Chairs and the Scientific Program Committee, I am delighted to present these proceedings of the AMIA 2017 Annual Symposium!

No single meeting captures the breadth and depth of informatics better than the AMIA Annual Symposium. Since the first convening of this meeting, more than forty years ago, the use of informatics has grown exponentially to improve health and to make better healthcare decisions. Today, informatics is the key to accelerating the current goals of healthcare reform.

We received a record number of submissions this year, and I am duly impressed by the high quality of work selected for these proceedings that reflect the breadth of topics across the five domains of informatics: translational bioinformatics, clinical research informatics, clinical informatics, consumer health informatics, and public health informatics.

While it is impossible to fully convey the excitement and energy of the in-person events and presentations of the meeting, these proceedings reflect the core scientific content that were essential for the success of AMIA 2017. These proceedings therefore reflect the continuation of AMIA meetings past, and the beginnings of future discussions of how informatics can truly impact health and health care.

Enjoy!

Neil Sarkar, PhD, MLIS, FACMI
Chair, 2017 Scientific Program Committee
Brown University
2017 AMIA Board of Directors

Officers

Thomas H. Payne, MD, FACMI
University of Washington
Chair

Peter J. Embi, MD, MS, FACMI
Regenstrief Institute
Chair-elect

Titus K. Schleyer, DMD, PhD, FACMI
Regenstrief Institute/Indiana University School of Medicine
Treasurer

Eneida A Mendonça, MD, PhD, FACMI, FAAP
University of Wisconsin – Madison
Secretary

Directors

Tiffany J. Bright, PhD
Agency for Healthcare Research and Quality

Wendy W. Chapman, PhD, FACMI
University of Utah

Sarah A. Collins, RN, PhD
Partners Healthcare System/Brigham and Women’s Hospital/Harvard Medical School

Theresa Cullen, MD, MS
Veterans Health Administration

Paul Fu, Jr., MD, MPH, FAAP
Los Angeles County Harbor-UCLA Medical Center/University of California, Los Angeles

Cynthia S. Gadd, PhD, FACMI
Vanderbilt University

Gretchen Purcell Jackson, MD, PhD
Vanderbilt University Medical Center

Wanda Pratt, PhD, FACMI
University of Washington
Neil Sarkar, PhD, FACMI
Brown University

Dean F. Sittig, PhD, FACMI, FHIMSS
University of Texas Health Sciences Center at Houston

Jessica Tenenbaum, PhD
Duke Translational Medicine Institute

Adam Wright, PhD
Brigham and Women’s Hospital/Harvard Medical School

Ex-Officio Board Members

Christopher G. Chute, MD, DrPH
American College of Medical Informatics President
Johns Hopkins University

Douglas B. Fridsma, MD, PhD, FACP, FACMI
President and Chief Executive Officer
AMIA

Karen A. Monsen, PhD, RN, FAAN
Academic Forum Executive Committee Chair
University of Minnesota School of Nursing

Michael Weiner, DO
Industry Advisory Council Chair
IBM

Laura K. Wiley, PhD
Student Working Group Representative
University of Colorado
AMIA 2017 Annual Symposium Scientific Program Committee

Chair
Neil Sarkar, PhD, MLIS, FACMI
Brown University

Vice Chairs
Jessica Ancker, PhD, MPH, FACMI
Weill Cornell Medical College

Brian Dixon, MPA, PhD

NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publishers of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they are not responsible for any errors or omissions or for the results obtained from use of such information. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this book is accurate and that changes have not been made in recommended dose or in the contraindication for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.
Enabling Interoperability between Healthcare Devices and EHR Systems

Swapna Abhyankar, MD1, Paul Schluter, PhD2, Kathryn Bennett3, Daniel J. Vreeman, PT, DPT, MS1,4, Clement J. McDonald, MD5

1Regenstrief Institute, Inc, Indianapolis, IN; 2GE Healthcare, Milwaukee, WI; 3IEEE, New York, NY; 4Indiana University School of Medicine, Indianapolis, IN; 5National Library of Medicine, National Institutes of Health, Bethesda, Maryland

Introduction

State-of-the-art healthcare devices are used across healthcare settings and produce an enormous amount of patient data. However, despite the advances in technology and the growing adoption of electronic health record systems (EHRs) in both inpatient and outpatient settings,1 most devices do not communicate with EHRs in a meaningful way. The problem is twofold: 1) device manufacturers use local, often proprietary codes to represent each measurement, so in order for an EHR to interpret device data, the local codes must be mapped to a language that the EHR understands; and 2) every manufacturer or device has its own set of local codes, so a separate map is needed for each device. Most healthcare institutions do not have the resources to create these maps, so the data are lost.

The IEEE Standards Association (IEEE-SA) and Regenstrief Institute, Inc. (RI), are working together to bridge the gap between healthcare devices and EHRs. IEEE-SA is a global standardization body within IEEE that is dedicated to creating consensus-based technology standards,2 including the IEEE device nomenclature, a unified, consensus-based terminology across device manufacturers. RI maintains the Logical Observation Identifiers Names and Codes (LOINC®) terminology, an international standard for health measurements, observations, and documents that is widely used in EHRs and adopted as a national standard in over 25 countries, including the United States.3 Mapping IEEE device nomenclature to LOINC will enable the flow of data from healthcare devices to EHRs and data repositories for use in patient care and research, with the ultimate goal of improving patient outcomes.

Methods

In 2015, RI and IEEE-SA signed a Memorandum of Understanding (MOU) to enable creation of a map between LOINC and the IEEE 11073™ family of standards for medical device communication. We began the mapping effort with the IEEE 11073-10101™ Standard for Health informatics - Point-of-care medical device communication – Nomenclature (“11073-10101”),4 followed by the 11073 10101a™ Nomenclature amendment (“11073-10101a”).5 We specifically included the concepts contained in the harmonized Rosetta (hRTM) content available in the National Institute of Standards and Technology (NIST) Rosetta Terminology Mapping Management System (RTMMS).6

The primary mapping work has been done by RI using: 1) the IEEE 11073 published standard, which includes the systematic name, reference ID, and description for each code; 2) an export of the associated content from NIST RTMMS, including additional vendor-specific descriptions and applicable units of measure; and 3) the LOINC database, which contains the information that defines each LOINC term, as well as relevant metadata.

For each IEEE 11073 concept, we examined all of the available information, and if a matching LOINC concept was found, a map was created between the existing codes. In cases where no appropriate LOINC concept was available but the meaning of the IEEE 11073 concept was clear, a new LOINC term was created. Finally, if the 11073 concept was not entirely clear to the RI team based on the available published resources, we sought input from members of the HL7 Health Care Devices (DEV) Working Group and IEEE 11073 Point of Care Devices (PoCD) Workgroup before mapping.

Results

The first mapping was published with LOINC version 2.54 (December 2015) and was available both as searchable content in the publicly-available LOINC database and as the standalone LOINC/IEEE Medical Device Code Mapping Table file at http://www.loinc.org/downloads. The table contained mappings for variables produced by ventilators, anesthesia gas machines, invasive blood pressure monitoring, and EKG devices. The mapping table includes the LOINC code and Long Common Name, and the IEEE 11073 Nomenclature Reference ID, numeric code (CF_CODE10), dimensionality (DIM), Unified code for units of measure (UCUM) units of measure (UOM), and description (when available). The mapping file was also published in RTMMS.
The initial IEEE 11073 Nomenclature to LOINC mapping included 358 mappings between 348 unique LOINC concepts and 355 out of the 418 active concepts (84.9%) in 11073-10101 that were part of hRTM. Most mappings were 1:1, but in a few cases one IEEE concept was mapped to multiple LOINCs and vice versa. For example, if the DIM of an IEEE concept encompassed more than one LOINC Property, e.g., mass concentration and molar concentration, one IEEE concept was mapped to two LOINC codes, each in a separate row with the appropriate IEEE DIM and UOM specified for each row of the mapping table as shown in Table 1.

Table 1. Example of multiple LOINC codes mapped to a single IEEE Reference ID based on units of measure

<table>
<thead>
<tr>
<th>LOINC code</th>
<th>LOINC Long Common Name</th>
<th>IEEE CF_CODE10</th>
<th>IEEE Reference ID</th>
<th>IEEE DIM</th>
<th>IEEE UOM_UCUM</th>
</tr>
</thead>
<tbody>
<tr>
<td>75928-2</td>
<td>Hemoglobin [Moles/volume] in Arterial blood</td>
<td>CF_CODE10</td>
<td>MDC_CONC_HB_ART</td>
<td>NL-3</td>
<td>mmol/L</td>
</tr>
<tr>
<td>30313-1</td>
<td>Hemoglobin [Mass/volume] in Arterial blood</td>
<td>159764</td>
<td>MDC_CONC_HB_ART</td>
<td>ML-3</td>
<td>g/dL, g/L, g/cL</td>
</tr>
</tbody>
</table>

As we add new LOINC content, both based on IEEE 11073 concepts and requests for LOINC terms independent of this work, we continue to expand the mapping table. New versions are published with each twice-yearly LOINC release as well as added to RTMMS. The mapping file in the December 2016 LOINC release contained 590 rows with 568 unique LOINC concepts mapped to 578 unique IEEE concepts. These 578 concepts represent more than 70% of the approximately 800 active concepts in the combined 11073-10101 and -10101a standards that are included in hRTM and represent expanded coverage of concepts related to anesthesia and physiologic monitoring.

**Discussion**

RI and IEEE have created a mapping that bridges the gap between healthcare devices and EHRs. This map allows information from a variety of devices to flow into and integrate with a patient’s EHR record in a way so that the data are interpretable, actionable, and accessible for research. This is a work in progress, and more than 100 new mappings based on new and existing LOINC terms will be in the June 2017 LOINC release, including content related to ventilator management and personal healthcare devices. We are prioritizing the concepts that are defined clearly and are clinically most important, and some of the IEEE 11073 Nomenclature content, such as device modes, settings, alerts, and alarm triggers, may not need mapping. Future work includes mapping content contained in 10101 amendments in process, including neuromuscular and infusion pump domains.

**Conclusion**

The LOINC/IEEE 11073 mappings provide a path for information to flow from healthcare devices to EHRs.

Applying a Process-based Framework to examine Interunit Patient Transfers

Joanna Abraham, PhD, Shirley Burton, MPH, Imade Ihianle, MD MPH
University of Illinois at Chicago, Chicago, IL

Introduction
Interunit hospital transfers involve the transfer of patients between clinicians from the sending and receiving units [1, 2]. Approximately on average, 29 million patients in the US are transferred per year from the emergency department (ED) to inpatient clinical units [3] for diagnostic and therapeutic care services. Despite its role in addressing care delivery and management needs [4], the underlying interunit transfer process can be complex and prone to bottlenecks [5, 6], with a detrimental impact on care continuity outcomes [2, 5, 7, 8]. Fragmented interunit transfers have been reported to result in patient non-colocalization (i.e., placing patients in inappropriate beds) [1], inappropriate use of hospital resources, increased length of inpatient stay, patient decompensation leading to emergent transfers to higher-level of care [9], and propagation of a sense of confusion and stress on patients and their families [8]. Several studies on interunit patient transfers have been conducted between emergency and inpatient units [9], between critical care units [10] and between nursing units [8]. The complex nature of interunit transfers can best be characterized by the reported barriers mainly related to communication gaps [7, 9], negotiation failures [3] and care coordination bottlenecks [8] between the units. Although strategies such as the use of standardized protocols [11], incorporation of negotiation skill-based staff training, implementation of inter-service rounds [3] and cross-boundary integrators/mediators for patient transfer coordination [12] have been proposed, we found that interunit transfers continue to pose a threat to patient safety. This can partly be attributed to the fact that these strategies, although useful, serve to work-around the unit-based challenges, without addressing their downstream effects on the rest of the process across the unit boundaries. In order to develop evidence-based guidelines for designing sustainable interunit transfer strategies, we need to gain an in-depth understanding of the entire patient transfer workflow and also identify points of vulnerabilities in the process. To address this, we conducted a multi-site qualitative study of ED-MICU (emergency department to medical intensive care unit) transfer process conducted by residents to examine factors affecting the process and also potential strategies used to address them.

Method
We observed ED-MICU patient transfers at two hospital sites caring for inner-city urban patient population in Illinois. We selected these sites primarily for their varying patient populations and their organizational differences, which may have an impact on the transfer process. Site 1 is a 495-bed acute care hospital and Site 2 is a 210 bed, tertiary care facility for veteran patient population. Care delivery and management activities were handled similarly at both sites by patient care teams. Our primary participants in this study included resident physicians from the ED and MICU at both hospitals. The study was approved by the IRB at both sites and all participants provided written consents for the study. Our data collection was primarily through participant observations of patient transfer activities in the ED and MICU over a 7-month period (500hrs at both sites), followed by semi-structured interviews with residents (n=21- site 1: ED=5; MICU=5; site 2: ED=5 MICU=6). We used the grounded theory analytical approach to code our observational data on ED-MICU transfers and the interview data analysis was informed by the pre-defined codes from the open codes.

Results and Discussion
Using a process-based framework [13], we scoped and characterized the ED-MICU patient transfer process into three phases: pre-transfer (i.e., focused on ED preparatory coordination activities), transfer (i.e., focused on ED-MICU handoffs) and post-transfer (i.e., focused on MICU care management activities). We identified that the inherent activities within and across these phases were interdependent and effective management of interdependencies between the phases led to timely procurement of needed resources, prevention of unnecessary duplicate tests and procedures, patient assignment to appropriate
units, improvements in patient and clinician satisfaction, and also overall care continuity across the ED-MICU care continuum. We also observed that these ED-MICU interdependencies were successfully managed only when there was a seamless and effective transfer of information, responsibility and control from the ED resident to the MICU resident. Interview and observations suggested that the root contributors affecting the transfer of information were primarily related to the use of the telephone medium for verbal communication between the ED and MICU residents and the lack of a standardized handoff template for patient transfer communication and documentation at both hospital sites.

Nevertheless the transfer of responsibility and control, with respect to accountability and authority slightly varied across the sites and was impacted by transfer delays (resulting in ED boarding of MICU patients) due to the lack of available MICU beds.

**Conclusion**

Study findings can have implications for the design and implementation of: (1) structured face-to-face communication, supported by standardized care coordination bridging interventions; (2) process changes related to ED boarding policies and incentive programs for clinician accountability.

Medical Benefit Drug Claims: Assessing the NDC Documentation Gap
Terrence J Adam, RPh, MD, PhD, Bithia Anderson, PharmD, MPA, Angeline Carlson, PhD, Mahsa Salsabili, PharmD, Glenn Trygstad, MS, Stephen Schondelmeyer, PharmD, PhD.
1. Univ. of Minnesota College of Pharmacy, Minneapolis, MN. 2. Data IQ, Eden Prairie, MN. USA

Introduction: Prescription drugs are typically covered as part of a pharmacy benefit and may be obtained at retail and other pharmacy settings such as community, long term care, mail order, specialty, and clinic pharmacies. In growing frequency, consumers are administered prescription drugs in a range of health care settings such as physicians’ offices, hospital outpatient clinics, emergency departments, urgent care facilities, dialysis clinics, outpatient surgery centers, home health providers, or home infusion centers. These locations administer prescription drugs and related services—generally as a single dose of a drug while the patient is in the office—typically through an insured medical benefit (medical benefit drug claims).

Medical benefit drug claims data is not as easily accessible as traditional pharmacy claims, and key differences exist in how prescription claims are adjudicated under pharmacy benefits as compared with medical benefits. In addition, prescription drug utilization and spending in these non-traditional settings has been increasing substantially. As a result, market reports which typically focus exclusively on the retail pharmacy sector present an incomplete picture and limits our understanding of prescription drug information. This raises issues for health policy, the management of prescription drug spending, and the appropriate use of and accountability for drug therapies as well as the capacity to build a learning health system. In addition, the structured data which is used to identify medication use varies by the setting in which it is delivered. National Drug Codes (NDC) provide the primary data representation for medications in the traditional pharmacy setting with the classification code based on medication labeler (manufacturer or distributor), the product code (identifying the medication strength, dosage and formulation) and package code (package size and type). The codes are defined based on the labeler and Food and Drug Administration assignments. For medical benefit drug claims, the coding for reimbursement utilizes Healthcare Common Procedure Coding System (HCPCS) codes to identify the medication provided to patients which may include Current Procedural Terminology (CPT) codes. Understanding the relationship between NDC and HCPCS codes is a critical unmet need for secondary data analysis of medications.

Methods: Expert review of available sources of medication data was completed using public use and proprietary data sources including the Center for Medicare and Medicaid Services public use HCPCS files, Medi-Span HCPCS Codes Database, Release (9/2015), Medi-Span Price Rx Pro® Release (9/2015, Micromedex, the Minnesota All Payer Claims Database (MN APCD) and expert knowledge (physician and pharmacist experts). Medications, medication administration, medication testing, diagnostic pharmaceuticals and pharmacogenomics testing related services were identified along with their corresponding HCPCS. An iterative development approach was used to develop a final terminology crosswalk file including HCPCS codes, medication class data (Medi-Span generic product identifier) and NDC codes. After developing the medication list, it was then used to identify medication use and associated reimbursement using HCPCS codes in the MN APCD database for validation. In addition, the total cost associated with medical benefit drug claims was also evaluated to identify the approximate healthcare cost burden associated with these medications as compared with traditional pharmacy medications.

Data Source: The Minnesota All Payer Claims Database from the years 2009 to 2013 was used to identify medical benefit drug claims representing over 4 million unique individuals from the state of Minnesota receiving medical care and medication therapy. Data analysis was completed using SAS 9.2 along with Microsoft Excel for data summarization.

Results: The comprehensive HCPCS medication list identified 2175 unique HCPCS codes associated with medical benefit drug claims. In attempting to map the HCPCS codes to NDC codes using database methods, manual review and expert consensus, a total of 2075 of the eligible HCPCS codes were linked to an NDC code with 100 HCPCS lacking an identifiable NDC mapping (4.6% of eligible HCPCS). However, a number of the HCPCS had overlapping mappings to the same NDC, resulting in a one (NDC) to many (HCPCS) relationship for many medications. As a result, a total of 1044 unique NDCs were included in the crosswalk including 1031 instances with multiple HCPCS codes mapping to a single NDC. To evaluate the validity of the medication HCPCS list, the code list was queried against the MN APCD database identifying a total of 1912 of the HCPCS codes which had one or more medical claim instances over the 5 year observation time period or 87.9% of the eligible HCPCS codes.
**Cost Evaluation:** Since the relative numbers of medication codes used with medical benefit drug claims are substantially smaller than for traditional NDCs, the overall medical benefit drug claims and costs were evaluated for their health system relevance. For the last year of the data set (2013), there were 62.1 million traditional pharmacy claims and 14.6 million medical benefit drug claims, representing 19% of total medication claims by volume. For the same year, the cost of traditional pharmacy claims was $4.74 billion and for medical benefit drug claims, the cost was $2.64 billion or 35.8% of medication spending, indicating the medical benefit drug claims had a substantial cost burden and were a large proportion of total medication cost.

**Discussion:** The use of HCPCS provides a means to facilitate reimbursement for medications, but is also creates a substantial problem for secondary data use and quality measures due to insufficient specificity for several classes of medical benefit drug claims. The use of HCPCS for medications also creates a data granularity problem, which is a major concern since the codes may not fit well with the actual drug packaging or typical dosing regimens. The development of higher HCPCS data granularity to better specify dosing related information could enhance data quality. However, the one (NDC) to many (HCPCS) problem occurs, in some instances, as a result of the effort to make the HCPCS function for a variety of dosages which may be used in clinical practice. Further analysis of these instances may help provide insight on potential coding granularity enhancements, which could facilitate better alignment with NDC coding and improve interoperability across the coding systems.

Several HCPCS use the “not otherwise specified”, “not otherwise classified”, or “other” subclasses for certain medications. While providing a coded component for reimbursement, these subclasses fail to provide specific insight on the actual medications utilized. In attempting to find a solution to the low granularity of the HCPCS and to help manage secondary data use, all HCPCS codes were reviewed and linked in a cross-walk file to NDC codes. However, many of the HCPCS did not have a corresponding NDC due to the inclusive nature of the HCPCS coding selection process, which included medication HCPCS codes related to drug administration and drug testing. Outside these “nondrug” elements, which would be expected to have a low propensity to match to NDCs, the ambiguity of the HCPCS code system was a bigger problem. The vast majority of the actual medications likely have an NDC code which could be linked, however, the NDC data was not universally present at the point of claim creation. As a result, the inherent HCPCS ambiguity prevented these medications from being readily linkable retrospectively to other drug information sources even after extensive expert review.

A plausible solution to this linkage problem is the concurrent requirement of NDCs for reimbursement and secondary data set development; however, NDCs may be insufficient by themselves to provide adequate documentation for medical benefit drug claims. The inclusion of additional fields including the quantity dispensed, the quantity administered and the units of measure are needed to complete the documentation of the drug use pathway. The gaps in potential linkage between HCPCS and NDCs are substantial with drug analytic testing, medication administration, and medications used in diagnostics since these medication process components are not generally included in traditional pharmacy practice. Greater granularity of the HCPCS coding or inclusion of other terminologies such as Logical Observation Identifiers Names and Codes (LOINC) may be potential solutions to improve data representation. However, the use of LOINC would create greater complexity in managing comprehensive secondary medication data representation by adding another terminology not typically used for the medication data management process. Potential HCPCS enhancements could focus on aligning the code granularities to actual medication usage patterns which could provide interim improvement in data representation.

Major limitations of medical drug claims data include the lack of direct links in the reimbursement data between the HCPCS and the associated drug NDC, limited drug quantity dispensed/administered data and insufficient units of measure creating major secondary data use problems. These relationships likely exist for most all clinical scenarios, but it was not a vendor requirement in the claims data reporting and potentially may be missing in the payer reimbursement process. The inclusion of these fields is needed for future work to adequately facilitate secondary data use for research, quality improvement and policy evaluation. In addition, for medication-related medical benefit drug claims, the components related to drug administration, testing, and management also need to be evaluated concurrently with the actual drugs to provide a full picture of the medication use process. Given the large component of health cost and clinical utilization volume associated medical benefit drug claims; this component of the medication use cycle needs better data representation for secondary data applications and health policy.

Advanced Use of EHRs in US Hospitals and the Emergence of a Digital "Use" Divide

Julia Adler-Milstein, PhD¹ and A Jay Holmgren, MHI¹
¹University of Michigan, School of Information and School of Public Health, Ann Arbor, Michigan

Introduction

Over the past five years, hospital EHR adoption has become widespread.¹ However, we know little about whether hospitals are using EHRs in advanced ways that are critical to realizing improved patient outcomes. There is concern that while hospitals with fewer resources – small, rural, safety-net² – have largely kept up with EHR adoption¹, they are falling behind in advanced EHR use. In this study, we sought to measure advanced ways in which hospitals use EHRs and to assess evidence of an emerging digital “use” divide.

Methods

We used national hospital data from the 2008 to 2015 AHA Annual and IT Supplement surveys. We first measured adoption rates of “basic” and “comprehensive” EHRs to provide the latest national numbers. We then used newly available questions on the 2015 Supplement to assess hospital use of EHRs and EHR data for (1) ten quality improvement functions and (2) ten patient engagement functions. To assess the potential for a digital “use” divide, we ran logistic regression models to identify hospital characteristics associated with (1) eight or more quality improvement (QI) functions and (2) eight or more patient engagement functions. Analyses were limited to general medical-surgical acute care hospitals in the United States that responded to the 2015 AHA IT Supplement (N=2,803). We used non-response weights to generate nationally representative estimates.

Results

80.5% of hospitals had adopted at least a basic EHR system in 2015, an increase of 5.2 percentage points from 2014.

The most common EHR-supported QI functions were monitoring patient safety (71.4% of hospitals) and creating dashboards of individual provider performance using EHR data (68.1%). (Table 1) The least common function was creating an approach for clinicians to query data (39.8%). Hospitals more likely to have 8 or more EHR-enabled QI functions if they participated in an ACO (OR=1.55; p<0.001), PCMH (OR=1.67; p<0.001), or both (OR=3.06; p<0.001). For-profit hospitals as well as critical access hospitals were less likely to have 8 or more functions adopted (OR=0.33 and 0.58, respectively; p<0.001).

The most common EHR-supported patient engagement functions were patient ability to view data online (95.1% of hospitals) and downloading that information (86.8%). (Table 1) The least common function was submitting patient-generated data (36.7%). Large hospitals (OR=1.97; p<0.001) as well as those participating in an ACO (OR=1.80; p<0.001), PCMH (OR=3.05; p<0.001) or both (OR=3.12; p<0.001) were more likely to have 8 or more functions. Safety-net hospitals (those in the 3rd and 4th quartiles of DSH payments; OR=0.71 and 0.43; p<0.002 and p=0.001, respectively; and critical access hospitals; OR=0.68; p=0.02) and public hospitals (OR=0.59; p<0.001) were less likely to have 8 or more functions.

Continued on next page
Hospital EHR adoption is widespread and many hospitals are using EHRs to support QI and patient engagement. However, this is not happening across all hospitals. Participation in payment reforms was associated with broad engagement in both QI and patient engagement functions while critical access hospitals were less likely to be broadly engaged in either domain. This is concerning because EHR use for QI and patient engagement is essential to improving hospital performance. Our results suggest that policy efforts are impacting adoption of these functions. Patient engagement functions included in the meaningful use program were among the most widely adopted functions, and participation in reform programs was associated with greater likelihood of adoption of both QI and patient engagement functions. Policymakers therefore have a set of levers – both direct funding for health IT and indirect incentives through promoting value-based payment and delivery models – that they can continue to use to drive greater adoption. Policymakers may need to consider specific actions to target safety net hospitals, which could include funding as well as technical assistance with implementation.

Brief abstract
Chronic obstructive pulmonary disease (COPD) is associated with poor quality of life, hospitalization and mortality. The clinical phenotype of COPD is diagnosed by the finding of significant airflow obstruction on pulmonary function tests using Forced expiratory volume in one second (FEV1). FEV1 values are often difficult to identify in structured electronic health record (EHR) data. We developed an automated tool to improve ascertainment of FEV1 in EHR in the Veterans Aging Cohort Study (VACS).

Introduction
Forced expiratory volume in one second (FEV1) is a measure chronic obstructive pulmonary disease (COPD) severity that is routinely included in pulmonary function tests (PFTs) and is associated with decreased quality of life and increased risk for hospitalizations and mortality.1, 2 PFTs are frequently performed on vendor equipment that may not be linked to the primary electronic health record (EHR) for patients who undergo these studies. Unreliable linkage to the EHR makes recovery of PFT values such as FEV1 challenging for health services researchers. Further, these barriers to accessing PFT results hinder our ability to assess pulmonary function on the scale necessary to develop standard phenotypes of lung diseases outside of dedicated observational studies and clinical trials. Phenotyping physiologic lung function based upon direct measurement of trajectories of FEV1 is important for patients, clinicians and researchers to advance our understanding of the clinical burden of COPD as well as other lung diseases and to inform genetic discovery.

In the Veterans Affairs (VA) EHR, PFTs can be identified using Common Procedure Terminology (CPT) codes, entries into the Corporate Data Warehouse (CDW) files, scanned documents in the EHR, transcriptions into progress notes or through combinations of these approaches. CPT codes do not include quantifiable measurements from PFTs such as FEV1. While some VA PFT equipment directly uploads structured FEV1 measurements into the CDW (the VA central research data warehouse), software requirements prevent most sites from contributing FEV1 measurements to the CDW. To fill this gap, automatic tools can be used to identify FEV1 in the EHR but are not necessarily integrated in real time to be relevant to clinical setting.3 These tools can identify FEV1 values within structured or unstructured data and must be tailored to individual EHR systems. Development of clinically meaningful phenotypes for patients with COPD depends on developing an accurate approach to extracting FEV1 measurements from these different sources of EHR data. We developed and adapted an FEV1 extraction method for this purpose.
Methods
Using data from a nationally representative cohort of HIV-infected and uninfected Veterans (Veterans Aging Cohort Study [VACS]; 1996-2015), we identified patients who had PFTs within the VA system using relevant CPT codes (94010, 94150, 94060, 94726-9; 93720-93722, 94240, 94260, 94350, 94360, 94370, 94720, 94725). To extract FEV1 measurements, we then collected progress notes, which are stored as Text Integration Utilities (TIU) documents, in the CDW. TIU documents for these patients were processed in a structured query language (SQL) database (Microsoft SQL Server) supporting full-text (keyword) search. We processed TIU documents by developing an SQL-based algorithm for automated extraction of FEV1 entities (FEV-1, FEV1, FEV_1; negation for “fever”) and FEV1 values within 20 characters of the FEV1 entity from the TIU documents. We developed an SQL procedure to perform a full-text search to identify documents containing the keywords of “FEV1” or “FEV-1” or with spaces were retrieved. We also included keywords to determine if the FEV1 was measured following administration of bronchodilator medications. Within text identified by the full-text search, we then extracted numeric values within a plausible range and in a format consistent with the reporting of FEV1 values.

To evaluate the performance of this process, we generated a reference standard from a random subset of TIU documents that were identified as having more than one FEV1 entity in the text; a pulmonologist reviewed 128/250 (51%) of records with multiple FEV1 entities. The pulmonologist determined the presence of an FEV1 measurement closest to the date of the progress note reviewed and recorded that value. We compared results from the SQL tool FEV1 value extracted with CDW data for FEV1 to determine whether the SQL tool added substantially to the number of unique FEV1 measurements extracted.

Results
Using the SQL tool among patients identified using CPT codes, an FEV1 measurement was identified in 18,183 TIU documents among 5,958 unique patients. Compared with CDW data with quantifiable FEV1, the SQL tool identified an additional 3,849 patients with numeric values for FEV1 that can be used for phenotyping this population. Of note, these FEV1 values were otherwise unavailable for analyses.

In our reference standard subset (n=128 documents, 117 unique patients), the SQL tool had a positive predictive value of 89% for identifying records containing quantifiable FEV1 values. Extraction of these values yielded a correctly identified FEV1 measurement in 77% of cases with fair-good agreement (Cohen’s kappa=0.66; 95% confidence interval: 0.47-0.74). Cases where both reviewer and the tool identified quantifiable FEV1 values had excellent agreement (Spearman’s coefficient=0.99).

Conclusion
This demonstrates that FEV1 values can be extracted using SQL queries with excellent ascertainment and good accuracy from unstructured text-based documents generated by the VA EHR and increases the yield for the number of complete FEV1 values when added to structured data sources from CDW. Next steps will include characterization of data sources for patients who have CPT codes for PFTs but whose EHR does not includes FEV1 measurements. Future work is needed to further develop the phenotype, apply these rules to other VA populations, and refine/test the SQL tool for FEV1 extraction and ascertainment outside of the VA EHR.

Why predicting postprandial glucose using self-monitoring data is difficult

Introduction

Type 2 diabetes (T2DM) is a common and deadly disease if not treated to minimize its effects; it is costly ($245 billion a year in 2012) and prevalent, affecting over 8% of the US population [1]. While T2DM is a very complex disease, the treatment goal of T2DM is relatively simple: reduce hemoglobin A1c (HbA1c) below 6.0-6.5%. However, HbA1c is a slow moving laboratory variable that is roughly the sum effect of the previous three months of glucose dynamics—HbA1c is linearly related to mean glucose over the previous three months—but the current, quickly changing glucose levels must be reduced in order to reduce the slowly evolving HbA1c. The most typical approaches to reducing and stabilizing daily blood glucose levels is through medication and self-management. Typical self-management activities include introducing regular exercise, and altering one’s diet, among several others. For each of these activities, it is important for individuals to anticipate their impact on their blood glucose levels. For example, to make informed nutritional choices, individuals need an ability to anticipate the impact of different meals on their blood glucose. While there exist general guidelines for healthy eating in diabetes, due to the high individual differences in glycemic response to nutrition, each individual needs to make their own informed choices in regards to their meals based on their ability to anticipate the impact. However, previous research showed that making such predictions is challenging for both individuals with diabetes and their healthcare providers [2], [3]. In this research, we investigate novel computational modeling techniques for generating accurate real-time blood glucose forecasts for individuals with diabetes using data assimilation and machine learning approaches. This abstract focuses on reasons why forecasting postprandial glucose is difficult in general and is made more difficult by the presence of T2DM. By leveraging the source of the errors incurred by computational models when forecasting postprandial glucose, we will better understand why it is so difficult for individuals with T2DM to translate general nutrition guidelines into productive meal choices. Finally, we discuss what we believe will be the most accurate glucose forecasting methodology in the future.

Methods

We use nutrition and blood glucose data previously collected by individuals who participated in several ongoing T2DM intervention studies; two individuals included among our data do not have T2DM and have continuous glucose monitor data. The data were collected using a mobile application and constrained to realistic T2DM outpatient data collection, including sparse finger prick glucose measurements before and after meals and pictures of meals whose nutrition content was estimated by trained nutritionists. We use two forecasting engines to predict postprandial glucose. First we use a dynamic Gaussian process regression [7] on moving windows of various lengths of previous meals to train and forecast glucose. Second we use several data assimilation (DA) machines to integrate data with mechanistic models, including a dual unscented Kalman filter (UKF) [6] and other inverse-problem Bayesian methods [3]. The DAs rely on the ultradian endocrine model [4], can take blood glucose, insulin, and carbohydrates as input, and have 30 other physiologic parameters. Using the patient data and the computational engines, we generate personalized, real-time nutrition-based post-meal glucose forecasts. Mean squared error (MSE) of the model forecast compared to measurements is used to evaluate forecast errors [7].

Results

All of the forecasting engines personalized and converged to the individual patients with varying forecast accuracy. The DAs that simulate the endocrine system compare well with continuous glucose monitor data even when trained on sparse finger-prick data. The continuous DA output and the continuous glucose monitor data reveal the first reason why glycemic impact is difficult to predict: glucose oscillates between 60-160 mg/dl over the course of quarter hours and therefore the glycemic impact of a meal may be difficult to understand from a single random postprandial glucose measurement. Further complicating the situation, blood glucose forecasting error for some of the forecasting engines (e.g., the Gaussian process model) increases linearly with mean glucose statistically significantly (p=0.02). Moreover, there is sensitivity to the length of history used to estimate parameters for the forecasting engines.

Conclusion

The forecasting engines are able to forecast postprandial glucose measurements with varying success; DA based methods were the most accurate. Nevertheless, despite accurate pointwise postprandial glucose forecasts, a single postprandial glucose forecast or measurement may not accurately represent the glycemic impact of the nutrition choice because of the complexity of glucose dynamics. This explains the difficulty of generating such predictions for individuals with diabetes, even after reviewing their records collected with self-monitoring. Moreover, uncertainty of postprandial glucose forecasts increase with severity of T2DM, as...
characterized by mean blood glucose levels. Sensitivity to the length of history used to forecast postprandial glucose further complicates the forecasting task of individuals with T2DM. It is likely that an understanding of glycemic impact of nutrition choices will require computational help.

Figure 1 The finger-prick and continuous blood glucose measurements and the data assimilation based continuous and on-measurement blood glucose forecasts for days X-Y for the ultradian model. As more measurements are accumulated, the data assimilator adjusts the parameters given the individual’s data allowing for personalization.

Figure 2 Mean squared error between glucose forecasts and measurements for the dynamic Gaussian process model with varying training history length. Individuals P1 and P2 have T2DM while individuals P3 and P4 do not have T2DM. The linear relationship between $\text{HbA1c}$ and forecasting error is increasing (1000) and statistically significant (p=0.02).
Introduction

As healthcare systems have shifted from paper-based documentation to Electronic Health Record (EHR) systems, issues with timely documentation and the burden of documentation on providers have developed. A 2011 American Medical Informatics Association (AMIA) Policy Meeting report identified challenges to fully realizing the potential benefits of EHRs as described by the National Academy of Medicine, including “identifying how electronic documentation of key data can best be integrated into clinical workflow” and “clarifying the roles of care team members, including the patient, in creating and accessing the electronic record”. As a result, healthcare systems have invested in information technology tools that support both providers and other clinician documentation, including specifically nursing documentation but the patient’s role in documentation remains limited in most cases. The goal of this study was to evaluate the effects of an innovative pain management interactive patient care (IPC) tool supporting automatic patient/parent pain documentation in the EHR and automated nurse notification and its effect on nursing pain reassessment documentation rates in an inpatient pediatric hospital.

Methods

The interactive pain management interface implemented at the University of Minnesota Masonic Children’s Hospital is designed to allow for bidirectional communication between the television-based IPC tool, the EHR, the medication dispensing system, and the nursing call system (Figure 1). The medication dispensing system triggers a time-based patient pain rating scale after a medication is dispensed. When patients or parents respond, the system then triggers the nurse’s phone to serve as a reminder to perform a hands-on pain reassessment and documentation.

This study involved a retrospective analysis of inpatient records covering an eleven-month period post interface implementation from January to November 2015. Inpatient records with at least one narcotic medication administered from a formulary developed by the hospital’s pharmacy team for setting the automatic triggers were included and extracted from the University of Minnesota research Clinical Data Repository. Also included in the extracted dataset were values from 14 unique flowsheet rows, representing nursing pain reassessment documentation observations, as well as values from one unique flowsheet row, representing patient/parent pain responses automatic documentation (Figure 2). Records were summarized by frequencies and percentages based on the presence/absence of nurse documentation values and patient/parent pain-rating responses. A chi-square test was used to compare nurse documentation rates to other categorical factors. P-values less than 0.05 were considered statistically significant.
Results
A total of 27,224 records had at least one narcotic administration during the study time period. The total number of patients/parents pain responses through using the IPC tool was n=1,767 with usage rates of (6.5%). On the other hand, nursing pain reassessment documentation values were found in 14,534 (53.4%) of records. Of the records where the patient/parent did provide a pain rating response with the IPC tool, 63.4% (n=1,121) had a nursing documentation value and 36.6% (n=646) did not. Whereas 47.3% (n=12,044) of patients who did not report their pain with the IPC tool had no follow up nursing documentation, this decreased to 36.6% (n=646) for the patients/parents who used the IPC tool, a relative difference of 10.7% (p<0.001) (Figure 3).

Discussion
The study findings illustrate a number of benefits of implementing IPC tools supporting automatic timely documentation through an inpatient pediatric use case. Our implementation of a unique customized IPC tool at the University of Minnesota Masonic Children’s Hospital, demonstrated relatively low use by patients/parents, but also found that among the group of patients/parents that did use the tool, their use was associated with a statistically and clinically significant increase (10.7%) in nursing pain reassessment documentation rates. Increasing the awareness of patient/parents on the important contribution they are able to make by using this tool may increase utilization rates among patient/parents, and potentially further improve nursing documentation rates. Future research focuses on exploring the reliability of the patient/parent response values in comparison with the nurse pain reassessment documentation values, to explore with hospital leadership the use of automatic patient/parent initiated pain documentation in lieu of nursing reported documentation compliance, and understanding barriers and facilitators of adoption of the tool by end users, including both patient/parents and nurses.

Quick Sequential [Sepsis-related] Organ Failure Assessment (qSOFA) and St. John Sepsis Surveillance Agent to Detect Patients At-Risk of Sepsis: An Observational Cohort Study

Robert C. Amland, PhD1, Bharat B. Sutariya, MD1
1Cerner Corporation, 2800 Rockcreek Parkway, Kansas City, MO 64117; USA.

Learning Objective
After participating in this session, the learner should be able to evaluate sepsis surveillance systems involving how to measure time to event and compare different alert system clinimetric performance on detection of at-risk patients and outcomes.

Abstract
The 2016 Sepsis-3 guidelines included a new clinical surveillance algorithm to identify patients at-risk of sepsis. A multiple center observational study design was used to compare the utility of Quick Sequential [Sepsis-related] Organ Failure Assessment (qSOFA) to the St. John Sepsis Surveillance Agent, which has been implemented in 550 hospitals in the USA. The St. John Sepsis Surveillance Agent, when compared to qSOFA, activated earlier and was more accurate in predicting patient outcomes.

Introduction
The 2016 consensus guideline on sepsis (Sepsis-3) includes a new sepsis surveillance alert definition termed Quick Sequential [Sepsis-related] Organ Failure Assessment (qSOFA). The purpose of qSOFA is to identify non-ICU patients currently under suspicion of infection, and potentially deteriorating into a sepsis complication. The qSOFA algorithm differentiates from earlier consensus guidelines, such that it incorporates latency and narrows clinical risk factors to tachypnea, hypotension, and altered mentation within the immediate 24 hours after onset of infection. In contrast, the St. John Sepsis Surveillance Agent, developed by Cerner Corporation in 2010, contains two alert mechanisms for sepsis and severe sepsis based on the earlier consensus definitions of SIRS, sepsis, and severe sepsis/shock and provides continuous 24/7 hospital-wide monitoring. The system has now been implemented in 550 acute care facilities in the USA. The objective of the study was to compare the utility of qSOFA to St. John Sepsis Surveillance Agent among patients with suspected infection.

Methods
The study employed a multiple center observational cohort study design to examine the comparative effectiveness of qSOFA and St. John Sepsis Surveillance Agent on the primary outcome of in-hospital mortality, and the secondary outcome of the composite of death or ICU admission. The St. John Sepsis Surveillance Agent applied a binary alarm paradigm with two alert definitions: (1) indications of SIRS (proxy for sepsis) and (2) indications of Sepsis (proxy for severe sepsis). Each alert, unless suppressed by a localized rule, delivered a real-time notification to a provider which included specific clinical criteria responsible for activation. Subsequently, we developed the analytic dataset with a qSOFA flag and its trigger time stamp, and a suspected infection clinical event with its onset time stamp. These two events were joined by examining their respective time stamps to create a qSOFA clinical event. Consistent with Sepsis-3, the qSOFA clinical event was suppressed if the qSOFA triggered before onset of suspected infection, after 24 hours from the onset of suspected infection, or after ICU admission. For each patient, we studied their first alert for each of the two surveillance models. A baseline risk model included age, male sex, recent discharge from hospital, onset of infection in the ED, and admitting facility. The study population comprised 17,044 patients between January and March 2016, of which 35% (n = 5,992) patients met inclusion criteria for suspected infection. For the primary analysis, receiver operator characteristic curves were constructed for patient outcomes using qSOFA and the St. John Sepsis Surveillance Agent, and the areas under the curve were compared against a baseline risk model. Time-to-event clinical process modeling was also applied.

Results
The St. John Sepsis Surveillance Agent (n = 2,228; 37%) identified substantially more patients at-risk of sepsis than qSOFA (n = 649; 11%). This increased sensitivity corresponded to the St. John Sepsis Surveillance Agent having screened-in 32 patients per 1,000 patient days compared to the qSOFA rate of 9 patients per 1,000 days. Approximately 1 in 4 patients screened-in by the St. John Sepsis Surveillance Agent occurred before onset of
infection, while the remainder of patients were mostly detected within one hour after onset; in contrast, most patients with qSOFA activated several hours after onset of infection. Model discrimination for in-hospital mortality was higher for St. John Sepsis Surveillance Agent (AUC = .74 [95% CI = .71 to .77]) compared to qSOFA (AUC = .69 [95% CI = .66 to .73]). Holding specificity constant, the St. John Sepsis Surveillance Agent and qSOFA correctly reclassified, in absolute terms, 13% and 5% patients, respectively, from the baseline risk model. This reclassification of risk translates to a relative improvement in sensitivity ∆↑ 23% for St. John Sepsis Surveillance Agent and ∆↑ 9% for qSOFA, respectively. Applying the Kaplan-Meier survival framework, Figure 3 illustrates the number of hours elapsed after triggering the St. John Sepsis Surveillance Agent or a qSOFA clinical event to the cumulative composite outcome, trimmed at 96 hours after the alert. A difference in estimated survival curves existed between the three patient cohorts (P = .026). Time-to-event measures with cases censored at 96 hours after detection showed the cohort with the St. John Sepsis Surveillance Agent “Sepsis alert” (n = 306 of 930, 33%), median 5.73 (IQR = 4.88 to 6.58) hours after detection, and approximately 1 in 17 (n = 17 of 306, 6%) patients were censored; compared to the cohort with a qSOFA clinical event (n = 163 of 649, 25%), median 5.30 (IQR = 3.46 to 7.14) hours after detection, and had twice the rate of censored cases (n = 19 of 163, 12%); and last, the cohort with a St. John Sepsis Surveillance Agent “SIRS alert” (n = 292 of 1298, 23%), median 6.35 (IQR = 4.68 to 8.02) hours after detection, and had a similar rate of censored cases (n = 37 of 292, 13%) as qSOFA.

Discussion
Comparing earlier consensus definitions on sepsis with the 2016 Sepsis-3 qSOFA, we found the earlier definitions more robust for sepsis surveillance applications. In contrast to qSOFA, the St. John Sepsis Surveillance Agent screened-in more high-risk patients, activated much earlier in their infectious process, and was more accurate in predicting adverse outcomes. Considering consequences of missing patients or the introduction of avoidable delay, qSOFA fell far behind on these objectives while the St. John Sepsis Surveillance Agent was promising.

Identifying and Predicting Falls among Elderly Residents of Baltimore City Using Hospital Discharge Summaries and Health Information Exchange Data

Laura Anzaldi1, Elyse Lasser1, Joshua Sharfstein1, Hadi Kharrazi1
1 Johns Hopkins School of Public Health, Baltimore, MD, USA

Abstract
This study evaluates the use of hospital discharge summaries along with health information exchange data to identify and predict falls among elderly in Baltimore City.

Introduction
CDC estimates the direct cost of falls to be $30 billion each year (1). Baltimore Falls Reduction Initiative Engaging Neighborhoods & Data (B’FRIEND) is a public-private partnership in Baltimore City based on innovative use of health data to decrease the rate of falls leading to an emergency room (ER) or hospital admission among elderly. The overall aims of the project include:

- Develop and validate a case identification methodology;
- Develop and validate a fall’s risk prediction model; and,
- Evaluate the fall risk score and disseminate results (not reported in this abstract)

Methods and Study Design
This study is a retrospective analysis of hospital discharge summaries of 327,727 Baltimore residents (2014) provided by Maryland’s Health Services Cost Review Commission (HSCRC) and Maryland’s Health Information Exchange (HIE; aka CRISP). Phenotyping criteria of falls were translated into a scalable query to identify falls among elderly leading to an ER/hospital admission. The study denominator consisted of 29,301 Baltimore residents, age 65+, 61% female, and, with an unintentional fall resulting into an ER admission or hospitalization in 2014. A semi-systematic review of the literature identified potential causes and risk factors of increased falls among elderly. Logistic regression, with L2 regularization, was used in R (GLMULTI package) to assess the explanatory power of the potential risk factors in predicting falls leading to an ER/hospital admission. Model development used a 100-fold 75%/25%-split training and validation method. AIC was used for model selection.

Findings
The case identification process identified 13% of elderly with at least one high-risk fall in Baltimore City in 2014 (40% higher than the national average). Figure 1 shows the rates of fall by neighborhood derived from real-time HIE data in Baltimore City:

![Figure 1. Prevalence of falls among elderly in Baltimore City zip codes (based on HIE cross-sectional data)](image)

The systematic review of literature identified 28 variables as predictors to high-risk falls, which were limited to 19 variables after applying conceptual and algorithmic feature reduction-methods. The logistic regression identified
history of a prior fall to have the highest predictive value (OR 6.02). A history of fracture, substance abuse, Parkinson, kyphoscoliosis, depression, mental illness, age, and sex (female) had a positive predictive value in explaining high-risk falls, while Charlson index, vision impairment, obesity, CVD, hypertension, cancer, low back pain, joint trauma, and lower joint surgery had a negative predictive value (all statistically significant at alpha .05). The model’s AUC was .703 with an AIC of 15495 (Table 1).

Conclusion

B’FRIEND results will guide, trigger and evaluate a variety of clinical and environmental interventions that will be tailored for the subpopulations of similar trajectories. For example, if a community-level trajectory of falls risk is being detected under the B’FRIEND project, housing resources can be deployed to reduce community risks associated with the predicted increased rates of falls. On an individual basis, trajectory alerts will be sent to patients’ primary care physicians via HIE connectivity for additional follow up.

We acknowledge the support of Darcy Phelan-Emrick (Chief Epidemiologist) and Mike Fried (CIO) of Baltimore City Health Department for this project.

Funding Source

RWJF DASH and JHU inHealth

Learning Objectives:

1. Explain the use of hospital discharge summaries and health information exchange data in detecting and predicting high-risk falls among elderly in Baltimore City

2. Define potential sources of data to improve the prediction of high-risk falls among elderly including EHR and geographic/social data

Differing patterns of satisfaction and perception among clinical and non-clinical users following replacement of a legacy EHR system

Nate C. Apathy1; Joshua R. Vest, MPH PhD1; Nir Menachemi, MPH PhD1; John W. Putz, PhD2; Justin G. Morea2, DO; Christopher A. Harle, PhD1

Introduction

Implementation and adoption of new health information technology (HIT) is complex, time-consuming, difficult, and expensive for health care organizations.1 Despite widespread use of electronic health records (EHRs), organizations will continue to implement new HIT as they upgrade and replace existing systems in response to pressures to improve care quality and reduce costs. For example, the new federal Quality Payment Program builds on EHR Meaningful Use measures and establishes new measures related to HIT use.2 Therefore, it is important to understand the effects that HIT system changes have on health care organizations’ providers and clinical staff.

Recent literature has primarily focused on physicians and other clinical users of new HIT and their perceptions of implementation and HIT system utility.1,3 Less is known about the impact of organization-wide HIT implementation on non-clinical users. These roles comprise important segments of HIT users, especially given the increasing importance of quality reporting, population health, and multidisciplinary care.4 Yet, HIT implementation strategies often de-prioritize non-clinical HIT users.5 Therefore, to examine how HIT changes affect different types of users, this study presents a longitudinal analysis of changes in perceptions and satisfaction among clinical and non-clinical EHR users in a large health system before and after implementation of a new enterprise EHR system.

Study Design and Methods

We conducted a longitudinal, prospective survey of 3,672 clinical and non-clinical EHR users at large public hospital system consisting of a 315-bed hospital and 10 affiliated clinics providing comprehensive primary and specialty services in Indianapolis, IN. In October 2016, the system switched from a homegrown legacy EHR to a commercial vendor’s enterprise EHR system. We developed a survey instrument modeled after a similar study3 to measure user satisfaction and perceptions of the EHR before and after the transition. Providers and staff identified as EHR users received email invitations one month prior to the new system go-live date and one and three months following the go-live. In total, 607 participants responded to all three survey waves (16.5% of those invited to the initial wave). For analysis, respondents were divided into clinical and non-clinical subgroups. The clinical user group included physicians, physician assistants, nurses, medical assistants, nurse practitioners, and other clinical care providers. The non-clinical group included all other roles unrelated to direct patient care, such as registration clerks, and analysts.

The survey included eight questions relevant to both clinical and non-clinical EHR system users and their workflows. These questions were identical for all respondents, regardless of role. We asked respondents about their access to information from other institutions (1 question), new work added or work eliminated by the EHR (2q), availability of support (1q), adequacy of training (1q), and overall satisfaction with both the EHR (1q) and one’s job (2q). All survey questions included a “not applicable option” and used five-point response scales ranging from “strongly disagree” to “strongly agree.” We dichotomized responses into “Agree” (agree or strongly agree) and “Disagree/Neutral” (neutral, disagree, or strongly disagree) and analyzed the proportion of respondents in the “Agree” category at each survey wave. Chi-square analysis was used to determine the significance of differences between the clinical and non-clinical subgroups over the three waves.

Figure 1. Percentage of respondents agreeing or strongly agreeing with items after 3 months. For added new work, more agreement is worse.
Principal Findings

Across all respondents, six of the eight items showed significant (p < 0.001) increases in the percentage of respondents who either agreed or strongly agreed after three months (Figure 1). Five of these six were changes favorable to the newly implemented EHR. The largest favorable increases were in the EHR’s elimination of work (11.1% agreeing pre-transition to 50.8% after three months), ease of access to information from other providers (30.6% to 58.0%), and availability of help (39.8% to 61.8%). The largest single change was in the EHR’s creation of new work (20.9% to 62.5%). No significant changes occurred across all participants or subgroups in overall job satisfaction, which remained above 75% either satisfied or highly satisfied across all survey waves.

The non-clinical user subgroup had 231 respondents (38%). The clinical subgroup had 376 respondents, [201 nurses/medical assistants (33%); 45 physicians/nurse practitioners/physician assistants (7%); 130 other patient care (21%)]. Compared to clinical EHR users, non-clinical users showed significant differences in patterns of satisfaction over time for several items: access to information from other providers, adequacy of training and support, and creation of new work. At baseline, when surveyed about the legacy EHR system, non-clinicians were more likely than clinicians to agree with ease of access (p = 0.016) and less likely to agree with adequacy of training (p = 0.018) and creation of new work (p < 0.001). However, there were no between-group differences in satisfaction after three months with the new system.

Conclusion

We found evidence that user perception and satisfaction around an EHR transition differed for non-clinical users compared to clinical users. Specifically, in the areas of pre-transition access to information from other providers, training adequacy, and the EHR’s creation of new work, non-clinical EHR users indicated differences before the transition that converged with clinical users’ perceptions and attitudes three months after the transition. Understanding how clinical and non-clinical EHR users differ can inform healthcare organizations as they manage HIT system changes. Especially in the area of pre-transition training, our results emphasize that non-clinical users may perceive lower adequacy of training, perhaps due to different levels of focus on training for different roles.

Novel Targeting of Clinical Decision Support: Utilizing Machine Learning To Improve Provider Acceptance – Repeat Imaging as an Example
Wasim Al Assad, MD, MSce1, Ivan Ip, MD, MS, MPH1, Li Zhou, MD, PhD1, Ramin Khorasani, MD, MPH1
1Harvard Medical School & Brigham and Women’s Hospital, Boston, MA 02115

Abstract
Clinical decision support (CDS) suffers low provider acceptance which potentially could be improved with machine learning. We extracted repeat imaging decision support data between 2007 and 2014, and built multiple classifiers to predict the acceptance of repeat imaging alerts. Our best classifier (Random Forest) achieved an accuracy of 75.1%. Machine learning could be utilized to improve provider acceptance of CDS alerts by targeting instances with high likelihood of acceptance.

Introduction
Clinical decision support (CDS) remains a challenging component of health informatics practice, continuing to suffer from a high override rate and low acceptance. Some CDS interventions have an acceptance rate of less than ten percent; others, rates of less than five percent1.

Repeat imaging, diagnostic testing that occurs within a specific time interval after an initial imaging study, is of concern on the national level. Imaging utilization has increased over the last few decades2 due to numerous factors. Increased imaging utilization is a contributor to increased healthcare spending that has outpaced the growth of the national GDP in the last decade3.

In prior work, we developed and implemented a CDS intervention with the goal of reducing unnecessary repeat imaging. The intervention consisted of providing a reminder of an existent relevant imaging study within the ninety days prior to the time of order entry, and asking providers to choose a clinical justification reason if they overrode the alert. This intervention reduced repeat imaging studies by nearly 7%. However, providers still overrode repeat imaging alerts over 90% of the time4.

In this paper, we utilize a data-mining approach to analyze CDS interactions. We employ machine learning algorithms in an attempt to improve repeat imaging CDS acceptance by targeting scenarios when acceptance is predicted by our algorithms. We envision that utilizing such an approach will reduce triggering of CDS alerts when acceptance is highly unlikely, thus improving overall acceptance.

This retrospective, Institutional Review Board-approved study was performed in a tertiary academic medical center including a 793-bed acute care hospital, a network of ambulatory clinics, and an emergency department with an annual volume of ~60,000 visits.

Between 2007 and 2014, alerts were triggered for any imaging orders with a prior exam of the same modality and body part performed within the previous 90 days. Alerts were shown to providers through the computerized provider order entry module of the electronic health record system (Percipio, Medicalis5). For each repeat imaging order, the system recorded provider interaction details including ordering provider, user type (physician, mid-levels, support staff), patient age and gender, ordering site, practice setting, and imaging modality. These data were stored in a database (SQL Server, Microsoft, Seattle, WA). We processed this data in SQL Server and built our machine learning models using Sickit-learn6.

During the time period of the active alert, 551,967 imaging orders triggered repeat imaging CDS alerts. Only 39,131 (7.6%) of CDS alerts were accepted with cancellation of the repeat imaging order; the remaining 512,836 alerts were ignored (overridden).

We divided the data into training (70%) and testing (30%) sets. Since the override dataset was nearly 13 times the acceptance dataset, we oversampled the acceptance dataset and matched it to a similar size of the override dataset. We used the following features, as they were available through our data collection system: patient age, patient gender, practice setting, imaging modality, number of similar orders in the prior 90 days, time elapsed since last order, average time elapsed for similar orders in the prior 90 days, user’s imaging CDS acceptance rate, provider medical school attendance (MD or not), and count of all provider imaging orders in our dataset.

We constructed three commonly-used classifiers, namely decision trees (DT), Random Forest (RF), and logistic regression7. We compared them using standard machine learning metrics of accuracy, error, sensitivity, and specificity7. Table 1 compares the results of the four classifiers.
Our best classifier (Random Forest) achieved an accuracy (total true predictions divided by total predictions) of 75.1%, sensitivity (true acceptance predictions out of all acceptance cases in the dataset) of ~70.9%, and a specificity (true rejection predictions out of all rejection cases of the dataset) of 79.3%. The positive predictive value (PPV) of our best classifier (RF) is 22.1%—a significant improvement over the current acceptance rate of nearly 7% for repeat imaging alerts.

**Conclusion**

In this study we built a classifier to predict repeat imaging CDS acceptance. Limitations include the low number of features in our classifier due to the limitation of our data collection systems, and the lack of clinical patient information involved in the classifier. Additionally, our assessment is based on clinician’s current acceptance of CDS alerts and thus the appropriateness of imaging utilization in cases of alert overrides has not yet been fully studied. Despite the limited features included in our classifier, the noisy nature of repeat imaging (i.e., repeat imaging occurs in the hospital for large set of reasons), and the complexity of predicting response to such a generic intervention; our classifier achieved results with an accuracy of over 70 percent. This indicates that our approach has potential application to improve CDS acceptance.

Implementing this classifier could theoretically improve acceptance of repeat imaging CDS alerts by nearly 3-folds (from 7.6% to 22.1%) by reducing a significant portion of alerts that are likely to be ignored. Future studies would be needed to test this classifier in a clinical implementation to assess its impact on repeat imaging CDS alert acceptance rate.

Clinical Trial Eligibility Criteria Fail to Meet Burden of Generalizability
Amelia J. Averitt, MPH1; Chunhua Weng, PhD1; Adler J. Perotte, MD MA1
1 Columbia University, Department of Biomedical Informatics. New York, NY

Introduction
Evidence-Based Medicine (EBM) requires medical practitioners to consider empirical and experimental evidence when treating their patients. EBM encourages practitioners to seek the most reputable evidence according to a hierarchy, in which randomized controlled trials (RCTs) are regarded as the gold standard source. While RCTs can offer precise and valid insights into the efficacy and safety, the results are often criticized for their poor generalizability and may therefore be unsuitable to serve as evidence for the practice of medicine.1,2 This failure of an RCT to represent an indicated population may be the result of cohort selection for a single condition of interest that is further narrowed by a breadth of eligibility criteria. This final cohort population may stand in stark comparison to the intended target population, which could have multiple problems and comorbidities.3,4 Observational data sources, such as the electronic health record (EHR), are regarded as more representative of the target patient population; but they cannot guarantee distributional similarity on confounding variables.1 We present empirical evidence that the construction of an observational cohort according to RCT eligibility specifications encourages convergence towards the true RCT effect estimate, but that these observational estimates are marked by residual confounding, which suggests that factors beyond eligibility criteria are necessary to determine the applicability of RCT results as clinical evidence.

Methods
Recent research investigates the representativeness of clinical trial participants for the approximation of a target population, however there exists a question of how effect estimates vary as a function of eligibility criteria.5 To address this knowledge gap, we propose two investigations, each of which will employ a unique RCT as a gold standard comparator. The first investigation explores the impact of eligibility criteria on the effect estimate (Study 1), and the second investigation examines potential sources of residual bias in effect estimates (Study 2).

Study 1: We hypothesized that each addition of an operationalized inclusion and exclusion criteria will increase distributional similarity between the observational and experimental cohorts, and will bring the effect estimate from the observational cohort closer to the effect estimates of published RCT outcomes. Inclusion and exclusion criteria extracted from published RCT protocols and literature were incrementally added to an observational cohort that was constructed according to the baseline study population of the RCT. As an example, we evaluated the occurrence of hypoglycemia associated with sitagliptin compared to glimepiride in elderly patients (65-80 years of age) with Type 2 Diabetes Mellitus (T2DM) and inadequate glycemic control.6 The baseline cohort of patients with these requirements was identified in the NewYork-Presbyterian Hospital data (~5.4 million patients). This baseline cohort was queried multiple times, with each query being subject to the addition of new eligibility criteria (See Table 1). With each incremental criterion, the unadjusted relative risk (RR) of hypoglycemia was calculated and compared to the RR that was calculated for this endpoint at the RCT’s close.

Study 2: To investigate the etiology of the residual bias to the effect estimate, observational cohorts that were curated according to eligibility criteria were compared to RCTs. Observational cohorts were created using the Observational Health Data Science and Informatics (OHDSI) ATLAS tools. The trial indication identified a core set of patients to which inclusion and exclusion criteria were applied to appropriately narrow the cohort. Subjects who
remained eligible after this pruning stage comprised the observational cohort of interest, which was compared to the RCT’s participant features that are reported in the baseline features table.

Results
Study 1: The unadjusted RR, calculated from observational data without any eligibility criteria, $RR_{obs} = 0.675$. After application of all eligibility criteria, the unadjusted $RR_{obs} = 0.498$. Figure 1 demonstrates the convergence of the effect estimate towards the RCT’s truth ($RR_{RCT} = 0.178$), which empirically confirms our hypothesis. Our research suggests that the incremental addition of RCT eligibility criteria encourages the distribution of meaningful covariates in the observational cohort to mirror that of the RCT, therefore reducing bias, and moving the observational effect estimate closer to the clinical trial estimate.

Study 2: Table 2 presents select features of this analysis using the landmark RENAAL Trial, which compares the effect of losartan and placebo on diabetic nephropathy. The data demonstrates that, despite curation of an observational cohort from NewYork-Presbyterian, statistically significant differences from the RCT exist among key features.

Discussion
This research and the brief examples provided above empirically demonstrate that the distribution of the clinical trial participants is different from that of the target patient population, even when subject to all eligibility criteria. Experimental trial participants are not only an inherently poor representation of the target population, but this research also suggests that the application of eligibility criteria may reveal new hidden bias. Based on these results, careful consideration beyond eligibility criteria is necessary to determine whether results of a given RCT are an appropriate source of evidence when considering the care of a given patient. These, and other related methods, will support a framework for causal inference and the practice of EBM. Funding: NIH BD2K; JANSRD CU15-2317

Introduction

Health information technology and the Internet have tremendous potential to transform health care¹. EHR portals in particular can improve patient care by providing more access to health information¹. However, they are underutilized by older adults, in part because they are hard to use and the information is often hard to understand². Because portals function more as repositories than collaborative tools, they do not engage patients and may not facilitate self-care. Self-managing illness requires understanding and using a wide range of health information. For example, to understand cholesterol test results, people need to interpret the numbers (e.g., HDL) in terms of risk of cardiovascular disease, and decide how to respond to perceived health threats (e.g., taking prescribed medication, changing diet, exercising). Patients with low health literacy and numeracy especially struggle to understand such information. Conversational agents (CAs) may be well suited for explaining complex concepts to patients with limited health literacy by using exemplary communication techniques without time constraints³. CAs can complement face-to-face communication, potentially reducing the amount of time physicians must spend instructing each individual patient. In fact, CAs have been shown to be at least as effective as human professionals in explaining medical information to patients³,⁴ and with promising findings for older adults acceptance⁵,⁶. While CAs are often used and evaluated in education settings⁷,⁸, evaluations of applications in health care are less frequent⁸. As compared to text-based or lower fidelity interfaces, CAs with realistic facial expressions, gestures, and other relational cues improve learning, support a variety of patient goals, and help diverse patients follow self-care recommendations⁴,⁵,⁶. CAs in EHR portals may especially help patients with low numeracy and literacy because, as in face-to-face communication, they can provide commentary with nonverbal cues (prosody, facial expressions) and verbal cues (risk category labels) to guide gist comprehension. In an effort to guide the development of a novel CA to describe clinical test results in portal environments, we assessed patient comprehension, and message satisfaction with this CA, compared to a video (and audio) of a healthcare professional delivering the same information.

Methods

The CA takes the form of a “talking head”, constructed from a 2D image. Specifically, the input to the system is a 2D frontal face image of a person in neutral expression. Landmarks such as lip corner, eye corners and nose tip are detected and located on the input image. A 3D generic model is morphed to match the appearance of the input image⁹. The CA audio is generated by a commercial text-to-speech synthesizer (Vocalware); the pitch and timing are modified to better match the tone (light, grave, or neutral) desired for each interaction. During the animation of the CA, both expressions and lip movements are synthesized by moving a set of control points on the 3D model to match the visemes with corresponding emotions; the CA audio is synchronized with the lip movement by matching the corresponding visemes, as illustrated in Figure 1 (left). We used a Dell 1908 monitor (resolution: 1440x900), with videos and CA messages presented on 1280x720 resolution and 23 fps.

Figure 1. Left: 2D image to 3D CA⁹. Right: Video-enhanced and CA-enhanced formats.

We conducted a study to evaluate the CA relative to the video provider and to a standard portal control condition. Participants were assigned to one of three message conditions: (a) video recordings, (b) synthesized CA constructed from the same physician’s videos (Figure 1: right) or (c) control condition, standard format typically used in actual EHR portals (table of numbers)¹⁰. All messages were about cholesterol test results and the enhanced-formats were accompanied by a graphical representation¹⁰. Older adults (n=108) matched on factors such as gender, age, and education (69% female; mean= 71 years old, 16 years education) watched a set of messages that described results indicating lower, borderline, or higher risk associated with the test results. They answered questions about the risk
level associated with the test results, and message satisfaction. Participants assigned to the CA condition were also asked to directly compare the CA and the video (also included audio) provider at the end of the session.

**Results**

No significant differences were found in message comprehension (Video=87.5%, CA=84.7% accuracy; t(35)<0.7;p=0.5;d=0.2;power=0.1). Compared to a standard format, both formats improved comprehension (CA=84.7%, Standard=67.6% accuracy; t(35)>3;p<.01; d=0.6;power=0.7). Furthermore, no differences were found for message satisfaction (Video=6.1, CA=6.0,9-pt scale; t(35)<0.3;p=0.8;d=0.1;power=0.1). These results reveal that blind to the existence of other formats, participants were equally satisfied with the CA and the videos. Also encouraging, the CA was overall preferred compared with the standard format (CA = 6.0, Standard= 5.1, 9-pt scale; t(35)=2.4;p<.01; d=0.4;power=0.4). However, when prompted to choose between the video and the CA, participants significantly preferred to receive their test results with the video of a real person (Video=81.9%, CA=18.1% preference; t(35) > 9.9;p< .01, d= 2.0; power=1). Participants preferred the video format because the person was more relatable, personable, conversational and with better voice inflections, or it explained more (despite both formats delivering identical content). Out of the justifications, 64% of participants preferred the video because it was delivered by a human, or conversely not by a “robot”. Those preferring the CA mentioned that it was easier to understand, and had superior eye-contact.

**Discussion**

Both video and CA effectively communicated cholesterol test results compared to standard messages. More generally, CAs can produce a significant effect on learning in part by engendering social responses. Nonetheless, often patient self-reported preferences and objective comprehension are not aligned. While the CA was as intelligible as the video, the CA appearance can be improved to boost preference. We next intend to provide choices from a set of CAs that vary in gender, age, and race, which may improve patients’ satisfaction. Further studies should explore different health care applications (e.g., medication instructions) and the appropriate level of CA realism (animated vs static) that produces trust and ‘social stance’. Increasing realism may have drawbacks and produce negative responses (e.g., ‘uncanny valley’ effect) and our photo-realistic CA may fall into that effect, such that less realistic CAs could be more effective. Ultimately, improving cognitive accessibility of health information through CA-based systems should increase portal utilization by older adults by boosting perceived usefulness as well as ease of use of the technology, as suggested by technology acceptance models. For example, older adult beliefs about ease of and usefulness of web-based services tend to predict intent to use. Portals that can be readily used by older adults with limited cognitive ability are likely to be used by a wide range of users.

EHR-based Quality Measurement to Reduce Antibiotic Use in Children

L. Charles Bailey, MD, PhD1,2, Hanieh Razzaghi, MPH1, Elizabeth R Earley, MPH1, Jeanhee Moon, PhD1, Levon H. Utitdjian, MD, MBI1,2, Jessica Hawkins, BS1, and Christopher B. Forrest, MD, PhD1,2

Introduction

Common low-acuity conditions such as respiratory infections are a major driver of antibiotic prescription and usage, leading to significant side effects as well as increasing antibiotic resistance in community flora. In young children, middle ear conditions are important contributors to this phenomenon. Otitis media with effusion (OME), a persistent collection of fluid in the middle ear, occurs due to impaired drainage rather than infection, and clinical guidelines have recommended for over a decade against use of antibiotics to treat OME. Nonetheless, prescription of antibiotics persists. Because OME is largely treated in the outpatient and primary care settings, it is particularly suited to quality measurement and improvement efforts across large populations. To address this requirement, we have developed an EHR-oriented quality measure intended to evaluate and promote antibiotic avoidance in children with OME. In order to test operating characteristics of the measure, we used outpatient data from PEDSnet, a collaboration among large pediatric health systems that includes sharing of structured EHR data standardized in the PEDSnet Common Data Model, an extension of the OMOP/OHDSI Common Data Model version 5.

Methods

Specification. Because OME exists on a clinical continuum with infectious acute otitis media, reliable automated recognition of OME from clinical documentation has proven difficult. We therefore specified the inclusion criteria based on recorded diagnoses reflecting the clinician’s diagnostic judgment. Codesets specific to OME were constructed from ICD-9-CM, ICD-10-CM, SNOMED-CT, and Intelligent Medical Objects (IMO) terminologies, based on medical records review, subject matter expert review, and crosswalks between terminologies. Similarly, codesets for frequently used oral antibiotics were derived from RxNorm and NDC based on review of prescription records in a large pediatric network. Subsequently, diagnoses recorded at visits where antibiotics were prescribed were reviewed, in order to compile codesets in each of the above terminologies reflecting common evidence-based reasons for antibiotic prescription. Measure specifications were expressed in HQMF using the Measure Authoring Tool, as well as in SQL and R for testing.

The measure was specified for outpatient clinical visits at which the patient was aged 2 through 155 months, a diagnosis of OME was recorded, and no other common diagnosis for which antibiotics were indicated was recorded. Each eligible visit was scored for the presence (failure) or absence (success) of an antibiotic prescription. Composite scores for individual clinicians or clinician groups were computed as the proportion of successful visits that were scored as success.

Testing. As a first step, the results of the computed measure were compared to manual record review in one health system (CHOP). A sample of 100 eligible encounters was drawn from CHOP data, with proportional representation of specialties and twofold over-representation of the top and bottom 10% of clinicians, and 125 non-eligible encounters were sampled from overall primary care (100) and otolaryngology (25) visits. Encounters were reviewed for accuracy of both diagnostic coding and medication capture.

In addition, because clinicians enter diagnoses using IMO’s proprietary terminology, which differs in granularity and structure from publically available diagnostic terminologies, results of the measure computed using IMO terms directly was compared to results using ICD-9-CM codes derived for billing.

To further evaluate performance in different contexts, testing was expanded to include data from six pediatric health system members of PEDSnet, using one of three different EHR systems. Score distributions across individuals, departments, and institutions were compared using one-way ANOVA. As a control for reliability, year-to-year score distributions within institutions were also compared using one-way ANOVA. In all cases, entities with <5 eligible visits per measurement year were excluded to limit effects of score quantization.
Results

Manual review. Using the results of manual review as a benchmark, sensitivity of the computed measure across the sample of 225 visits was 0.90; specificity was 0.92.

Diagnostic terminology. While SME review of crosswalks between IMO and ICD-9-CM demonstrated discordance between the terminologies (e.g. IMO “with effusion otitis media” mapped to ICD-9-CM “acute nonsuppurative otitis media”), correlation of scores using SME-assigned IMO terms directly and using mapped ICD-9-CM codes was excellent, (Figure 1).

Reliability and Discriminant Ability. The test dataset contained 197,786 eligible visits spanning 104,649 patients and 5,193 clinicians. Overall clinician performance was good, with mean scores >70%, and the 3rd quartile at 100% for all sites (Table 2). Nonetheless, the range of scores was broad, and ANOVA demonstrated meaningful differences across sites (F=35.62, p<0.001).

Table 3b. Pre- and post-ICD-10-CM ANOVA

Discussion

We describe the development and initial testing of a clinical quality measure tailored to EHR-derived data (an emeasure) intended to detect overuse of antibiotics to treat OME, a non-infectious condition. Physiologic recognition of OME is hard, so we specified the measure using clinician-asserted diagnoses rather than techniques such as text mining of physical examination findings; this approach significantly increases feasibility of the measure, and can be appropriate for measures of therapeutic decision-making rather than disease recognition.

Our testing strategy focused on evaluation of measure operating characteristics over a large test population rather than detailed manual record review. This allows for testing across a wider variety of technical and clinical contexts, but relies on the specification of the measure over well-defined discrete data elements. The terminology standardization provided by the OHDSI CDM further accelerated testing.

Acknowledgments

The authors are grateful for the data contributed by PEDSnet patients and families, and the work of PEDSnet informatics teams in construction of the data network. Usability and Acceptability of a System to Identify Pediatric Patients at Risk of 30-day Hospital Readmission Prior to Discharge

Amie Barda¹, MS, Lingyun Shi, MS¹, Andrew Urbach, MD², Srinivasan Suresh, MD², and Fuchiang (Rich) Tsui, PhD¹

¹Tsui Lab, Department of Biomedical Informatics, University of Pittsburgh, Pittsburgh, PA
²Children’s Hospital of Pittsburgh of UPMC, Pittsburgh, PA

Introduction: In a joint venture between the Biomedical Informatics Department of the University of Pittsburgh and the Children’s Hospital of Pittsburgh (CHP) of the University of Pittsburgh Medical Center (UMPC), the System for Hospital Adaptive Readmission Prediction and Management (SHARP) was developed as part of an effort to reduce 30-day pediatric hospital readmissions. SHARP utilizes a variety of structured and unstructured electronic health record (EHR) data to provide real-time estimates of an inpatient’s risk of readmission. The SHARP interface is integrated into the Cerner Millennium system currently in use at CHP and displays a variety of information related to readmission risk, including plots depicting readmission risk trends for individual patients, high-level categories of factors contributing to risk (e.g., laboratory risk factors), patient lists ranked by decreasing readmission risk, and heatmaps depicting readmission risk distribution within units/wards. The interface was developed iteratively using input from a small clinical team at CHP. It was anticipated that the information in SHARP would allow inpatient care providers to better target high-risk patients and intervene prior to discharge to reduce readmissions.

To prepare users for interacting with SHARP, an educational training video was prepared. The 9-minute video developed includes a brief overview of the system development and a demonstration of how to access and navigate SHARP within the Cerner system. The purpose of this study was to obtain end-user perceptions on the 1) completeness and clarity of the educational video, 2) usability of the SHARP interface, and 3) acceptability of using information in SHARP to change current clinical practice.

Methods: We recruited a convenience sample of inpatient care providers from CHP to participate in a 2-phase study. To recruit participants, we attended existing hospital group meetings (e.g., readmissions workgroup, monthly resident meeting) and asked some of our hospital contacts to recruit colleagues who might be willing to participate. Preference was given to care providers who had not actively participated in SHARP development. In the first phase, participants were asked to partake in a 1-hour session that consisted of watching the 9-minute educational video on SHARP, completing a brief survey, a 15-minute question and answer session, and a 30-minute semi-structured interview. The survey consisted of 4 questions regarding relevant participant characteristics (e.g., clinical position, prior knowledge about SHARP) and 12 Likert-scale questions designed to assess the participants’ initial perceptions on the usability and acceptability of SHARP. After completing the survey, participants were given the opportunity to ask questions regarding the development and use of the SHARP system. Based on participant availability, both individual and group interviews were conducted in which participants were asked about perceived barriers and facilitators to the adoption of SHARP within CHP.

For the second phase of the study, we invited all participants to pilot SHARP in a live clinical setting. Participation was on a volunteer basis only and participants were recruited during the phase 1 session. Willing participants were given access to the system and asked to use it as part of their regular workflow for a 2-week period. At the end of the 2-week period, participants were asked to answer a series of structured and unstructured questions about their experiences with SHARP in the live clinical setting. When possible, questions were asked during 30-minute in-person interview sessions to allow for follow-up questions. In cases where a volunteer was unable to sit for an interview, answers to questions were collected via an online survey with no follow-up questions.

In addition to taking notes, all interview and question-answer sessions were audio-recorded when permitted and later transcribed. Feedback from structured questions was summarized using percentages and basic statistics. Transcribed audio files, interview notes, and free-text feedback from unstructured questions were grouped by study phase and analyzed for underlying themes.

Results: For phase 1, a total of 31 care providers participated in 6 separate sessions (2 individual, 4 group). Recordings were obtained for 4 of the 6 sessions. Participants consisted of at least one representative of each major clinical role at CHP (e.g., resident, nurse, care manager, etc.) and had been practicing clinically anywhere from 6 months to 31 years (median = 2.3 yrs, mean = 5.8 yrs). Most participants had little to no knowledge of SHARP prior to attending the session (81%). Only 2 participants had been actively involved in the initial development of
SHARP. The phase 1 sessions revealed that although participants felt comfortable about interacting with the SHARP interface based on the educational video alone, they wanted more information about the development and validation of the risk prediction model to improve perceived trustworthiness of the system. Additionally, participants expressed concern that the long length of the educational video would prevent many users from watching it in full. It was noted that SHARP seemed intuitive and easy to learn and that the educational video might be too detailed.

Although 81% of participants thought that using SHARP would not disrupt their current workflow, only 22% of participants anticipated using it frequently. The simple, intuitive interface design and integration into existing EHR workflow were noted by most participants as facilitators to use; however, most participants expressed concerns about SHARP’s ability to impact clinical practice based on the current information available. More specifically, the high-level risk factors provided by SHARP were considered clinically irrelevant or not specific enough to be actionable. Some participants stated that they often knew which of their patients would be readmitted and many mentioned that they were unsure what could change about current clinical practice to help alleviate the risk. Furthermore, participants felt that current time-constraints left no room for additional attention to be spent on high-risk patients without knowledge of specific, effective interventions. Some participants stated that SHARP may be useful in streamlining decisions about patient discharges, but most saw little utility for the information in the inpatient setting. Many participants thought that post-discharge interventions (e.g., follow-up phone call) would be the most effective way to reduce readmissions.

For phase 2, only 5 total care providers volunteered to participate (1 attending, 1 care manager, 2 nurses, 1 nursing unit director). Only 1 user had been actively involved in the initial development of SHARP, while the remaining 4 had not been familiar with the system prior to attending the phase 1 training session. Only 2 of the 5 users could provide feedback via an in-person interview. During the 2-week period, 1 user reported using SHARP very frequently, 1 reported using SHARP occasionally, and 3 reported using SHARP infrequently or very infrequently. All users agreed that the SHARP system was well-integrated into Cerner and current EHR workflow, and 2 reported that the visibility of SHARP access points in Cerner prompted them to use the system. None of the users reported having issues understanding the information within SHARP and 4 reported that they felt the information in the system was accurate. Although no usability issues with the SHARP interface were uncovered during piloting, all but 1 user reported that they would not use it daily as the information is either not clinically actionable or not relevant to the specific patient population for which they care (e.g., intensive care patients).

**Discussion and Conclusion:** Overall, both phases of this study revealed that although the SHARP interface is highly usable and well-integrated into EHR workflow, the anticipated acceptability of SHARP to impact clinical practice is not promising. The two main barriers to utilizing SHARP information to change clinical practice were 1) a lack of actionable or relevant information in SHARP and 2) resistance to increased time spent on high-risk patients without specific interventions that have perceivable benefits. Concerns about improper use of the system were further exacerbated by the potential for users to resist the education process due to the video length.

This study suffered from a poor volunteer rate in the second phase. The resulting low number of participants can be attributed to a lack of interest in demoing the SHARP system in the live clinical setting, which further demonstrated the low acceptability of the information provided by the tool. Specific reasons for high readmission risks were not available from the predictive model, thus limiting the amount of actionable information in SHARP. Based on input from the original development team, it was anticipated that providers would still use SHARP to identify high-risk patients and subsequently use the provided risk categories in conjunction with clinical judgement to determine specific reasons for risk and develop an intervention plan. This extra level of work was unacceptable to study participants, which suggests that a more user-centered approach to system design should have been utilized. More specifically, in depth examination of end-user information needs and workflow should have been completed.

Despite the limitation of a low number of participants, the low acceptability found during this study led the technical and clinical development team to agree that additional planning is required before deploying SHARP within the inpatient clinical setting. A new intervention plan is under development, in which the current SHARP system will be used by a small set of users to perform targeted post-discharge interventions (e.g., tailored follow-up phone calls to high-risk patients). Additionally, information needs and intervention strategies for the inpatient setting are currently being reassessed. SHARP will be modified accordingly and the acceptability of the system will then be reevaluated prior to deployment in the inpatient setting. The results of this study can be considered when developing implementation strategies for readmission risk prediction models in clinical settings.
Large-Scale Text Mining of Social Determinants from Electronic Health Records: Case Studies of Homelessness and Adverse Childhood Experiences

Introduction

Social determinants of health (SDH) have recently received a growing interest as they provided evidence for being associated with an early onset and progression of various diseases, and a risk of premature death.[1] This interest was also reflected in a report from the National Academy of Medicine emphasizing the importance of capturing SDH in Electronic Health Records (EHRs).[2] The objective of this study was to implement a big data approach for extracting two severe SHD, homelessness and adverse childhood experiences (ACE), from a large dataset of notes.

Methods

Figure 1 illustrates the architecture of our approach.[3] Using the Vanderbilt de-identified version of the EHR, which includes >100 million notes, we integrated unsupervised learning and information retrieval (IR) methods to capture the two SDH profiles and to identify the patients that best matched these profiles. First, we built a list of query terms for each profile. Since ACE is a complex phenotype with experiences ranging from sexual to psychological abuse, we relied on domain expertise to identify the initial query of this SDH. For homelessness, we employed two data-driven methods, lexical association[4] and word2vec,[5] to expand two seed keywords, homelessness and homeless. We trained word2vec on 10 million notes randomly sampled from the EHR and used a vector dimension of 100. Next, we computed the similarity between a query and the notes of each patient by using an IR vector space model trained word2vec on 10 million notes randomly sampled from the EHR and used a vector dimension of 100. Next, we computed the similarity between a query and the notes of each patient by using an IR vector space model architecture based on the standard TF-IDF weighted cosine metric. We implemented the IR model on top of our EHR database, a secure IBM Netezza data warehouse consisting of a parallel computing architecture, to ensure the scalability of our system. Each search over the entire EHR lasted <20 min. After retrieval, negation detection[6,7] was employed to exclude the patients with a high prevalence of negated terms. Finally, the top retrieved results were manually examined by seven assessors. Query reformulation based on relevance feedback was adopted by analyzing the top 20 ranked results of each retrieval. For homelessness query expansion, the most relevant terms were selected from the top 50 keywords generated by the data-driven methods. After each query was settled, the final retrieval was executed and the top ranked patients were manually assessed. Specifically, for ACE, the top 1,000 patients were categorized as either ACE, not ACE, or undetermined. For homelessness, the assessment was performed at visit level using five categories: homeless, settled, at risk, undetermined, and pediatric. Since our next objective is to investigate associations between homelessness and various diseases using a case-control study design, for assessment, 600 patients were selected from 3 distinct sets: 1) the case set contained the top 200 ranked patients, 2) the fuzzy set–randomly selected patients with a rank >5000, and 3) the control set–randomly selected patients who don’t have homelessness terms in their notes. The evaluation was performed using precision-recall curves, the precision of top k ranked results (P@k), and the area under the precision-recall curve (AUPRC). The 95% confidence intervals (CI) of AUPRC estimators were computed using a bootstrap procedure.

Results

Lexical association and word2vec proved to be viable methods for homelessness query expansion. Table 1 lists the top 8 ranked keywords relevant for this determinant. However, a comparative study on the top 50 keywords extracted by the two methods revealed superior performance values achieved by word2vec (Figure 2 and Table 2).

As a result of query expansion and reformulation, the final query terms used for retrieval assessment were 1) for homelessness: homeless, homelessness, shelter, unemployed, jobless, and incarceration; and 2) for ACE: child shelter, and incarcerated.
abuse, sexual abuse, child neglect, childhood trauma, child protective service, physical abuse, psychological abuse, verbal abuse, poverty, food insecurity, cps supervisor, cps report, cps worker, and cps investigation. Based on these terms, the system retrieved 35,220 (1.3%) and 27,861 (1.1%) patients for homelessness and ACE, respectively. For both SDH, a substantial inter-rater agreement (kappa=0.8) was achieved. Out of the top 200 patients of the homelessness retrieval, 15 were pediatric, and 172 were found as relevant for this determinant (i.e., they have at least one visit assessed as relevant for homelessness). As listed in Table 3, the homelessness precision of the top 185 adult patients was 93% (172/185). This is substantially higher when compared with the precision of 40% achieved on the fuzzy set. For ACE, the system obtained a precision of 70% for the top 1,000 ranked patients. A comparative evaluation of the top 185 patients retrieved for the two SHD (Figure 3) indicated a higher AUPRC of 94% for homelessness identification (see details in Table 3). An analysis of the ACE patients revealed that most adverse experiences included sexual and physical abuse and top prevalent abusers were father and mother (Table 4). An alluvial diagram of the patients assessed for homelessness across consecutive visits (Figure 4) indicated that this condition was chronic for most of the homeless patients. The prominent cyclic transitions between the at risk and homeless categories captured an episodic trend of homeless patients.

Discussion

We described a feasible solution for mining SDH from a large-scale EHR, which opens the way for conducting large phenome wide association studies[8] on the impact of these determinants on the overall quality of life. To the best of our knowledge, this is the first study on SDH text mining from all the notes of a big EHR repository. Our system performance could be improved by integrating structured data in the retrieval model. However, the only structured data we could use from our EHR is the V60.0 administrative code for homelessness, which is not sufficient for extracting this determinant.[9] In this study, we found that only 62.8% of patients assessed as relevant for homelessness have the V60.0 code. Future work could expand the applicability of our system to identify additional determinants of health.

A Digital Health Advisor for High-Need, High-Cost Patients: Exploring Needs, Functions and System Constraints

Onil Bhattacharyya, PhD, MD1,3, Arnav Shah, MPP2, Lovisa Gustafsson, MBA2, Kathryn Mossman, PhD3, Eric Schneider, MD, MSc2
1University of Toronto, Toronto, Ontario, Canada; 2The Commonwealth Fund, New York City, NY, USA; 3Women’s College Hospital, Toronto, Ontario, Canada

Introduction

High-need, high-cost (HNHC) patients often have multiple conditions, are seen in a range of different institutions, and account for a disproportionate amount of system cost, yet they are poorly served by a health system built around diseases and institutions1,2,3. Digital tools that support an individual’s system for maintaining their health could help address the needs of frail elderly and people with multiple chronic conditions. Information technology has transformed many industries, empowering consumers and often reconfiguring services around their needs. There are over 165,000 health apps currently available, but a recent review found most available digital tools for chronic disease are piecemeal and do not address the needs of patients with complex chronic conditions4. Electronic health records with integrated health portals exist, but these tools and data are usually the property of a health institution and not owned by patients, who are seeking more customized care for their specific needs. To promote the uptake of integrated tools we need to consider patient concerns as well as those of providers, payers and policymakers. Through qualitative research methods, we explored the needs of HNHC patients that could be addressed by a digital health advisor (DHA), identified key functions of this tool, and the policy and system constraints that need to be overcome to promote its development and widespread dissemination.

Methods

We carried out focus groups and interviews to better understand the perspectives of key stakeholders regarding the key features of a DHA and the barriers that need to be addressed to develop it. We started with system stakeholders to understand current activity related to the DHA, moved to patients and caregivers to see what was desirable in such a tool, and went back to the system stakeholders to understand what was feasible and how to achieve it.

- The first focus group included clinicians, researchers, technologists, health system leaders, regulators, investors, entrepreneurs, patient advocates, and policymakers. It focused on the feasibility of developing such a tool, its potential impact, and key use cases among HNHC patients.
- We then conducted semi-structured interviews with 8 patient-caregiver pairings, focusing on patients with multiple chronic conditions and the frail elderly, to identify a broad set of needs and goals of HNHC patients. They were asked to iteratively prioritize a series of potential functions for a DHA based on illustrative examples.
- The second focus group involved ten stakeholders, including policymakers, regulators, clinicians, experts in informatics, advertising, and health services, as well as patient advocates, a technology industry executive, and health system leaders. We presented the proposed functions of a DHA, explored market opportunities and system constraints and discussed how to overcome them.

We conducted qualitative analysis of the focus group and interview data to identify patterns and key themes, focusing on identifying stakeholder needs, DHA functions, market opportunities and system barriers related to these functions.

Results

Feedback from the first focus group suggested that a DHA is both feasible and necessary, and some isolated components already exist. Participants noted that while the digital tool might face challenges involving security and privacy, these problems could be overcome5. The tool was considered particularly useful for HNHC patients, whose needs should be further explored. In our interviews with HNHC patients and their caregivers, we identified a broad set of needs and goals that a DHA may be able to address. These fell along two dimensions, ranging from functional needs and emotional needs, and medical and personal needs. This included the following themes: “live my life” (manage day to day tasks that are important to them); “love my life” (preserve dignity and connections while adapting to changes in their health status); “manage my health” (feel empowered to make smart medical and health decisions); and “feel understood” (communicate how conditions affect their physical and emotional state to their
family, friends and care team). Based on these needs, we developed a clickable DHA prototype with the following simulated functions:

- Tracking health indicators with a metric dashboard that collects data from apps and wearables, providing simple recommendations to help patients take action to make healthy decisions
- Providing advice on health-related questions either through digital assistant integration, like Siri or Alexa, or by connecting to a medical practitioner by phone or video, drawing on information from medical records, personal metrics, and available community resources
- Providing a care journal to help create a holistic picture to share with practitioners and foster deeper connections with the medical team
- Providing a shared calendar with all medical appointments, a document centre, and a task manager to improve coordination and communication assistance between patients and their care team, including help with scheduling appointments and transportation

In our second focus group, we presented these proposed DHA functions and identified a number of system and policy constraints to consider in developing the DHA. These include:

- The focus of the DHA needs to be on supporting patients in thriving rather than the management of disease
- Health care delivery organizations are critical to this effort, but it also needs to foster support in target communities, including patients, caregivers, families and social networks
- Extensive collaboration is needed to develop a robust DHA, which should be an integrated suite of tools
- Novel analytics alone are not sufficient; data must be made available in a usable format, and it is currently held by many different groups
- A useful DHA is more likely to emerge in response to bottom-up and middle out efforts rather than a top-down approach, which could include unique partnerships with organizations focused on consumer needs, such as consumer advocacy groups, and large retail companies
- We need to go beyond the policy sphere to engage with public markets, which can provide a competitive environment in which to test and refine the DHA
- The potential returns on investment and incentives need to be clear to attract social entrepreneurs and other developers to create a DHA
- The business case and policy incentives need to be developed to encourage broad data sharing among community, government and commercial initiatives

**Discussion**

This research identifies the key needs, functions and system considerations for developing a DHA that address the needs and goals of HNHC patients who could benefit most from this type of digital tool. It highlights the importance of community support and buy-in, along with creative partnerships between diverse organizations and a role for both policymakers and the marketplace in developing a robust DHA. These findings can also inform development of similar technologies for patients and help health system leaders consider the potential and challenges of patient-facing digital tools to meet the needs of their highest-cost patients.

Introduction

Background: Potential safety events in the outpatient setting are difficult to identify, quantify and categorize, leading to unique challenges in addressing ambulatory risk through quality improvement initiatives. Over the last 7 years, the OpenNotes initiative has sought to empower and engage patients and family members by inviting them to review visit notes through the patient portals, and now reaches over 12 million patients nationwide. Patients who read notes have reported feeling increased control over managing their health care and improved medication adherence, among other benefits. Furthermore, patients and caregivers may also assist in improving the accuracy and quality of ambulatory documentation. In a recent report, 21% of adult primary care patients who provided feedback on their online notes through an electronic reporting tool reported a potential inaccuracy. The majority of these reports (57%) resulted in a change to the medical record. However, no studies have explored the impact beyond the primary care setting and among other patient populations, such as the pediatric population, where parents most often manage care on behalf of the patient.

Objective: As part of an ongoing quality improvement project dedicated to improving the quality of clinic visit notes, the objective of this study was to quantify and characterize patient and parent reports of potential documentation inaccuracies and resultant safety concerns among ambulatory primary care and subspecialty open notes available through an online patient portal at 2 urban academic hospitals.

Methods

Design: A prospective cohort quality improvement (QI) initiative designed with patients and families

Setting: The quality improvement initiative was implemented at an urban academic adult medical center (Beth Israel Deaconess Medical Center; BIDMC) starting in August, 2014 and a free-standing urban academic children’s hospital (Boston Children’s Hospital; BCH) starting in June, 2016.

Patients/participants: Participants at the adult hospital included patients using the online patient portal (PatientSite) who had an eligible clinic note during the study period. Eligible clinic notes included pilot teams at 2 primary care practices and all the obstetrics and gynecology clinics. Participants at the children’s hospital included patients (≥ 13 years old), parents (for patients < 18 years old) and medical guardians of adult patients who had access to an eligible clinic note through their online patient portal (MyChildren’s). Eligible clinics included all primary care and specialty clinics with the exception of clinics with a higher risk of managing confidential or sensitive information who did not share their notes on the portal (i.e. adolescent clinic, adolescent substance abuse clinic, child protection team clinic, psychiatry clinic and gynecology clinic). Providers could also “hide” individual clinic notes so that they did not appear on the portal, if necessary.

Intervention: The intervention was a ≤ 10 item online patient reporting tool that was co-developed and pilot tested by the patient and family advisory council (PFAC), embedded through a link at the end of the note (PatientSite) or in the secure message notification regarding note availability (MyChildren’s). At both sites participants were invited to provide feedback on their note as part of a QI initiative. Reports flowed through a QI algorithm for real-time responses. The reporting tool requested feedback about whether and how well the note reflected what happened at the visit, whether the patient/parent understood the described care plan, whether they would follow the care plan, and whether there were any inaccuracies in the visit note. The reporting tool queried any language that bothered respondents and provided space for voluntary positive feedback about the provider. We defined a potential safety concern as a “No” response to “Did you understand the care plan” or “Do you plan to follow the care plan?”, or a “Yes” response to “Did you find a possible inaccuracy?”. Each safety concern was reviewed by Patient Relations personnel and outreach was made to patients/parents, and providers, as needed. Any resulting changes to the record or practice were coded accordingly.

Outcomes

We received a total of 1,059 patient family reports; 318 at BCH and 741 at BIDMC. Overall, 30% of reports at BCH identified a potential inaccuracy and an additional 3% were unsure if they had found an inaccuracy. At BIDMC, 22.3% identified potential inaccuracies, while 2.4% were unsure. The majority of inaccuracies reported at both sites included inaccuracies in the description of the chief complaint, inaccuracies in the problem list and medication list,
as well as information that was missing from the note (table 1). A few additional notable categories of inaccuracies included errors in laterality and wrong name/wrong patient errors. Most of the inaccuracies resulted in a change to the medical record (70% at BCH and 77.8% at BIDMC) (Table 2). 45% of respondents at BCH and 69% of respondents at BIDMC also included positive feedback for their providers.

**Discussion**

Our findings add to a growing literature that patients and families can identify errors or problems in care and can be valuable partners in quality improvement initiatives. Nearly a third of the patient/family reports identified a potential safety concern, with the majority resulting in an amendment to the medical record or a change in practice. Few patients or parents reported language that was bothersome and over half of the respondents provided positive feedback for their providers.

Evaluating the Quality of Patient Address Data in an EHR system

Michael N. Cantor, MD MA
NYU School of Medicine, New York, NY USA

Introduction

As the role of community-level social determinants of health (SDH) grows, accurate geolocation data for patients is increasingly important. Geographic information can be used to identify and target high-risk neighborhoods, for example. In densely populated areas, mapping by zip codes may not be specific enough to represent the diversity of the underlying population for these efforts. Mapping by census tract gives more specificity, and also allows for the incorporation of data from the U.S. Census and similar surveys. In support of a project building a database around community-level determinants of health mapped to New York City census tracts, we attempted to map our entire active patient population’s addresses to their respective census tracts. Our EHR system (Epic) imposes no standardized approach for entering address data for either patients or staff, so the address dataset required significant cleansing.

Accurate address data is important throughout the healthcare enterprise, particularly as part of an accurate patient identifier to support care delivery and coordination as well as information exchange. Several vendors provide address cleaning solutions, but these services can involve sharing the information with vendors (e.g. Google Maps) and lead to potential privacy issues, so local solutions are generally preferable. Many researchers assume that address data is standardized and accurate in EHRs. Though there is extensive literature on linking geographic data to clinical data, particularly as related to social determinants of health, we found no articles that mentioned the quality of patient address data that went into their geocoding efforts. Of note, the purpose of this project was to evaluate the quality of address representation, not whether the patient’s address was the correct one.

Methods

This project was a subset of SDH-related work for the New York City Clinical Data Research Network (NYC-CDRN, our PCORnet instance), where the overall aim was to link NYC addresses to their census tracts and a database of community-level determinants (https://github.com/mcantor2/FACETS). With this in mind, we obtained a list of the raw address data from active patients in our EHR system, separated from any other identifying information. Active patients were defined as those whose data had been sent to the NYC-CDRN’s central database. We pre-processed this data using Perl scripts to eliminate common errors and expand common abbreviations (e.g. AVE) to comply with the formatting of publicly available address databases (openaddress.org and NYC’s open data website). We compared both the pre-processed and post-processed street address list (removing apartment information) with the entries in the publicly available databases to determine the number of matches in the dataset and the common factors that led to errors in the address data (e.g non-alphanumeric characters).

Results

We obtained approximately 640,000 unique complete addresses (i.e. with apartment numbers) for 709,000 patients with NYC zip codes in our EHR system. With no processing, we found only 28,600 matches. With pre-processing, we were able to match approximately 595,000 patients’ (84%) street addresses. These addresses represented approximately 557,000 unique address (87%) entries and 297,000 unique street addresses after processing. We had approximately 66,000 unique unmatched street addresses after processing. Within this set of addresses were approximately 37,000 instances of 9250 unique “errors” (e.g. “Strett” is a unique error with 27 instances), which fell into 6 general categories: problem with reference content; algorithmic errors; misspelling; ambiguous abbreviation; PO Boxes; and unstable housing. Samples of these errors may be found in the Table. The Table also shows the prevalence of the different error types, which we obtained by analyzing the most common errors (those with >10 occurrences, comprising 4% of the unique errors and 81% of the total instances) manually.

Discussion

Because patient data can be entered through several different means in our EHR, addresses are susceptible to errors that make them difficult to align with a list of addresses in standard format. One of the main factors behind the low match rate on raw data, for example, is that apartment numbers were often listed as part of the street address, rather than separately. Adding safeguards or other systematic error checking in the EHR, similar to functionality provided by the U.S. Postal Service or other vendors in standardizing addresses when they are entered, could prevent many of

these errors. Some of the matching issues may be unique to a highly concentrated urban environment like NYC, where apartments are more common than private houses. Additionally, idiosyncrasies of NYC addresses, such as the hyphenated street numbers in Queens, may also have led to subtle errors that affected the matching in the same way that idiosyncrasies of the standardized datasets, such as giving street numbers as a range rather than an individual value; streets that were missing from the reference datasets; or streets with more than one official name. The reference data also have their own idiosyncrasies, such as only using numbers in streets names (5 vs Fifth). Similarly, some unmatched addresses were not necessarily erroneous, such as PO boxes or shelters, but also do not give accurate geographical information. Of course, the quality of the representation of the address data is important but ensuring that the address for a patient is correct is ultimately most important when drawing clinical conclusions. Standardized representation is just the first step in this process.

We used exact rather than fuzzy matching at this phase of the project because experience with fuzzy matching found too many possible alternatives, leading to creating as many new errors as those that were solved by process. Additional errors resulted from ambiguities that are unique to address data, such as “ST” representing either “Street,” “Saint,” or a suffix after a number, or non-standard representations of common abbreviations. Vendor systems such as Google Maps do an excellent job of addressing these errors, but, as noted above, may lead to privacy issues and can be expensive. Because the pattern of errors is relatively random, ranging from misspellings to spacing to mismatched addresses and zip codes, the next steps in this project may involve a deep learning approach to improve automated error correction. Other institutions may have more consistent address data, either due to limits on how the data is entered, or a systematic approach to catching and correcting errors before they are entered in the official medical record.

Conclusions

Accurate representations of addresses in the EHR are essential for linking patients to data related to their community-level social determinants of health. Though relatively straightforward processing led to matches for 84% of patients, the remaining address errors occurred across several categories, and were often difficult to address using automated tools and because of their random nature. Standardizing addresses upon their entry, using approaches that are common across many ecommerce sites, would eliminate most of the errors encountered.

Data-driven Risk Characterization and Prediction of Renal Failure among Diabetic Type 2 Patients using Electronic Medical Records

Prithwish Chakraborty, Vishrawas Gopalakrishnan, Sharon M.H. Alford, Faisal Farooq

1 IBM Watson Health, Cambridge, MA; 2 SUNY Buffalo, Buffalo, NY; 3 IBM Watson Health, Southfield, MI; 4 IBM Watson Health, Yorktown, NY

Introduction

The ready availability of Electronic Medical Record (EMR) systems has allowed providers and researchers to obtain a longitudinal view of disease and treatment progression from patient encounter histories. In recent years, EMR data from online and cloud-based data marts that collect and normalize data across a wide range of institutions, both acute and ambulatory, have further helped in reducing temporal blind-spots in patient medical history. Intelligent analysis of such meta-records can often lead to a revision of recommended treatment plans. Typically, most studies on disease outcome characterization using EMR records focus only on factors prescribed by experts. However, EMR records may also contain hidden/indirect factors that are correlated with higher risk of disease outcomes. For example, an increased number of diabetic related patient encounters can indicate an increased risk of extreme outcomes. In this study, we aim to identify potentially correlated factors from EMR records using data-driven methods. Specifically, we analyzed EMR records to identify relevant data-driven factors that are correlated with higher risk of renal failure in diabetic type 2 patients - one of the most prevalent afflictions worldwide. We used a L1 regularized cox-proportional hazard model to identify the factors and validated these factors by using these as covariates in a ‘generalized linear model’ based method to predict for renal failures in such patients. Note that we do not posit causality, only, correlated factors, which could be investigated with experts to better understand and possibly to predict disease progression.

Methods

Experimental Setup: We used a de-identified EMR corpus of approximately 47 million unique patients covering 1.6 billion medical encounters. We constructed a diabetic type 2 cohort spanning the time period 1990 to 2016 and covering 4 million patients, following a three step definition: (a) patients must have been diagnosed with diabetes type 2 anytime within this period (presence of Dx codes), (b) they must have had abnormal HbA1C levels (HbA1C ≥ 5.7) from lab observations corresponding to such diagnosis, and (c) had at least 3 diabetes related encounters within this period. A patient satisfying all the three criteria was considered to be diabetic and included in the cohort and, the first time-point when these criteria were satisfied was considered to be the first diagnosis date for the patient. This definition ensures that patients have been identified as diabetic from both procedural and diagnostic methods and hence reduces false positives. From the EMR records, we create normalized medical histories of patients using a number of steps such as encounter-observation and encounter-outcome co-reference resolution. Furthermore, we annotate encounters with renal failures (both acute kidney failure and chronic kidney disease) - both positive and negative cases.

Feature Identification: Typically, experts look at a fixed set of factors such as age, weight and HbA1C level in blood while analyzing renal failures in diabetic patients. In this study, we aim to identify other possible indicators, as supported by the data, from the corpus of near-complete patient medical histories. Following classical biostatistical approaches, risk factors for extreme outcomes like renal failure can be characterized using survival models such as Cox Proportional Hazard (CoxPH) models. In these models,

*This work was done when the author was an intern at IBM Watson Health*
conditional event rates or hazards \( \lambda(t) \) associated with factors \( X_i = \{X_{i,1}, \ldots, X_{i,p}\} \) characterizes the corresponding risk of outcomes which, for a patient \( i \), can be given as:

\[
\lambda(t | X_i) = \lambda_0(t) \exp(\sum_{j} \beta_j X_{i,j}) = \lambda_0(t) \exp(X_i \cdot \beta)
\]

where, \( \lambda_0(t) \) denotes the baseline hazard at time \( t \) (independent of patient covariates) and \( \beta_j \) denotes the regression weight of the factor \( j \). To identify and characterize such factors from the data, we use L1 regularized survival models which have been proven to be effective in other domains\(^3\). Specifically, we find these parameters by fitting the regularized log-likelihood ratio (eq. 1) against normalized EMR history of the patients in the cohort.

\[
\ell(\beta) = \sum_{j} \left( \sum_{i \in H_j} X_i \cdot \beta - \sum_{t=0}^{m-1} \log \left( \sum_{i:Y_i \geq t_j} \theta_i - \frac{\ell}{m} \sum_{i \in H_j} \theta_i \right) \right) + \gamma \|\beta\|_1
\]

where, \( \gamma \) is the L1 penalty factor and we identify the factors which are (a) statistically significant for survival outcomes and (b) associated with the largest regression weights (\( \beta(> 0) \)).

**Renal Failure Prediction:** We validate the data-driven factors by using these as covariates to predict for renal failure in diabetic type 2 patients based on their medical histories. Although survival models are not particularly suited for prediction on time-intervals outside the training data, we note that the partial log-likelihood in CoxPH models have close ties to logistic GLM regressions\(^4\). We use a regularized logistic regression (eq. 2) to use these factors to predict the occurrence of renal failure in the prediction period (the next 3 months).

\[
\ell_{logistic} = \min_{w,d} \|w\|_1 + D \sum_{i=1}^{n} \log \left( \exp(-y_i(X_i^T w + d)) + 1 \right)
\]

### Results

Table 1 tabulates the top statistically significant data-driven factors w.r.t. survival as identified via eq. 1 from our diabetic type 2 patient corpus. Table 1 shows that our method uncovers several observational attributes, *from the data* and *without expert input*, that are potentially correlated with an increased risk of renal failures. We validate the importance of these factors using our predictive model as shown in Table 2 which shows that risk prediction performance increases when expert factors are supplemented by data-driven factors - thus indicating that the data-driven factors may be uncovering hidden correlations and thus, of potential interest to experts. Here, we found the L1 penalty using 5 fold cross validation and for each observation period, we used 10 fold cross-validation to quantify accuracy, sensitivity, and specificity.

### Discussion

Our experiments indicate that we are able to identify relevant factors for renal failures from EMR attributes that are often collected as part of regular patient encounters. These factors can be investigated by experts in a more clinical setting and potentially lead to the early prediction of renal failures and/or implement preventive measures.

Using Electronic Health Records Data for Comparative Effectiveness Research

David Cheng, AM1, Ashwin Ananthakrishnan, MPH, MD2, Tianxi Cai, ScD1,3
1Harvard T.H. Chan School of Public Health, Boston MA; 2Massachusetts General Hospital, Boston, MA; 3Harvard Medical School, Boston MA

Introduction

The development of large electronic health record (EHR) research platforms has expanded opportunities for biomedical research. EHRs are becoming a valuable source for conducting comparative effectiveness research to assess treatment strategies and identify predictors that can explain treatment effect heterogeneity (TEH) for precision medicine. Conducting such analyses in EHR data, however, is challenging. One well-known issue is that the treatment assignment may depend on many confounders. Another primary challenge is the lack of direct observation on a pre-specified treatment response outcome. Ascertaining the outcome requires labor-intensive manual chart review, prompting the need for phenotyping algorithms that impute the outcome given available data. However, naïve use of imputed outcomes may lead to biased results especially when the quality of imputation is unclear. To address these issues, we developed robust methods that can infer the average causal treatment effect (ATE) and TEH in the EHR data setting, leveraging natural language processing (NLP) and semi-supervised learning (SSL) methods.

Methods

Algorithm: We frame the problem of estimating the ATE and identifying predictors of TEH with EHR data in an SSL setting, where a small set of patients are labeled with the true treatment response outcome and a large set of patients do not have their true outcome directly observed. Through NLP we extracted clinical terms from physicians’ notes that are relevant to the description of the treatment response outcome and developed a flexible imputation model for the outcome. Additionally, we estimated the propensity score to adjust for treatment by indication bias through a novel method based on modeling both the treatment assignment and the mean outcome given patient characteristics prior to treatment initiation. This novel propensity score estimator is more efficient and robust to mis-specification of its underlying models than traditional methods. Throughout we estimate model parameters using efficient shrinkage estimators that can accommodate high-dimensional covariates. Finally, we developed a semi-supervised response informed calibrated propensity score (RiCaPS-SS) estimator of the ATE and TEH using these imputations and propensity score estimates. Our algorithm results in estimators that are robust to mis-specification of the imputation model so that information from surrogate variables can be safely leveraged to improve the efficiency in estimating the ATE and TEH. The RiCaPS-SS estimators are also doubly-robust in that they will be valid provided that either the initial propensity score model or baseline outcome model is correctly specified. They are expected to be substantially more efficient than both complete-case (CC) estimators that neglect the unlabeled data and related missing data/causal inference estimators that we adapt to this setting to make use of the unlabeled data.

Data and Metrics for Evaluation: We evaluate the performance of our RiCaPS-SS algorithm based on simulation studies and an application to an EHR cohort of patients with inflammatory bowel disease (IBD) from Partner’s Healthcare. We designed the simulations to allow for mis-specification of either the propensity score model or baseline outcome model. The imputation model is mis-specified throughout. The relative efficiency, defined as the ratio of the mean-square error for the standard CC doubly-robust estimator (DR-CC) relative to each estimator, was used to compare the performance of our estimator to existing methods.

The EHR cohort included eligible patients with at least one ICD-9 code for Crohn’s disease (555.x) or ulcerative colitis (556.x) who were classified as IBD patients by a validated algorithm. Patients were also required to have at least 1 codified mention and 3 narrative mentions of adalimumab (ADA) or infliximab (IFX), with an interval of more than 0 days between the first and last narrative mentions. The final cohort consisted of 1,243 IBD patients, including 200 patients initiating treatment with ADA and 1,043 with IFX. The study aimed to compare ADA and IFX with respect to treatment response within 1 year of initiation. Through chart review of EHR records, the true treatment response status (responder vs none) was annotated for 117 randomly selected patients. We considered 35 post-treatment surrogates comprised of NLP mentions of clinically relevant terms that predict treatment response and adjusted for 12 baseline covariates including demographics, comorbidities, and prior utilization in the propensity score to mitigate confounding. We estimated the ATE using various estimators and their standard errors, relative efficiency compared to DR-CC, and confidence intervals (CI). We also performed analysis to identify predictors of TEH.
Results

Simulation: Simulations demonstrate that our proposed RiCaPS-SS algorithm produces an estimator that is substantially more efficient than existing estimators (Figure 1). We find that the efficiency gains hold regardless of the model mis-specification scenarios considered. RiCaPS-SS was found to be more than 50% more efficient than other estimators when both the propensity score and baseline outcome models are correct. When either the propensity score or baseline outcome models is mis-specified, the advantage of the RiCaPS-SS estimator is even more dramatic since the performance of the other estimators deteriorate due to mis-specification.

EHR IBD Study: The estimated ATE, defined as the difference in treatment response rate between ADA and IFX, from various approaches for the IBD study are shown in Table 1. The ATE comparing ADA vs. IFX is estimated to be -6.7% (95% CI -14.5% to -1.0%, p=0.039) using our approach. In this data our approach is estimated to achieve more than 220% efficiency gain over CC estimators 320% gain over missing data/causal inference estimators we adapt to leverage the unlabeled data. Our analyses also suggest that the Charlson comorbidity score is predictive of TEH between ADA vs. IFX. The difference in the adjusted log-odds ratio for ADA vs. IFX for those scoring higher by 1 Charlson score was -0.24 (95% CI -0.47 to 0.00), indicating that ADA should be recommended to patients with a lower score.

Discussion

In EHR data when the treatment response outcome is available on a small fraction of the observations, it is possible to leverage surrogate variables from unlabeled data to obtain more efficient estimators of the ATE and TEH. We develop an imputation approach coupled with a novel propensity score estimate that yields estimators of the causal treatment effect that are robust to mis-specification of the models imposed for the imputation and propensity score estimates. We find in simulations and data analysis that substantial efficiency gains are achieved over standard approaches. Even if both propensity score and baseline outcome model are not exactly correct, previous simulations indicated that similar results to hold as long as both models are not grossly mis-specified. This efficiency gain translates to being able to estimate treatment effects with much greater precision, or, alternatively, requiring potentially far fewer labeled observations to achieve a desired precision. Such a method could help facilitate comparative effectiveness research in EHR data when labeling patient records with a gold standard outcome is resource-intensive.

Citation of work published in peer-reviewed journals in the last year:

Introduction

Antimicrobial resistance is a serious threat to public health and antibiotic use is the key driver. Antibiotic use in hospitals is high and on the rise, with 41-91% of all antibiotics prescribed in hospitals worldwide considered inappropriate. Antibiotic computerized decision support systems (CDSS) have been developed to improve antibiotic decision making through the accessibility of patient-specific clinical data and local antibiotic guidelines, at the point of prescribing.

Antibiotic CDSS are particularly useful for antibiotic selection for empiric therapy, as optimal selection is complex when the causative pathogen is unknown. Antibiotic CDSSs have been shown to improve antibiotic prescribing and patient clinical outcomes including the reduction of mortality. However, there is limited information on factors influencing physicians' acceptance or patients' receipt of CDSS-recommended antibiotics. Understanding these factors can guide strategies to improve patients' receipt of antibiotic therapies recommended by CDSSs and enhance clinical care.

Objective

We conducted a prospective cohort study to evaluate the extent to which hospitalized patients received antibiotics as recommended by our in-house antibiotic CDSS, Antimicrobial Resistance Utilization and Surveillance Control (ARUSC), and to identify patient and physician factors associated with patients’ receipt of empiric antibiotic therapies recommended by ARUSC when the prescribing physician had an initial preference for using broad-spectrum antibiotics and targets for improvement.

Methods

The study was conducted in a 1500-bed tertiary-care academic medical center in Singapore.

In 2009, the hospital launched its in-house antibiotic CDSS, ARUSC, which integrates antimicrobial stewardship with the hospital's computerized physician order entry system (CPOE) and provides patient-specific evidence-based antibiotic recommendations at the point of prescribing (Figures 1A-D). All medication orders in the hospital are made via the CPOE (Figure 1A). From September 12, 2011, whenever a physician makes an electronic prescription of piperacillin-tazobactam or a carbapenem for an inpatient, the prescription automatically triggers the launch of ARUSC (Figure 1B). Piperacillin-tazobactam and carbapenems are antibiotics of last resort for many bacterial infections, particularly those caused by multidrug-resistant pathogens. Hence, it is crucial to ensure the judicious use of these antibiotics.

Using a rules-based algorithm, ARUSC provides guidance on antibiotic selection and dosing, based on guidelines developed by the hospital's antimicrobial stewardship committee, which recommends the narrowest-spectrum antibiotic appropriate for common organisms responsible for the diagnosed infection taking into account the local epidemiology of infectious diseases, local microbiology and antibiotic susceptibility patterns in the hospital in the prior 5 years, and incorporating evidence-based international guidelines including the Infectious Diseases Society of America’s Practice Guidelines and Australia’s Therapeutic Guidelines: Antibiotics. Data from individual patients’ electronic medical records including medication history and drug allergies, as well as laboratory results such as creatinine levels are also pulled into ARUSC and included in the algorithm. ARUSC recommends the most appropriate antibiotic for the patient, taking into account the patient’s antibiotic allergies and renal function (Figure 1C). The prescribing physician can either accept or reject ARUSC-recommended antibiotics, which are assumed to be always appropriate (Figure 1D).

All patients admitted to the hospital, from October 1, 2011 through September 30, 2012, who were prescribed piperacillin-tazobactam or a carbapenem for empiric therapy and auto-triggered to receive antibiotic therapies recommended by ARUSC were included in the prospective observational cohort study. Prescriptions for prophylactic or definitive therapy were excluded. We chose to focus our study on empiric therapy, as empiric antibiotic prescriptions have been found to be the least concordant with recommended antibiotic guidelines. Furthermore, empiric antibiotics are usually the first antibiotics received by a patient in an infective episode; appropriate empiric antibiotics is a critical determinant of clinical outcome. Patients were followed up prospectively from the automatically-triggered launch of ARUSC at the point of antibiotic prescribing up to 30 days post-discharge from hospital.
Results

One-quarter of the 1886 patients received CDSS-recommended antibiotics. More patients treated for pneumonia (33.2%) than sepsis (12.1%) and urinary tract infection (7.1%) received CDSS-recommended antibiotic therapies. The prescribing physician—but not the attending physician or clinical specialty—accounted for some (13.3%) of the variation (Table 1). Prior hospitalization (OR 1.32, 95% CI 1.01-1.71), presumed pneumonia (OR 6.77, 95% CI 3.28-13.99), intensive care unit (ICU) admission (OR 0.38, 95% CI 0.21-0.66), and renal impairment (OR 0.70, 95% CI 0.52-0.93) were factors associated with patients’ receipt of CDSS-recommended antibiotic therapies (Table 1). 60% of patients who were auto-triggered into the CDSS due to a prescription of piperacillin-tazobactam were consequently recommended piperacillin-tazobactam by the CDSS, but not all received antibiotic therapy in the dose and frequency recommended by the CDSS. In the subgroup analysis of 1213 pneumonia patients, prior hospitalization (OR 1.37, 95% CI 1.01-1.86), ICU admission (OR 0.39, 95%CI 0.20-0.74), renal impairment (OR 0.73, 95% CI 0.52-1.02), and prescription made at night (OR 1.35, 95% CI 1.02-1.79) were associated with receipt of CDSS-recommendations. For the 673 non-pneumonia patients, ICU admission (OR 0.27, 95%CI 0.06-1.22, P=0.088) and renal impairment (OR 0.54, 95%CI 0.29-1.04, P=0.065) were marginally associated.

Conclusion: This study gave insights into predictors of patients’ receipt of empiric antibiotic therapies recommended by a CDSS when the prescribing physician had an initial preference for using broad-spectrum antibiotics. Patients admitted to the ICU or who had renal impairment were less likely to receive CDSS-recommended antibiotics. The clinical complexity of ICU and renal-impaired patients had required physicians to override CDSS-recommendations which were more tailored for general inpatients. Enhancements to the antibiotic CDSS can help address some of the unique patient needs, but the more complex clinical conditions and antibiotic needs of such patients may still require a physician’s assessment in addition to the CDSS recommendations.
Opportunities and Challenges for an Interdisciplinary Team to Guide Adoption of Technology to Dissipate Threats to Patient Safety in Real-Time

Anuj K Dalal, MD,1,2 Theresa E Fuller,1 Pamela Neri, MS,1 Dominic J Breuer, MS,3 David W Bates, MD, MSc1,2 and James C Benneyan, PhD3

1Brigham and Women’s Hospital, Boston, MA, 2Harvard Medical School, Boston, MA 3Northeastern Healthcare Systems Engineering Institute

Introduction: Minimizing preventable harm in the acute care setting is an ongoing challenge, but one that is necessary to create a safe healthcare system.1 Implementing health information technology (HIT) with the goal of improving patient safety is especially challenging in complex healthcare settings.2 Collaboration across disciplines, departments, and institutions is necessary to ensure successful implementation and sustainability but is often lacking. We assembled an interdisciplinary team with expertise in systems engineering, human factors and usability, and data analytics as part of a large AHRQ-funded Patient Safety Learning Laboratory (PSLL) initiative between Brigham and Women’s Hospital and Northeastern University. An important goal of our team was to facilitate institutional adoption of the HIT components (Figure 1: patient portal, screen-savers, safety dashboard) as a unified system integrated with our vendor-based electronic health record (EHR). In this study, we describe opportunities and challenges encountered for implementing novel HIT to identify, assess, and mitigate threats to patient safety in real-time.

Methods: This study took place at a large academic medical center in Boston, Massachusetts. We employed a sociotechnical approach to identify opportunities and challenges for facilitating adoption and sustainability of our technology in four categories: stakeholder engagement, organizational priorities, user experience, and technical and data integration.2 Institutional stakeholders were engaged in a series of meetings and presentations to ensure alignment with organizational priorities and initiatives. Our team worked with information system and quality and safety leaders to identify requirements for technical and data integration. We conducted interviews and observations of patients and clinicians to identify usability challenges. We identified key themes using a 2-person consensus approach.

Results: Key opportunities and challenges are presented in Table 1. In general, we found high degree of support for using screen-savers and dashboards for real-time visualization of data from the EHR as this aligned with the overarching institutional goal of reducing preventable harms due to hospital-acquired conditions (catheter-associated urinary tract infection). Specifically, these tools were seen as potent interventions for improving quality and safety process measures (nursing-driven Foley protocol ordering) reported to clinical dyads as part of a hospital-wide initiative when dashboard use data were provided simultaneously. Ensuring consistent interpretation of data displayed by various clinicians (“red” indicating action is needed) and appropriate follow-up action (updating documentation, entering orders in EHR) were important challenges identified by usability and human factors experts. Identifying potential failure modes (failure modes and effects analysis) and actual safety events (failure-based root-cause analysis) were methods employed by systems engineers in collaboration with safety leadership, and represent a crucial opportunity to encourage learning that would be used to iteratively refine HIT components. The user experience was enhanced by technical integration of safety icons into screensavers displayed on bedside workstations to engage both patients and clinicians in identifying and understanding safety risks. For clinicians, the user experience was also enhanced by integrating a research and innovations portal into the EHR on which information from the EHR (CAM score, sedatives, QTc) and appropriate action pertinent to mitigate a specific harm (delirium) were displayed. Finally, use of the acute care patient portal by patients and caregivers was improved considerably by enabling a “bring-your-own-device” strategy, but could be further enhanced by integration with the enterprise patient portal and by optimizing the enrollment process.

Conclusion: Overall, the experience of our team underscores the key opportunities and real-life challenges when implementing novel HIT to identify, assess, and mitigate threats to patient safety. Clinicians and institutional stakeholders were generally enthusiastic about using several HIT components (safety screen-savers, safety dashboard) because of clear alignment with institutional priorities and initiatives to improve patient safety.

Figure 1. Technological Components of Patient Safety Learning Laboratory

The Systems Engineering, Usability and Human Factors, and Integrative Data-Analytics (SEU)(3) core was involved with a continuous safety improvement process including surveillance to identify at-risk patients, individualized risk assessment of threats to identified patients, mitigation strategies to reduce harm likelihood, and systematic analysis of threats and harms identified in the first 3 phases in order to narratively refine the individual HIT components and overall “system” over time.
Use of Clinical Phenotypes and Non-negative Tensor Factorization for Heart Failure Prediction

2College of Computing, Georgia Institute of Technology, Atlanta, GA

Introduction
Heart failure (HF) is a diverse syndrome associated with multiple risk factors and diseases. Heart failure affec ts millions of adults in the United States annually, and for some subtypes of patients with HF, 5-year mortality is higher than 50%. In order to intervene earlier to reduce morbidity and mortality with targeted therapies it is important to identify patients at high risk for HF. Electronic health records (EHR) provide extensive information on patients that one can use as features for outcome prediction. Many machine learning (ML) methods are able to deal with large feature sets and complete the prediction task successfully. However, there are few efficient algorithms that also yield results that are easily interpretable. Furthermore, when applied to EHR data, such methods (e.g. logistic regression) will struggle from over-fitting due to low number of events per variable. Recent applications of non-negative tensor factorization (NTF) to EHR records show potential compromise between sparseness of EHR data and ease of comprehension of the model. Here, we assessed the performance of a novel ML method for detecting patients at risk of HF. In the first step, the NTF algorithm generates phenotypes of patients specific to patient diagnosis and pharmacological profiles prior to HF. Each patient is assigned to its own “fingerprint” label according to his membership to the different phenotypes. The fingerprints were then used as a feature set to predict HF. Ease of comprehension is achieved through transforming the high dimensional space (raw features) to a reduced clinical phenotype space (“fingerprints”).

Methods
We extracted medication (RxNorm codes) and diagnosis (ICD9 codes) from 1/1/2005 to 11/30/2016 on patients with possible HF from the Northwestern Medicine Enterprise Data Warehouse (EDW). We mapped diagnoses codes into a higher level of hierarchy based on PheWAS and Anatomical Therapeutic Chemical Classification System. We further reduced the study population to HF cases and controls only.

We identified a HF case if he/she has (i) at least 2 HF diagnoses from outpatient encounters; or (ii) at least 2 medications prescribed for a HF diagnosis; or (iii) at least 1 HF diagnosis from an outpatient encounter and at least 1 medication prescribed for a HF diagnosis. This definition was previously validated by Geisinger Clinic. For each case, we matched control patients on gender, year of birth and similar encounter information. We analyzed records of each patient within a 2-year time window prior to HF onset date to ensure that each patient had the same length of prediction window. Only cases and controls having a full 2-year period of records and at least 1 visit during these 2 years were kept in the final sample. Once a HF patient was identified, the first appearance of HF related medication or diagnosis was assigned as the onset date. A tensor was constructed with 3 modes including a patient mode, medication mode and diagnosis mode. Each tensor element represents the co-occurrence between medication and diagnosis for a certain patient during the available time window. NTF was applied on the tensor to generate patient phenotypes. The cutoff parameters (alpha: 1.0; gamma: 0.001, 0.08, 0.07) for NTF were set to reduce the noise of data and keep the phenotypes concise. A series of dummy variables were created for each patient based on phenotype membership. Those variables were then used as predictors for logistic regression (LR) and random forest (RF) prediction. The predictive performance of this method was compared to the performance of algorithm based on raw features transformed lower dimension space of principal components (PCA). The 3 main principal components were passed as predictors to RF algorithm. The area under receiver operator characteristic curves (AUC) were used to evaluate model discrimination ability (Fig 1).

Results and Discussion
We identified 518 subjects as qualified HF cases in the EHR. Patient onset age ranges from 20 to 89 years old with majority of HF onset age at 45-89 years old. For both RF and LR prediction, “fingerprint” labels outperformed raw features and principal components when the number of clinical phenotypes is greater than 20. The AUC score for raw feature/PCA based method is 0.628±0.145 (green solid and dashed lines in Fig. 1), while corresponding values for “fingerprint” –based methods are 0.733±0.05 (LR: red dots and lines in Fig. 1) and 0.760±0.136 (RF: blue crosses and lines in Fig.1). Based on how NTF handles noise of the data, number of cases and controls at the final
step (orange line in Fig.1) will be smaller than original number of patients selected for the study. Therefore, for small samples, accuracy of the final prediction will be significantly affected by the reduction of overall number of the patients. In our study, the case:control ratio is approximately 1:3. Even after adding weights to controls for imbalance adjustment, analysis will still suffer from reduction of HF case patients during NTF. We used the number of HF cases remained after NTF together with AUC value as criteria for selection of optimal number of phenotypes. It appears that 90-phenotypes is the optimal number (both classification performance and number of patients reach a plateau). We sorted phenotypes importance based on use of features in RF prediction. The 5 phenotypes out of top 12 were selected as the most significant risk phenotypes (table 1) for developing HF event. 66.73% of future HF case patients are in those five phenotypes, while contribution of these phenotypes to controls is only 16.24%.

</table>

Physician evaluation shows clinical meaningfulness of the 5 phenotypes that contributed the most to the risk of subsequent HF. The prominent comorbidities in the five phenotypes in decreasing order of contribution were atrial fibrillation/flutter, lipoid disorders, hypertension, and type 2 diabetes mellitus, with the fifth being an amalgam of lipoid metabolism, hypertension and ischemic heart disease. Clinically, this order may suggest that some acute conditions (e.g. atrial fibrillation) may contribute more to subsequent heart failure risk in the short term (2-year window) than chronic conditions which may take years to lead to subsequent cardiovascular injury.

Conclusions

Our preliminary results show better performance of NTF membership linked classification over other popular dimension reduction method and suggested a plausible hierarchy of HF risk based on associated comorbidities. NTF also shows potential in capturing novel HF prediction phenotypes (i.e. features) with distinct clinical characteristics. Such phenotypes are likely to improve HF prediction and help discover mechanisms of HF pathogenesis.

Meeting User Needs for a Data Discovery Index of Biomedical Big Data

Ram Dixit, BS1, Deevakar Rogith, MBBS, PhD1, Vidya Narayana, MS1, Mandana Salimi, MS1, Anupama Gururaj, PhD1, Lucila Ohno-Machado, MD, PhD2, Hua Xu, PhD1, Todd Johnson, PhD1

Introduction

‘Big data’ in biomedicine is a reality and an opportunity for new forms of research and knowledge discovery1. However, the diverse locations, formats, and types of data combined with a lack of standards for describing datasets makes taking advantage of this opportunity challenging2. The NIH Big Data to Knowledge (BD2K) initiative issued a call to assemble these heterogeneous data from multiple sources into a single Data Discovery Index (DDI)1. A prototype DDI, DataMed (accessible at http://DataMed.org), was launched with the goal of enabling researchers to search for, access, and cite datasets3. Bringing together datasets from multiple sources poses challenges in information retrieval and user interface design to providing meaningful and useful search results to the users4, 5. Studies have been done to understand user needs and information seeking behavior in literature and citation indexes such as PubMed6, 7, but there is a gap in knowledge on user needs, expectations, and information seeking behavior regarding biomedical data discovery. We present the initial findings from our user needs and usability evaluation of DataMed. We discuss the challenges in biomedical data discovery to inform future DDI development efforts.

Methods

To understand biomedical researchers’ needs and guide the development of the DataMed, we conducted user analyses in two phases. In the first phase, we focused on why and how researchers look for online biomedical datasets through semi-structured interviews (13 participants) that informed the initial development of DataMed. In the second phase, we conducted iterative “think-aloud” usability evaluations of versions 0.5 (8 participants) and 2.0 (11 participants) of DataMed. We present results from the qualitative analysis of interviews and usability studies with these researchers, that focused on four main areas: searching for data, data formats, data visualization, and metadata.

Results

We present the summary of key findings from the user analyses:

Table 1. Summary of user analyses findings and design decisions for DataMed – a Data Discovery Index

<table>
<thead>
<tr>
<th>Phase</th>
<th>Key Findings</th>
<th>Design Decision</th>
</tr>
</thead>
</table>
| I – User Needs Assessment     | • Users search for online data to find similar datasets they can compare with their own analyses or to find complementary (cross-domain) datasets that can enrich their analyses  
• Key metadata such as source, type, contents, and availability, are necessary to assess dataset relevance and utility.  
• Users need to know appropriate tools and methods to process a chosen dataset.  
• Visualization is important for navigating and interacting with large-scale data. | • Link dataset to similar datasets  
• Link dataset to publications citing and similar publications  
• Natural Language Processing of query and UMLS concept mapping to improve breadth of search  
• Incorporate Data Tag Suite (DATS) as core metadata model for indexing datasets  
• Visualization of timeline and word cloud |
| II – Usability Testing        | • Users liked that the search interface matches PubMed interactions.  
• While they appreciated aggregated results from multiple repositories, users needed more information about search results and detailed descriptions of individual datasets. | • Metadata was improved to DATS 2.0 with additional nodes.  
• Process for ingestion of datasets into a uniform metadata descriptor |
While DataMed supported retrieval of highly specific datasets, exploring general topics datasets or discovering new datasets continues to be challenging. Assessing search results proved to be difficult due to incomplete or inconsistent metadata across datasets. Ongoing study – Potential design changes:

- Improvement to metadata model
- Improving indexing based on user preferences and interactions with datasets.

Discussion

The results presented here highlight key issues of metadata, data standards, and visualization in searching for and using biomedical data. Researchers attempting to find data online face a complex environment with diverse sources, formats, and types of data that can be difficult to navigate and require significant time and effort to utilize. Standardized formats, vocabularies, and documentation for datasets need to be developed for user to easily find and assess relevant data. Further, visualization techniques have the potential to support navigation and analysis of datasets, but current methods do not support this kind of interaction at scale.

To support user needs in finding relevant data, DataMed attempts to resolve the disparity in data sources by defining a common metadata model and applying tools for information retrieval. DataMed thus satisfies the basic definition of a DDI and provides an intuitive model for searching datasets. However, our initial findings show that searching for biomedical data poses a similar, but distinct problem from searching for websites or publications. Researchers' assessment of the usefulness or relevance of a dataset is not possible from only from summaries such as keywords, title, or abstract. Initial usability testing revealed that while aggregating metadata into a common search engine is an appealing solution to this problem, the inconsistency and incompleteness of most dataset metadata limits its usefulness for users. Ongoing usability evaluations indicate common and essential information such as the samples collected, collection technique, data processing methods, and statistical summaries are necessary to determine whether a dataset is suitable for a research topic.

Conclusion

Simply making data available is not enough: we emphasize the importance of conducting user needs analyses and usability evaluations in developing data infrastructures to support biomedical research. Promising research areas for improving the discoverability of data include: refining metadata models for describing datasets, developing standardized and analytic summaries of datasets, and improving user interfaces to large amounts of data through visualization. Future efforts in developing a DDI can leverage these insights to provide researchers with efficient and usable interfaces to datasets.

Leveraging Electronic Health Record Data for Community Health Assessment and Surveillance

Brian E. Dixon1,2, P. Joseph Gibson1,3, Karen Frederickson Comer4, Jian Zou5, Jennifer Williams2, Marc Rosenman2,6
1IU Fairbanks School of Public Health, Indianapolis, IN; 2Regenstrief Institute, Indianapolis, IN; 3Marion County Public Health Department, Indianapolis, IN; 4Indiana University-Purdue University Indianapolis, Polis Center, Indianapolis, IN; 5Worcester Polytechnic Institute, Worcester, MA; 6Feinberg School of Medicine, Northwestern University, Chicago, IL

Abstract

Increased adoption of electronic health records presents an opportunity to enhance assessment, a core function of public health, by enabling access to up-to-date data on disease burden and outcomes. We will present how we’ve leveraged routinely collected and geospatially-enhanced EHR data available from a regional health information exchange to augment assessment at a county health department. We will highlight neighborhood level indicators developed for the project, data visualizations, and issues of representativeness or bias in the data.

Introduction

Public health authorities monitor population health to identify burden of disease, manage health assets, establish policy, and evaluate interventions. This assessment usually relies on information available through surveys, vital records, and paper-based disease reporting. These sources capture sparse data at the community level. Electronic health record (EHR) systems may provide more timely and dense data for geographic areas of interest. Yet there exist a number of challenges to routine use of EHR data, including health information exchange (HIE) between clinical and public health organizations as well as lack of mechanisms to routinely capture social determinants.

Methods

Data from multiple EHR systems within the five major health systems serving the residents of Marion County, Indiana were extracted from the Indiana Network for Patient Care (INPC), one of the oldest and most comprehensive health information exchange (HIE) networks. (1) Founded by the Regenstrief Institute and managed by the Indiana Health Information Exchange, the INPC receives data from over 100 hospitals, several physician practices, laboratories, and other healthcare facilities representing over 12 million unique patients and 6 billion pieces of clinical data.

This study included data on living individuals who resided in Marion County and had at least two clinical encounters within the health systems participating in INPC during a 3-year period beginning January 1, 2011 and ending December 31, 2013. The INPC represents 80% of Indiana citizens, but it contains data on >90% of citizens in Marion County. Representativeness is based on the 2010 decennial census data from the U.S. Census Bureau.

The study focused on population health indicators of highest interest and typically not available to health departments at levels below the county. The indicators included items measuring prevalence (e.g., prevalence of diabetes, prevalence of asthma) as well as chronic disease management (e.g., control of HbA1c, lipid control), and they were largely based on HEDIS (Healthcare Effectiveness Data and Information Set) measures that are routinely reported by health systems to payers and employers.

The denominator for prevalence measures represented the number of living individuals who received care from INPC providers during the three year time period. Health management denominators represented the number of individuals diagnosed with the disease as documented in the INPC. Numerators were defined using a combination of ICD9-CM clinical diagnostic codes as well as laboratory results and medication history data from longitudinal records in INPC.

Indicators were calculated at these geographic levels: local health department planning area (average population 40,000-50,000), ZIP code (average pop 8,000), geopolitical neighborhood (average pop 6,000), census tract (average pop 4,000), and census block group (average pop 1,500). Once calculated, indicator data were mapped using ArcGIS (ESRI, Redlands, CA) to visualize the data for local health department personnel.
Results
We generated 10 different population health indicators using data integrated from multiple EHR systems. Indicators ranged from the proportion of individuals with depression or a sexually transmitted infection to the proportion of patients with cardiovascular disease who had poor lipid control.

In Figure 1, we present a map of Marion County, Indiana, with the prevalence of diabetes by census tract. In Figure 2, we present a map of Marion County, Indiana, with the rates of diabetes control as measured by glycosylated hemoglobin (HbA1c) levels below 8.0% by those with a confirmed diagnosis of diabetes by census tract. Individuals at the Marion County Public Health Department, when viewing the maps and data depicted in Figures 1 and 2, stated that the availability of population data at geospatial levels smaller than a county is more insightful than examining the county wide rate of diabetes. Granularity was perceived as useful, because health department staff believe they may be able to target diabetes education or prevention efforts in the areas shaded in dark blue where there are either high rates of diabetes (Figure 1) or low rates of diabetes management (Figure 2) within a census tract.

During our project, we discovered that calculating rates at the census tract level or larger (e.g., average populations > 4,000 persons) is preferable. Rates at the census block level were more challenging to interpret as many blocks contained a count of zero or one. This makes comparing rates difficult, and it would be hard for health departments to release small numbered cells given concerns for privacy and confidentiality of health data.

Discussion
EHR systems include more people with more frequent contacts than do existing, standard public health data sources like surveys and death certificates. Whereas the Behavior Risk Factor Surveillance System’s estimated prevalence of diabetes is based on 500 individuals, the INPC contained information on 559,905 adults with an average of 2,500 persons per census tract. Therefore data from EHR systems could allow more frequent measurements of disease incidence and outcomes as well as more precise (tighter confidence intervals) identification of disparities.

Yet data from EHR systems also have limitations that need to be understood to fully interpret their meaning when influencing population health decisions. For example, data captured by EHR systems largely represents “sick care” as opposed to health as many people do not utilize health care facilities every year. Furthermore, some health care is provided outside of existing HIE networks, including but not limited to urgent care clinics independent of large health systems and public health clinics that are often not connected to the HIE. These additional data sources, as well as the Census Bureau and community organizations, may have unique, social determinant data that are often missing from EHR systems. Strategic partnerships and HIE models, as well as evaluation of these models, will be necessary to integrate and analyze data for population surveillance as well as community health assessment processes.

Predictors of OpenNotes use by Veterans receiving Mental Health Care

Steven K. Dobscha\textsuperscript{1,2}, Lauren M. Denneson PhD\textsuperscript{1,2}, Maura K. Pisciotta MS\textsuperscript{1}, Donald S. Bourne MPH\textsuperscript{2}, David Philipps-Moses BS\textsuperscript{1}, Susan Woods MD, MPH\textsuperscript{3}

Introduction

Several healthcare systems across the U.S., including the Veterans Health Administration (VHA), offer patients online access to their clinical notes. Clinical notes are progress notes clinicians and other staff write in patients’ medical records to document healthcare visits. Online patient access to clinical notes, also referred to as OpenNotes, is facilitated by electronic patient health portals. Patient access to clinical notes has been shown to facilitate patient engagement and to strengthen the patient-clinician relationship (1,2). Some individuals have raised concerns about potential negative consequences of patients reading mental health clinical notes (3). However, recent research suggests that reading clinical notes online can strengthen patients’ trust in mental health clinicians and improve the therapeutic relationship (4). Despite these potential benefits, it is unknown to what extent, and which, patients with mental health conditions read their clinical notes online. The objective of this study was to identify demographic and clinical predictors of utilizing OpenNotes among veterans receiving mental health care.

Methods

This study was approved by the Institutional Review Board of the VHA Medical Center (VAMC) where the study took place. The VAMC is located in the Pacific Northwest. Approximately 200 mental health clinicians provide mental health services to 18,000 unique veterans across a range of programs and sites. We recruited and enrolled participants from February to July of 2016. Veterans were eligible to participate if they had 1) completed at least one in-person mental health appointment at the VAMC; and 2) logged into VA’s electronic health portal, MyHealtheVet, at least twice in the 6 months prior to recruitment. Exclusion criteria included: dementia or cognitive disorder diagnosis in the prior year, having a legal guardian, or recent discontinuation of mental health care at the VAMC. We mailed recruitment letters to 3,381 potentially eligible patients, and 598 indicated interest in participating. After describing the study and confirming eligibility, 407 participants were consented and enrolled. Fourteen participants withdrew prior to being sent questionnaires, resulting in 393 total participants. Participants were invited to complete a self-report questionnaire which assessed their use of, experiences with, and opinions regarding OpenNotes. The questionnaire included the eHealth Literacy Scale (eHEALS) (5) and several items adapted with permission from the Robert Wood Johnson Foundation’s OpenNotes project (1,6,7). We also extracted diagnostic and utilization data for the year prior to the study from VHA’s Patient Care Database. In analyses, multivariable logistic regression and tests of trend were used to examine relationships between self-report of having read OpenNotes and demographic and clinical characteristics; EHEALS score; patient-clinician communication about OpenNotes; confidence in understanding of the purposes and uses of Blue Button, and level of importance to the veteran of using OpenNotes.

Results

Of 393 participants who received questionnaires in August 2016, 359 (91%) returned questionnaires. Three hundred thirty-eight (94%) had complete sets of responses. There were no statistical differences in demographics when comparing respondents and those who failed to return questionnaires. The average age of respondents was 57.8 (sd=12.3); 68% were male; 55% married; 89% white; 56% not working; 9% with a high school education or less; and 32% lived in rural areas. In the prior year, 58% were given a diagnosis of post-traumatic stress disorder (PTSD), 60% were given a depression diagnosis, and 17% were given a bipolar disorder or schizophrenia diagnosis.

Fifty percent reported having ever read or downloaded their clinical notes through the My HealtheVet portal, and 17% recalled having spoken to their mental health clinicians about OpenNotes. The mean eHEALS score was 28.7 (s.d=6.7). In bivariate analyses, younger veterans (55.6 vs. 60.5; p=.001), veterans with PTSD diagnoses (63.9% vs. 52.7%; p=.047), and veterans who recalled having discussed OpenNotes with mental health clinicians (83.4% vs. 16.6%; p=.0001) were significantly more likely to report having read OpenNotes. In the final multivariate logistic regression model, PTSD diagnosis (OR=2.30 [1.31-4.07]), having spoken with a mental health clinician about the
availability of OpenNotes (OR=3.84 [1.69-8.72]), and patient confidence in understanding of the purpose and uses of OpenNotes were significantly associated with having read or downloaded OpenNotes. There was also a significant trend for the association of OpenNotes use with patient rating of the level of importance for health and recovery to have access to personal health information using OpenNotes (p<.001).

Discussion
To our knowledge this is the first study to examine predictors of use of OpenNotes in a population of patients receiving active mental health care who had access to them through an electronic health record portal. Not surprisingly, in our bivariate analyses, we found that younger age, education, and eHealth literacy were associated with OpenNotes use; these factors have been found to be associated with use of the internet and eHealth resources in prior studies of other patient populations (8,9). Recalling having spoken with their mental health clinician about OpenNotes was a strong predictor in the final model of having used OpenNotes.

We found that veterans with PTSD were more likely to be use OpenNotes that other patient groups; PTSD diagnosis was also a predictor of OpenNotes use in the final model. It is possible that anxiety or the challenges with trust (10) that have been associated with PTSD may drive desires to examine clinical notes. We also found in a prior study (4) that veterans with PTSD often have active claims for disability; such claims frequently depend on information in the record. Clearly, this finding needs to be explored in more depth. We also found that patients with schizophrenia or bipolar disorder were not less likely to use OpenNotes compared to other groups—findings regarding this population’s use of the internet have been mixed. Although one prior study showed that veterans receiving mental health care were not less likely to use MyHealthVet than veterans not receiving mental health care (8), other studies have found that veterans with serious mental illness report less internet and electronic health portal use relative to the general veteran population (8,11,12). Our study was limited by use of self-report of OpenNotes use.

Conclusion
Together, our findings demonstrate the value of mental health clinicians openly discussing OpenNotes with their patients if they wish to help them take advantage of the benefits OpenNotes may offer. We likely need to develop and disseminate tools to clinicians to help them engage in these proactive discussions, and further research should be conducted to better understand potential barriers to use of OpenNotes among patients with mental health conditions.

The Role of Chronic Inflammation as a Response Biomarker to Immune Checkpoint Inhibition in Cancer

Sherif M. El-Refai, PharmD, MBA¹, Val R. Adams, PharmD¹, Esther P. Black, PhD¹, Jeffery C. Talbert, PhD¹
¹University of Kentucky, Lexington, KY, USA

Abstract

Chronic inflammation provides cancer patients the ability to mobilize a swift immune response to tumor cells with checkpoint inhibition. Prior studies utilized animal models or human tumor samples, however, we have taken a novel approach to leverage national claims data to couple patient histories with response to therapy. We seek to identify a biomarker of response to immune checkpoint inhibitors that improves patient care using healthcare histories and molecular markers that correlate with therapeutic efficacy.

Introduction

Agents that unmask the anti-tumor immune response have provided some patients durable clinical benefit. Nivolumab, an immune checkpoint inhibitor (ICI), is effective in a small group (10-20%) of non-small cell lung cancer (NSCLC) patients when used as single-agent therapy. The approved biomarker of response is expression of the immune cell surface molecule, programmed death ligand 1 (PD-L1), on tumors measured by immunohistochemistry (IHC). The limitations of this assay include timing of tissue acquisition, tumor heterogeneity, and timing of therapy relative to the expression of PD-L1. Applying precision medicine to immuno-oncology requires the discovery of predictive biomarkers that can identify the patients most likely to benefit from this class of treatment.

Inflammatory diseases are, in part, caused by poor lifestyle choices and can contribute to cancer development. Paradoxically, the presence of inflammatory diseases may serve as biomarkers of durable response to immune checkpoint inhibitors. Our work provides experimental evidence that improves our understanding of the role of chronic inflammation in response to ICI. To position both wet lab and clinical studies that identify and validate components of the best biomarker of durable response, we initiated this project using claims data and informatics tools to ask whether ICI response and associated chronic inflammatory conditions are related. We identified a biomarker of response to PD-1 or PD-L1 inhibitors that improves patient care using a combination of healthcare outcomes and molecular markers that correlate with therapeutic efficacy.

Our preliminary data shows that chronic inflammation plays a role in ICI response. In an institutional IRB-approved study, 45 former and current NSCLC patients treated with a PD-1 inhibitor were assessed for a correlation between their history of chronic inflammation and ICI response. Patients with a history of at least one chronic inflammatory condition received more cycles of nivolumab therapy than those patients who did not have these conditions (Unpublished Data).

Study Design & Methodology

We utilized the Truven MarketScan claims database to identify cancer patients treated with ICIs, their responses, and their health histories to correlate ICI response with inflammatory disease pathologies. We characterized the response of cancer patients to ICI to determine whether durable response correlates with a history of chronic inflammation using health outcomes data. This study design takes advantage of our prior experience in the analysis of Truven MarketScan claims data 1, 2. We hold licenses for the use of the Truven MarketScan Claims database and this study represents ongoing collaboration with the director of the Institute of Pharmaceutical Outcomes and Policy (IPOP), Dr. Jeffery Talbert.

Adults aged 18 and older treated with an ICI between January 1, 2010 and December 31, 2015 were identified using J codes associated with the medications nivolumab, pembrolizumab & ipilimumab. The rate of all-cause death up to one year after diagnosis was compared by Cox proportional hazard regression. Patients were required to have at least a 24 month pre-index period. Chronic inflammation exposure groups were defined as patients with prior diagnosis of diabetes, hyperlipidemia, hypertension, obesity or chronic obstructive pulmonary disorder. Patient demographic characteristics included age, gender, geographic region and urban residence. Clinical characteristics measured during the 12-month pre-index period included previous chemotherapy use, previous radiation exposure, and the Charlson Comorbidity Index (CCI) 3. This includes 17 categories of comorbid conditions and is widely
used for risk adjustment with health outcomes data. Propensity score matching was conducted using the following variables: age, sex, region, CCI comorbidities, previous chemotherapy and previous radiation exposure. Cohorts were matched using a greedy, nearest neighbor algorithm with a caliper set at 0.2 times the standard deviation of the propensity scores in the sample, allowing for up to two matches. Propensity score matching mimics the randomization process of a clinical trial so that each matched pair has the same baseline probability (propensity) to respond \(^6\). Two-sample t-tests and chi-square tests are conducted to assess differences between cohorts before and after matching. Cox proportional hazard regression models are used to assess response and risk of death. Hazard ratios and their 95% confidence intervals are reported.

**Results**

Among 3,252 ICI-treated cancer patients identified in the Truven dataset, 2,339 had a history of chronic inflammation. Pre-existing chronic inflammation improved overall survival compared to no history of chronic inflammation (HR 1.23, 95% CI 1.01-1.50), specifically in patients with melanoma (HR 1.26, 95% CI 1.01-1.58). No differences were observed in patients diagnosed with lung cancer (HR 1.35, 95% CI 0.82 – 2.23). All results presented in Table 1. This study is subject to the limitations of all claims-based studies \(^7\), \(^8\). Notably, claims data lack detailed information on laboratory values or information on tumor staging. Additionally, studies with longer follow-up are needed to confirm whether chronic inflammation alters ICI response.

**Table 1.** One-year survival analysis. Hazard ratios (HR) and associated 95% confidence intervals (CI) for the effect of chronic inflammation on survival within the propensity-matched sample.

<table>
<thead>

<td>1.01 - 1.58</td>
</tr>
</tbody>
</table>

**Conclusions**

Our study suggests that a history of chronic inflammation improves response to immune checkpoint inhibitors. These findings concur with our prior 45-patient retrospective analysis. Importantly, this is the first study that has assessed the impact of chronic inflammation on response to ICI. Lastly, while propensity score matching is known to reduce selection bias in non-randomized studies, residual bias may remain present. The potential of precision immunology is vast and, once validated, can be used to inform and direct treatment decisions to improve outcomes.

Applying unsupervised learning to characterize rare observations in clinical data: the DQ\textsuperscript{e}-p tool

Hossein Estiri, PhD\textsuperscript{1,2,3}, Jeffrey G. Klann, PhD\textsuperscript{1,2,3}, Kavishwar Waghokit, MD, PhD\textsuperscript{1,2,3}, Shawn N. Murphy, MD, PhD\textsuperscript{1,2,3}

\textsuperscript{1}Harvard Medical School; \textsuperscript{2}Massachusetts General Hospital; \textsuperscript{3}Partners Healthcare, Boston, MA

Introduction
Data stored in Electronic Health Records (EHR) provide promising opportunities to advance health sciences research, and thereby, improve healthcare delivery and policy. However, data quality concerns have hampered secondary use of EHR data\textsuperscript{1,2}. Plausibility is an important dimension of data quality that represents whether EHR data values are “believable” or “truthful”\textsuperscript{3}. For example, a value of 1090 is almost unbelievable as the top number for systolic blood pressure in an EHR record. It is very likely that such a record presents an inherent data quality issue. Detecting plausibility issues in EHR data values currently requires extensive hard-coded rules – e.g., for each clinical observation, we need at least two rules, to identify minimum and maximum plausible values. DQ\textsuperscript{e}-p presents an alternative algorithmic solution to identifying implausible clinical data values by applying unsupervised learning algorithms. Here we describe the tool’s working assumptions, algorithms, and initial results, and discuss our ongoing efforts to improve its algorithms and architecture.

Methods
Development of DQ\textsuperscript{e}-p is based on two working assumptions. The first assumption is that unsystematic errors are small in size. That is, we do not expect to frequently observe, for example, a blood pressure record of 1090/80 in the EHR. Under this assumption and in the context of growing EHR data networks, we can use data from multiple EHRs to compare an individual data value to a large set of similar values and identify rare records. The second assumption is that clinical data are clusterable, meaning that they can be partitioned into groups of similar observations. DQ\textsuperscript{e}-p applies unsupervised clustering to identify rare observations in clinical observation data. To develop and test DQ\textsuperscript{e}-p, we use a sample of a million laboratory records from the Research Patient Data Registry (RPDR) from Partners HealthCare\textsuperscript{4} that are utilized by two large research networks, Scalable Collaborative Infrastructure for a Learning Health System (SCILHS) and Accrual to Clinical Trials (ACT). This dataset contains laboratory results from 86 Logical Observation Identifiers Names and Codes (LOINC).

Results
Before developing the tool, we tested the second working assumption/hypothesis (that clinical data are clusterable) by calculating Hopkins statistic for each group of laboratory values. Hopkins statistic is a reliable measure of spatial randomness\textsuperscript{5}. Our results showed that 73 percent of the 86 distinct laboratory tests are clusterable. We then applied a data transformation procedure that extended the distance between data points based on their z-score, multiplying each raw lab value to a product of its z-score (as a measure of deviation from the mean). Hopkins statistic on the modified values showed that 100 percent of laboratory tests were clusterable. We later used clustering results from the raw and modified values to create a flagging system. To cluster the data, we tested a number of unsupervised clustering algorithms including variants of the k-means and hierarchical clustering algorithms. Each method had its benefits and constraints. We found that the hybrid hierarchical-k-means (H-K-means) clustering\textsuperscript{6} provided the best performance. DQ\textsuperscript{e}-p categorizes data into groups and applies H-K-means algorithm to cluster each group. DQ\textsuperscript{e}-p uses a bootstrap procedure, \textit{kluster}, which we have developed and tested to identify the optimum number of clusters for unsupervised clustering. It then characterizes rare observations as clusters to which less than one percent of observations belongs.

After clustering each laboratory test result into the pre-identified number of clusters, DQ\textsuperscript{e}-p generates three flags that represent the potential importance of implausible records and produces an html report of the flagged records for further evaluation. The most important flag type is when DQ\textsuperscript{e}-p identifies a record as rare from both the raw and modified observation values. From the 1 million observation records from RPDR data, DQ\textsuperscript{e}-p flagged 48 records under type one. These records included, for example, three Urine Protein test values above 11,300, and four Creatine Kinase test values above 104,100. Type two flags are for observation values that are characterized as rare from the raw values, but not from the modified values. DQ\textsuperscript{e}-p flagged 238 observations under this flag type, including, for example, multiple Absolute Lymphocyte Count (ALC) values of above 2,585. Type three flags represent rare events...
(records from clusters with less than one percent data points) that are only identified from the modified observation values, which present the most liberal case between the three flag types. For example, in Figure 1, DQ²-p classification on modified observation values has characterized a single observation with a value of around 579 as a potential rare observation for Low Density Lipoprotein Cholesterol (CLDL) – the record belongs to cluster 3. The three clusters for CLDL were identified using Bayesian Information Criterion with kluster procedure. DQ²-p flagged a total of 2,160 observations as type three flag.

Figure 1. DQ²-p classification of Low Density Lipoprotein Cholesterol (CLDL).

Discussion
DQ²-p offers an algorithmic solution to approximate implausible observations in clinical repositories as potential data quality issues. This approach is an alternative automated solution to the common manual procedure that require at least two hard-coded rules (minimum and maximum acceptable values) for each observation. In our development database, DQ²-p produced a report with a total of 2,398 flagged records (out of 1 million observation records, or 0.24 percent) from 86 laboratory tests – which would have required at least 172 (86×2) hard-coded rules to identify. We are evaluating the specificity and sensitivity of DQ²-p results by comparing them with results from hard-coded rules. To improve specificity and sensitivity of the tool, we are experimenting further refinements that include implementing autoencoders from Deep Learning algorithms family to complement the H-K-means algorithm, as well as distinguishing observations by gender, age, and race/ethnicity, in addition to the current of categorization by LOINC codes. We are also exploring DQ²-p as a patient characterization cell for informatics for integrating biology and the bedside (i2b2)7 to perform automated test of implausible values and characterize patients into groups with similar health status.

Decision Support to Efficiently Identify Patients for Advanced Heart Failure Therapies.

R. Scott Evans\textsuperscript{1,2}, Abdallah G. Kfoury\textsuperscript{2}, Benjamin D. Horne\textsuperscript{2}, James F. Lloyd\textsuperscript{1}, Jose Benuzillo\textsuperscript{1,2}, Kismet Rasmusson\textsuperscript{2}, Colleen Roberts\textsuperscript{2}, Donald Lappe\textsuperscript{2}

\textsuperscript{1}Medical Informatics, Intermountain Healthcare, \textsuperscript{2}Cardiovascular Clinical Program Intermountain Healthcare. Salt Lake City, UT

Introduction: Heart failure (HF) is associated with significant morbidity and mortality [1-2]. Of nearly 6 million HF patients in the U.S., 5-10\% have advanced disease that can result in poor quality of life, frequent hospitalizations and rising costs that pose a significant burden for the different health care systems in the U.S. and worldwide [3-5]. Due to a limited number of donor hearts, cardiac transplantation remains an option for only a few advanced HF patients [6, 7]. Device and advanced medical therapy can significantly impact symptoms, improve function, and reduce mortality [8-13]. Previous studies report that patients who receive early advanced therapy have better long-term survival [14-16]. Thus, it is important for the patient’s primary care physician and/or cardiologist to refer patients at the appropriate time who meet established guidelines for these advanced therapies [18, 19]. However, many HF patients who could benefit from advanced therapies are not referred to advanced heart failure facilities as soon as possible [17]. We developed a clinical decision support (CDS) application based on 2013 ACCF/AHA criteria for advanced HF guidelines [12] that promotes timely and appropriate referral for advanced HF therapies. This presentation will discuss the development, use and initial impact this CDS application has had on the care for patients identified with advanced HF.

Methods: The CDS application went into production in January 2015 and identified HF patients associated with specialized heart facilities in the Intermountain Healthcare (IH) central region when they transitioned to advanced disease. The CDS application processes patient information found during specific time periods and automatically sends patient specific email alerts to the patients’ physicians. The message in the email is dynamic, lists the different patient risk factors and HTML links are imbedded allowing the provider to easily obtain further detailed information about referring patients and management for advanced HF. Intervention patients were those identified as eligible for advanced therapies by the CDS application during 2015 and were compared to control patients in the same region who would have been identified during 2013-2014 by the same criteria and method. Patients who had previously received device therapy before they met the advanced HF criteria used by the CDS application were not included in the final analysis since they were already receiving therapy. The same IH independently developed EHR was used to monitor all patients within the IH Central region during 2013 through 2015. A before-and-after and intention-to-treat study design was used to measure the impact of the new email alerts to identify patients meeting criteria for advanced HF. Advanced HF eligibility dates were defined as the date the first email alert was sent in the intervention population or would have been sent in the control population.

Results: In 2015, email recommendations for advanced HF therapy were sent to physicians for 516 different intervention patients. An average of 1.22 (range 1-5) email alerts were sent per patient and physicians requested to no longer receive the email alerts for only 25 (4.8\%) intervention patients because the patients had been placed on palliative care or the physician was no longer treating that patient. We did not receive any response from physicians indicating the alerts were not valid or a nuisance Intervention patients were referred to specialized heart facilities significantly more often within 30 days (57\% vs 34\%; p < 0.001), 60 days (69\% vs 44\%; p< 0.0001), 90 days (73\% vs 49\%; p < 0.0001) and 180 days (79\% vs 58\%; p < 0.0001) than control patients. Age and sex were not associated with HF facility visits, but patients of non-white race were less likely to go to a specialized heart facility. Significantly more intervention patients were found to be alive at 30 days (95\% vs 92\%; p = 0.036) at 60 days (95\% vs 90\%; p = 0.0013), 90 days (94\% vs 87\%; p = 0.0002) and 180 days (92\% vs 84\%; p = 0.0001) than control patients. In addition to visiting a specialized heart facility, age and sex were predictors of mortality, but race was not. Moreover, patients in both the intervention and control populations who visited specialized heart facilities had significantly longer survival at 30, 60, 90 and 180 days than patients who did not.

Discussion: This study found that patients with advanced heart failure who visited a specialized heart facility had significantly lower mortality rates within 30, 60, 90 and 180 days of identification of advanced HF based on our criteria and supports previous studies [14-16]. However, physician familiarity with continuous advances in medical
and device therapy along with constant heart failure patient monitoring can be challenging. The CDS application that used patient specific information was found to be able to monitor HF patients each day and identify those eligible for advanced therapy and help get them referred to a specialized heart facility sooner along with a significant reduction in mortality. Cardiovascular clinicians report the CDS application and email alerts helps physicians identify patients eligible for advanced therapies sooner. Development of the application required a multidisciplinary team including cardiovascular experts specializing in advanced HF and medical informatics. As usual, the value of the CDS application could only be developed and improved through prospective use and evaluation from the cardiovascular experts.

Using Visual Analytics and Patient-Generated Data to Support Clinical Decision-Making in the Context of Nutritional Therapy for Individuals with Diabetes
Daniel J. Feller¹, Marissa Burgermaster¹, Ph.D, Lena Mamykina¹, Ph.D
¹Department of Biomedical Informatics, Columbia University

Background. As many as 9% of adults living in the United States have diabetes, resulting in $176 billion in direct annual medical costs.¹ Self-management such as dietary self-monitoring is critical to the successful management of diabetes.² Increasingly, persons living with diabetes use mobile health technology (mHealth) to capture data related to their activities and health, for example their meals and blood glucose levels.³ The growing availability of these tools has led to an explosion of patient-generated data, which can provide critical insights into health behavior and patient well-being outside of clinical encounters. However, vast amounts of patient-generated data have raised concerns regarding information overload among clinicians and previous research suggests that identifying trends in self-monitoring data is challenging.⁴ We hypothesize that visual analytics - the science of analytical reasoning facilitated by advanced interactive visual interfaces - can enable the use of patient-generated data for clinical decision making.⁵ This study sought to (i) use participatory design to develop a novel visual analytics tool capable of revealing meal patterns associated with blood glucose changes and (ii) evaluate the usability and efficacy of the interactive tool with registered dietitians.

Methods. Participatory design was used in the development of Glucolyzer, an interactive tool featuring hierarchical clustering and a heatmap visualization to help registered dietitians (RDs) identify associative patterns between blood glucose levels and nutrition in meals. 10 RDs were recruited for a within-subjects experiment to compare the interactive tool to a static HTML representation (that is consistent with a meal log structure typical for meal diaries). Participants had 25 minutes to examine 1 month of diabetes self-monitoring data including photos of meals and blood glucose readings captured by an individual with type 2 diabetes. A ‘think-aloud’ protocol was employed and trial transcripts were transcribed and analyzed to reveal thematic content.

Results. 10 certified diabetes educators (CDEs) participated in the study. Participants generated 101 observations using the interactive tool and 70 using the static representation. Participant statements were more accurate using the interactive tool (69% vs 62%). Glucolyzer enabled participants to consider large groups of meals and identify more than 2x as many person-specific trends in glycemic impact. Usability was high although participants were varied in their enthusiasm for hierarchical clustering, which identified groups of meals with similar macronutrients and glycemic impact.

Discussion. Our findings suggest that computational learning and visual analytics may encourage the meaningful use of patient-generated data in diabetes by clinicians. We evaluated an interactive tool that empowers registered dietitians to analyze large volumes of data and identify reveal groups of meals with similar nutritional profiles. Glucolyzer provided insight into patterns of health behavior and glycemic control which lies in contrast to contemporary approaches to tailored nutritional therapy that rely upon the subjective assessment of psychological traits.⁶ Our results suggest that visual analytics may ameliorate concerns of information overload and thus reduce barriers to the inclusion of patient-generated data in clinical decision-making.

New Relevance Search Algorithm for PubMed

Nicolas Fiorini, PhD¹, Zhiyong Lu, PhD¹
¹National Center for Biotechnology Information, Bethesda, MD, USA

Introduction

With more than 27 million articles in MEDLINE, retrieving and ranking the most relevant papers for a given query is increasingly challenging. Starting in the 2000’s, the machine learning community have focused on document ranking and created learning-to-rank (L2R) algorithms, demonstrating that robust and accurate relevance models can be built by utilizing various relevance signals and large training datasets. Recently, this technology has matured enough to scale up to real-world applications.

The method we present in this paper is twofold and is partly inspired from the works by Liu¹ and Dang et al.² in Web search: (a) a search engine retrieves papers that match a query and order them using a classical weighting model, commonly BM25³; (b) it reorders the most relevant documents retrieved using L2R – in our setup, L2R reorders the top 500 documents returned by Solr, an open-source indexing tool supported by a large community. L2R relies on a robust and accurate model heavily trained on thousands of queries. The main differences from previous approaches lie in that we need to design the system – further referred to as Solr-L2R – to fit the biomedical literature, and that we need to optimize it to handle PubMed load peaks.

Methods

In order for L2R to learn a model, it needs a gold standard to target. While there are many general Web search datasets available due to popular challenge tasks, biomedical datasets are rarer, smaller and some of them are outdated. Moreover, they do not always represent all behaviors we observe in PubMed, where various profiles have different information needs, query formulations, etc. We therefore created a training dataset from actual PubMed queries, using the anonymized queries stored in the logs, as well as any actions users subsequently took. We collected about one year and a half worth of logs, from which we created the training dataset. There are two main user actions that we consider to indicate that the document relevant. One is the abstract click, when a user clicks on a document in the list of results matching their query. The other is full text click, which occurs when a user requests the full text, after having clicked on an abstract.

We collect log data by following three steps. (1) We count all clicks for each article for each query; (2) we store the query and the corresponding articles that have at least one abstract click, as well as the 20 first results that have been returned by the system to the user; (3) we keep queries that appeared at least ten times – about 46,000 remain – and sum up the clicks for each article, for each query. This last step limits noise in the data by focusing on popular queries.

Documents have to be ordered by relevance in the gold standard, thus we propose a way to extract relevance from click data. Let us denote a document by \( d \) and a query by \( q \). \( a(d,q) \) is the number of abstract requests for \( d \) after \( q \). \( f(d,q) \) is the number of full text requests for \( d \) after \( q \). Say \( NFT \) represents the set of articles in the corpus for which the full text is not available. \( 1_{NFT}(d) \) is an indicator function such that:

\[
1_{NFT}(d) :=
\begin{cases} 
1 & \text{if } d \in NFT \\
0 & \text{if } d \notin NFT
\end{cases}
\]

The relevance of \( d \) with regard to \( q \) is calculated as follows:

\[
relevance(q,d) = \mu \cdot a(q,d) + (1-\mu) \cdot f(q,d) + \frac{a(q,d)}{\lambda} \cdot 1_{NFT}(d).
\]

Where \( \mu \in ]0,1] \) is the weight of abstract and full text clicks, and \( \lambda \in \mathbb{R}^+ \) is the boost provided to papers for which full text is not available. The reason justifying this boost is that two papers with the same number of abstract clicks and zero full text clicks should not be scored the same if full text is available for one and not for the other. In the gold standard, documents are ordered by descending relevance. \( \mu \) and \( \lambda \) were empirically tuned in offline experiments.

Our objective is to maximize the quality at the top of the list, i.e. the first page of results. To this end, we create a training set where, for each query, we assign scores between 12 and 3 with the articles Solr returns that appear in the top ten in the gold standard, then 2 with the following 10 documents, 1 for the remaining relevant documents and 0
for the remaining documents. We chose the NDCG\textsuperscript{4} (Normalized Discounted Cumulative Gain) metric in order to assess the ranking quality and train the ranker. It is defined as follows:

\[
\text{NDCG}@k = \frac{\text{DCG}@k}{\text{IDCG}@k} = \sum_{i=1}^{k} \frac{2^{\text{rel}_i} - 1}{\log_2(i+1)},
\]

where IDCG@k is the ideal DCG@k, that is, for the gold standard relevance order. rel\textsubscript{i} is the relevance of the document at rank i in the list to be evaluated. Finally, we designed a set of more than 150 features that capture the relatedness between the query and the document (e.g., the number of matches), document specifications (e.g., its publication type) and query specifications (e.g., the query length). The features capturing the relatedness between the query and a document contributed the most to the ranking quality. Query coverage (how well a query is represented in the text) and term proximity (how close the query terms are to each other in the document) are particularly important.

Results

LambdaMART\textsuperscript{5} was the best performing L2R algorithm in our tests. We first evaluated its ability to learn from the training set by scoring the two layers of the system. The first layer is Solr and is our baseline, the second layer is the method we compare, Solr-L2R. Solr gets a score of \textbf{NDCG@20 = 0.46}, while Solr-L2R gets a score of \textbf{NDCG@20 = 0.46}. This result confirms that LambdaMART can learn from the training set and the features we designed. We manually analyzed the output of Solr and Solr-L2R by submitting them to experts in various domains. It was found that Solr-L2R is able to return documents that are both relevant and recent.

We optimized the pipeline, as it needed to comply with PubMed’s load requirements. Especially, we optimized the complexity of feature calculation algorithms for the top 500 documents returned by Solr, as it was the most computationally expensive step. It is now able to process about a thousand queries per second in parallel at an average of 100ms per query on our computation cluster.

Finally, we evaluated the new system using an A/B testing approach with real users. We measured the performance of Solr-L2R and then-current PubMed by calculating the click through rates for each, that is, the proportion of queries where users click at least once on the first page of results. Solr-L2R showed an improvement in terms of click through rates of \textbf{10.8\%} over PubMed.

Discussion and conclusion

The results show not only that Solr-L2R provides documents that are much closer to ordering of the gold standard’s order (shown by NDCG increase), but also that the gold standard we created accurately represents how to answer users’ information needs (shown by click through rate increase). The new PubMed relevance search algorithm has been deployed in PubMed production system and is used when ‘Best Match’ sort order is selected by the users. Over time, users will generate more click data and Solr-L2R will be re-trained on more accurate targets, thus improving the search quality over time. We will be able to check this hypothesis by monitoring click through rates as we improve the model.

Forecasting the Maturation of EHR Functions among US Hospitals

Eric Ford¹, Hadi Kharrazi¹
¹ Johns Hopkins School of Public Health, Baltimore, MD, USA

Abstract
This study forecasts the maturation of EHR functionality and applications among non-federal US hospitals until 2035. HIMSS’ EMRAM data is used to train the Bass technological diffusion model. According to the forecast, the majority of hospitals will not reach Stage Seven of EMRAM until 2031, provided there are no major policy changes.

Introduction
The Meaningful Use (MU) program has propelled the adoption of EHRs among US non-federal hospitals. In 2008 only 9.4% of eligible hospitals used a comprehensive EHR, while this figure increased to 44.4% in 2012, and reached 83.8% of all non-federal hospitals in the US by the end of 2015 (1). Studies have shown that the adoption of EHRs (attesting to MU stage-2) has been slow in certain types of hospitals but the overall adoption has increased in all types of hospitals (urban and rural; teaching and non-teaching) (2). These studies, however, neither evaluated the adoption of advanced functionalities of EHRs (i.e., higher levels of HIMSS’ EHR maturation level (3)) nor forecasted EHR maturation over an extended period of time. The purpose of this study is to explore U.S. hospitals’ EHR technology development and adoption patterns (following a gradual upgrade of functionality and applications).

Methods
The HIMSS Analytics’ Electronic Medical Record Adoption Model (EMRAM) dataset was used to track historic uptakes of various EHR technologies and functionalities considered critical to improving healthcare quality and efficiency in hospitals (3). The Bass ‘BB-01 Generations’ model was used to model the technological diffusion rates for repeated EHR adoptions where upgrades undergo rapid technological improvements (4). The forecast used EMRAM data from 2006 to 2014 to estimate adoption levels to the year 2035. In addition, the model produced EMR sophistication forecasts describing how many hospitals will have achieved what level of capability in the near future. Microsoft Excel’s Visual Basic and SAS were used to train and apply the model to EMRAM data.

Findings
In 2014, there were over 5,400 hospitals that completed HIMSS’ annual survey of EMRAM. In 2006 the majority of the US hospitals were in stages 0, 1 and 2 of EMRAM while in 2014 most hospitals achieved stage 3, 4 and 5 of EMRAM (Figure 1).

Figure 1. Distribution of EMRAM scores in US Hospitals from 2006 to 2014
The overall Bass model reached an adjusted R-squared of .91. The final forecast depicted various trends for each of the EMRAM stages (Figure 2). The first year of observation (2006) already shows peaks of stage 0 and 1 as EHR adoption predates HIMSS’ EMRAM. By 2007, stage 2 reaches its peak while stage 3 reaches its height by 2011 and stage 4 by 2014. The first three stages create a graph that exhibits an ‘S-curve’ with inflection point being the peak diffusion rate. The forecast indicates that stage 5 will reach its peak by 2019 and stage 6 by 2026. Thought this forecast extends to the year 2035, no peak was readily observed for stage 7. Overall, although by 2020 most hospitals will achieve either stage 5, 6 or 7 of EMRAM, a considerable number of hospitals will not achieve stage 7 by 2035 (Figure 2).

![Figure 2. EHR adoption forecast among US hospitals using the EMRAM maturation stages](image)

**Conclusion**

By using the HIMSS EMRAM dataset and Bass diffusion models, we were able to forecast adoption of EHR capabilities from a paper-based environment (stage 0) to an environment where only electronic information is used to document and direct care delivery (stage 7). According to the forecast, the majority of hospitals will not reach stage 7 after the year 2031, provided there are no major policy changes.

**Learning Objectives:**

1. Explain the adoption of EHRs among US hospitals using HIMSS’ EMRAM maturation model
2. Understand the differences between meaningful use adoption of EHR levels and EMRAM’s forecasting of advanced EHR functionalities and applications

Creating a Computable Phenotype for Pregnancy for Clinical Research

Bret J. Gardner¹, Jay G. Pedersen, M.S.¹, James R. Campbell, M.D.¹, James C. McClay, M.D., M.S.¹

¹University of Nebraska Medical Center, Omaha, Nebraska

Introduction:

The simple question of whether a patient is pregnant is of critical importance in the clinic and for research. There are many tests and techniques to identify this status with confidence; however, these data are stored in various forms in diverse locations by unique electronic health record (EHR) systems limiting interoperability. With this diversity, determining an accurate answer to this query from EHR data has proven challenging. In an analysis of computerized physician order entry (CPOE) and decision support systems, Metzger et al noted 85% of adverse drug events related to pregnancy were not detected. With the increasing number of distributed research networks and federated queries for cohort identification, an accurate and interoperable approach to assessing pregnancy status is essential.

While many research protocols require knowledge of pregnancy status, the identification of pregnancy from EHR data is often made ad hoc and is not documented to be sensitive or specific. Our approach is to identify a validated pregnant population and age-matched control group, assess the frequency and predictive power of available facts from the EHR indicative of pregnancy, and create a valid logistic discriminant model for pregnancy status.

Method:

We proceeded to identify the cohort of all pregnant patients seen for any care at the University of Nebraska Medical Center (UNMC) during 2015 using a two-step process. We first employed our de-identified i2b2 data warehouse (IRB #132-14-EP) to retrieve obstetric episodes and employed the associated patient set to explore the discriminant value of data elements listed in table 2. Contingency tables were created to compare the pregnant cohort to a control population using Pearson Chi-Square tests for significance for each variable. For a control group we restricted our population to females between ages 15 and 50 years without a pregnancy episode noted. When IRB approval for exemption status for chart review is obtained, we will supplement case identification with record review of patients noted to have suggestive findings. NLP methods will be employed to search for episodes with scant EHR findings. The recorded date of delivery or termination of pregnancy coupled with estimated dates of conception based on gestational age will bound each pregnancy episode in the study cohort. We will confirm a study population of all patients with a pregnancy episode anytime in 2015. An age-matched control group will be randomly selected from women of the appropriate age who were seen for primary care services at UNMC during the same year.

Refining the Predictive Model:

Once the study population is confirmed, we will refine the criteria for a positive finding by review of temporal frequency of results in the study group. For example, in the case of a pregnancy test, we will choose random sampling times during the study year and explore the temporal relationship of positive findings to sample time. Since pregnancy tests are typically done as early as two weeks into a pregnancy and reliably become positive at 8 weeks, we would expect that random sampling of records would yield positive findings for pregnant patients with events in the previous 8 months. We might then conclude for optimal sensitivity and specificity that a positive pregnancy test within the last 7 months would be our best definition.

Once the variable set has been defined for categorical results, observation data sets will be retrieved for the study and control populations at several time intervals during the study year, probably quarterly. These data sets will be analyzed using multiple logistic regression techniques to determine the most parsimonious and valid model for a finding of pregnancy status. Varying the temporal definition of the independent variables, resampling at multiple times of year and varying the logistic threshold for assignment, we will perform sensitivity analyses and construct a receiver operating characteristic (ROC) curve for validation of the model. From the ROC we will determine the optimum discriminant strategy.

Preliminary Results:

The demographic characterization of the pregnant and control populations from the de-identified record review of step one are described in Table 1. The majority of both the pregnant cohort and control group were white (64% and 74%, respectively). The median age for this female population was 29 for the pregnant cohort and 33 for the control group. The frequencies and p-values for covariates are shown in Table 2. All variables demonstrated a statistically significant difference with the control population. The serum pregnancy test was more prevalent in the control group.

Discussion:
An accurate predictive model for identifying the pregnancy status of a patient is paramount for clinical research. We have described a set of discriminant variables, readily available within an EHR which may be employed to compute probability of a concurrent pregnancy. Based on these covariates, using a pregnant cohort and a matched control population, a predictive model will be developed, tested and reported at AMIA. Plans for validation and characterization of the model for use in research study design and execution are discussed.

References
INTRODUCTION

Infectious diseases and antimicrobial resistance constitute one of the most pressing challenges for healthcare systems. Current responses to such challenges acknowledge the vital role played by citizens and aim to benefit from increased population self-efficacy. Clinicians, patients and potential patients can benefit from timely, easily accessible, and region-specific information about communicable infectious disease activity in their communities. Access to such information has the potential to improve decision making in the context of extremely common conditions that account for a majority of acute, ambulatory healthcare utilization and are associated with threats to patient safety (e.g., unnecessary antibiotics, adverse drug events) and patient satisfaction (e.g., complaints relating not getting an antibiotic).

Advances in infectious disease molecular diagnostics, data warehousing and analytics, and data visualization and dissemination platforms have made it possible to provide front line clinicians and health care consumers with access to timely, population-level and regionally relevant information about infectious disease activity in the populations being served by healthcare delivery organizations. These technologies combine to provide unprecedented access to information that can aid and inform clinical decisions for both caregivers (effective diagnostic test utilization, improved antibiotic stewardship, improved patient education) and care seekers (aid with self diagnosis and management, knowing when to seek care, overall more informed consumers).

Utilizing clinical data routinely generated during healthcare delivered in an integrated delivery system including 23 hospitals and >150 clinics, GermWatch provides Utah’s citizens with timely information about regional infectious disease activity including common respiratory tract infections (e.g., Influenza, RSV, Pertussis).

METHODS

We used focus groups with clinicians and parents to elucidate design objectives and iterative design principles to guide development of multiple approaches for disseminating information about regional infectious disease activity in Utah. The focus groups with parents addressed five topic areas: response to symptoms, frustrations with healthcare encounters, information sources and needs, parent overall reaction to the GermWatch concept and suggestions for how to improve the system.

RESULTS

We identified several salient themes regarding acute respiratory tract infections that helped to inform the design of our consumer facing information resource including: 1) a need for information to help understand when to seek care (red flags, warning signs) and what care to expect (symptom management, role of diagnostic testing and antimicrobial therapy), 2) a need for information that helps empower them as a consumer and facilitate efficient diagnosis (what symptoms and concerns to discuss, what questions to ask), 3) information needs about diagnosis and expectant management (more than “it’s just a virus”), 4) consensus that just searching the internet is inadequate, often overwhelming and misleading and surveillance information is not relevant to my community, 5) the desire to consult a trusted local source (friend or family member in healthcare, their clinician or other medical experts) and have information presented in an easy to interpret form.

The high-level system architecture is shown in Figure 1 and the web site is available at www.GermWatch.org.
tables in the enterprise data warehouse, transforming and loading (ETL) it into a dedicated multidimensional schema. From there, we run additional ETLs to further process, analyze and aggregate the data for use and display in the various components of the system. We use COTS business intelligence tools (IBM Cognos and Tableau) to build, display and distribute data visualizations including dashboards, epidemic curves and HIPPA-compliant (via expert determination methodology) maps that display surveillance information aggregated at a sufficiently small geographic area so as to both protect privacy and provide information that is meaningfully granular in a spatial sense (Figure 2).

Surveillance information – “What’s going around” – is presented in an easy to interpret, activity-sorted list on the landing page. Clicking on an individual pathogen takes you to a dedicated subpage in our GermSchool, where the user can see a current epidemic curve and map for that pathogen (Figure 2) along with static content addressing consumer information needs including: typical seasonality, common signs and symptoms (also presented in a novel information visualization we call the ‘Infection Timeline’, as shown in Figure 3), method of transmission, diagnosis and treatment and when to seek care.

Web site and app traffic: between 9/1/2015 and 3/1/2017, the site has seen over 450,000 page views, 90,000 visits and 60,000 unique visitors. The site averages over 2,500 page views per week during summer and over 10,000 page views per week during the peak of cold and flu season.

DISCUSSION

This free service helps Utah’s healthcare providers and potential healthcare consumers stay informed about what germs are circulating our communities. Providers having access to information about what germs are going around helps them stay alert for the illnesses caused by these germs. This alertness can improve provider diagnostic accuracy (getting the right diagnosis), which, in turn, makes it easier for them to provide the right treatment and the right information to the right patient at the right time. Potential healthcare consumers having access to a responsively designed web site that connects them to this information resource along with tools that help them identify and access related healthcare resources has opened up exciting new opportunities for radically transforming extant acute healthcare delivery models to support a consumer-centric approach focused on delivering the right care to the right person in the right place. In these new models of care delivery, a potential healthcare consumer with an acute illness is able to see what illnesses are active in their region and if other people in their region are having similar symptoms. To address unmet information needs or concerns with a clinician, they can view nearby urgent care facilities and schedule an appointment at the clinic showing the shortest wait time with a provider knowledgeable about “what is going around”. Better yet, they might avoid the clinic visit altogether by learning enough to effectively self-manage their illness at home or by participating in a telemedicine consultation right from their device with a provider that is similarly knowledgeable about what illnesses are active in their community.

CONCLUSION

Sustained use of the consumer facing GermWatch system suggests significant and ongoing interest in this kind of information resource. Additional study is required to understand how this information is being used, how it is affecting health literacy in this domain how it is impacting (if at all) self-management and care seeking decision making, and care delivery quality and experience.

Measuring the Value of EHR’s Free-text in Identifying Geriatric Risk Factors

Fardad Gharghabi¹, Laura Anzaldi¹, Tom Richards¹, Jonathan Weiner¹, Hadi Kharrazi¹
¹Johns Hopkins University, Baltimore, MD, USA

Abstract

This study evaluates the added-value of EHR’s unstructured text in identifying geriatric risk factors. The study applied pragmatic pattern matching methods with sensitivity and specificity rates averaging around 84%. The denominator consisted of 18,341 elderly patients. When compared to patients identified using structured fields, free-text added a significant number of cases to each geriatric risk construct ranging from social support (99.4%) and malnutrition (87.5%), to pressure ulcer (23.5%) and dementia (17.3%).

Introduction

The elderly population is rapidly growing in the US (1), and aging adults are particularly vulnerable to health conditions that carry significant risk of morbidity and other adverse outcomes (2). Geriatric healthcare policy primarily draws from sources such as insurance claims data or structured fields in electronic health records (EHR), using diagnostic and pharmacy data to characterize patients (3). Generally, the richness of EHR free-text is overlooked due to the difficulty of extracting data (4). We examined the added-value of free-text compared to claims and/or structured EHR data in identifying 10 clinical constructs associated with increased geriatric risk: social support, malnutrition, vision impairment, falls, walking difficulty, urinary control, fecal control, weight loss, pressure ulcer, and dementia.

Methods and Study Design

The denominator consisted of 18,341 elderly patients with an average age of 75.9 years, 58.9% female, who had at least 12 months of continuous insurance enrollment and for whom EHR free-text notes existed (Table 1).

We retrospectively analyzed one year of free-text notes from the population using a regular-expression driven pattern-matching algorithm. The patterns were created from a corpus of phrases generated by geriatric experts’ manual tagging of one year of free-text notes for 185 selected patients. To maximize specificity, the algorithm identified a patient as having a construct if there were at least two positive mentions of that construct without any negative mentions of that construct. These constructs were compared to geriatric risk constructs extracted from claims and structured EHR data of the same patient population.

Findings

When compared to the manual tagging of the 185 patients, sensitivity of the proposed text-extraction method ranged from 26.8% to 89.5% and specificity ranged from 97.4% to 100% across all 10 constructs (Table 2). We further reviewed a random sample of 100+ patients from the larger population for each construct to evaluate the true positive rate for the whole population. The true positive rate ranged from 66% for weight loss to 100% for fecal incontinence, walking difficulty, malnutrition, and social support (not shown in tables).

We then compared the patients identified by our algorithm to those identified using claims and/or structured EHR data for each of the 10 constructs (Table 3). We found that free-text added a significant number of cases to each construct (% added value computed as the number of cases found only by the algorithm divided by the number of
cases found by any source): social support (99.4%), malnutrition (87.5%), vision impairment (65.9%), falls (50.2%) and walking difficulty (48.8%), urinary control (35.3%), fecal control (32.6%), weight loss (29.5%), pressure ulcer (23.5%), dementia (17.3%).

Acronyms: AFC: Absence of Fecal Control; C: Claims [structured data]; DEC: Decubitus Ulcer; DEM: Dementia;  
E: EHR [structured data]; FAL: Falls; NLP: Natural Language Processing [free text data]; MAL: Malnutrition;  
NPV: Negative Predictive Value; PPV: Positive Predictive Value; SSN: Social Support Network; URC: Urinary Incontinence;  

Conclusion

It is feasible to achieve satisfactory sensitivity and specificity using a pragmatic pattern-matching algorithm to parse the free-text of EHRs for geriatric risk markers. Claims and structured EHR data give an incomplete picture about several constructs that influence geriatric risk. There is a high possibility to miss patients with geriatric risk markers when excluding free-text from an analysis

Learning Objectives:

1. Compare the value of structured data in administrative claims and EHRs to information extracted from EHR’s free-text data in identifying geriatric risk factors and its effect on geriatric health policy
2. Explain simple methods to make EHR’s free-text useful in identifying geriatric risk factors

A Conceptual Representation of Exposome in Translational Research

Ramkiran Gouripeddi, MBBS, MS1,2, Nicole Burnett1,2, Mollie Cummins, PhD, RN, FAAN, FACMI1,2,4, Julio Facelli, PhD, FACMI1,2, Katherine Sward, PhD, RN1,2,4

1Department of Biomedical Informatics, 2Center for Clinical and Translational Science, 3Department of Chemical Engineering, 4College of Nursing; University of Utah, Salt Lake City, Utah, USA

Introduction

Recent definitions of the concept of the exposome include endogenous processes within the body, biological responses of adaptation to environment, and socio-behavioral factors beyond assessment of exposures1,2. Research in generating and utilizing exposomes is therefore translational in nature as it includes direct biological pathway alterations as well as mutagenic and epigenetic mechanisms of environmental influences on the phenome. In this presentation, we discuss an initial conceptual representation of these multi-model and multi-scale exposomic data for its use in translational research and its informatics implications.

Methods

In order to develop a conceptual representation, we reviewed 96 environmental health articles describing air quality studies. We manually extracted the type of study performed, and the description of the data used for analysis. In addition, we elicited use-cases from translational researchers for studies that could foreseeably use the Pediatric Research using Integrated Sensor Monitoring Systems (PRISMS) infrastructure we are developing3, and extracted the same information pertaining to the type of study and data description. We then classified the type of study4, categorized and matched the data based on their description to the overlapping domains of exposome1, and linked the data categories to study types based on the nature of use of the data for study analysis.

Results and Discussion

Based on the methods used for data collection (DC) (measurements or observations), we grouped exposomic data into six broad categories [Figure 1]: (1) Sensor, (2) Clinical, (3) Biospecimen-derived, (4) Participant reported, (5) Aggregates, and (6) Computational Models. We classified types of studies into (1) Basic Science and Engineering, (2) Person-centric clinical, and (3) Population studies4. When matching these data categories with existing exposomal domains1, we considered the possibility of these DCs being used for any of the above study types. Also use of these DCs need to consider differences and uncertainties in environmental measurements and true exposures. In addition, we modified the exposomic domains to reflect the proximity of DC to the subject under consideration: (1) Personal Environment: DCs from within, on or of the subject’s bodily environment, (2) Immediate Environment: DCs from close surroundings such as home, school or workplace, and (3) General Environment: DCs from larger geographic areas such as weather, environmental monitors or satellites.

Research using exposomic data is diverse and can fall anywhere in the translational spectrum5. These include those related to the research and development of sensor devices, chemistry of environmental species, atmospheric science, exposure pathways, mechanistic understanding of environmental species on the genomic for precision medicine6, pharmacodynamics studies, clinical trials, observational, comparative effectiveness, epidemiological and public health studies. When using exposomic data, limitations of the data, and in particular, uncertainties associated with using the data as exact quantifications of exposure should be important considerations (depicted in Figure 1). To our knowledge, there are no previous systematic efforts to characterize uncertainties in exposomic data for use in translational research. Discovering metadata associated with DC is a first step in characterizing these uncertainties. Integration of exposomic data requires a metadata-centric approach that stores data in its primitive form maintaining spatio-temporal integrity and minimizing transformational information loss3. Such a platform can support an ecosystem of analytic platforms and data models, environmental wide association studies2 and the eventual development of personal exposome records.

References

Figure 1. A conceptual representation of exposome for use in translational research. At the center of the figure are the three modified domains of exposome. The middle ring consists of six broad categories of exposomic data with examples. Arrows (purple or orange) between the data categories and exposome domains indicate the presence (or absence) of approximations when used to represent the latter. The outer ring represents types of translational research. Dashed arrows with +/- signs indicate uncertainties associated with using data from these domains in different types of studies. Integration of these data (e.g. with OpenFurther) requires capturing associated metadata and uncertainties.
Efficient Remediation of Terms Inactivated by Dictionary Updates

Benjamin J. Gross, MD, MMS,1 David H. Dubois, MBA, PMP,1 Mark H. Twelves MSW, LICSW,1 Roberto A. Rocha, MD, PhD1,2,3
1Clinical Informatics, Partners eCare, Partners Healthcare System, 2Brigham and Women’s Hospital, 3Harvard Medical School, Boston, MA

Introduction

Partners Healthcare System (PHS) uses a commercial EHR and a third party diagnosis dictionary, which serves as a clinical interface terminology. Providers document patients’ conditions by selecting from over 800,000 clinical terms, which are mapped to ICD-10-CM codes and SNOMED CT concepts. The diagnosis dictionary is updated periodically by the vendor, including the addition of new terms and inactivation of existing terms. PHS further customizes the dictionary, and with each update a varying number of additional terms are inactivated.

Most dictionary updates do not impede providers’ ability to enter new visit diagnoses or problems because the dictionary contains significant redundancy. Only a minority of terms has ever been selected since the EHR was first implemented over two years ago (21% of terms) and even fewer are selected frequently (99% of usage is covered by only 7% of terms). However, certain inactivated terms require replacement with semantically equivalent active terms because they have dependencies. When terms appear in patients’ records and can be used downstream we say they have “process dependencies” and when terms are linked to other system elements, we say they have “configuration dependencies”.

Diagnosis terms with process dependencies must be active to allow subsequent downstream workflows such as billing. For example, terms on a patient’s problem list may be copied as new visit diagnoses, and terms may be associated with orders that are yet to be performed. To ensure proper billing and ordering processes, these associated terms must be active. When providers attempt to access or reuse inactive terms, the EHR system offers alternatives when replacement terms are available. Providers can either accept the suggested diagnosis term, or search for alternative terms. Conversely, diagnosis terms with configuration dependencies must be active in order to prevent runtime errors or functionality gaps. Examples include terms linked to questions on a history questionnaire, and terms that trigger a decision support rule.

Inactivated diagnosis terms can be replaced in advance. For terms with process dependencies, replacements help reduce provider workflow interruptions and save them time. Automated replacements can be made using available system tools. For terms with configuration dependencies, system tools facilitate replacements in some areas, but in other areas system analysts need to make replacements manually. In rare cases, instead of replacing inactive terms, system analysts can remove or change the affected configuration items. We will describe how we identify the most appropriate replacement terms, and how replacements are made in configuration and data records.

Methods

Mapping inactive terms to semantically equivalent terms requires clinical expertise and each replacement must be approved individually. PHS has developed reports to suggest multiple options for each inactivated term. The suggestions are ranked by the assumed likelihood of equivalence, so likely matches are ranked at the top. The criteria for suggesting alternative terms and their ranking order are listed in Table 1. Suggestions with a given rank are only those that do not meet the criteria of a higher rank. For instance, a suggested term that has “similar text + matching SNOMED CT concepts + matching ICD-10 codes” to the source term (rank 3) will rank higher than a term that has “similar text + matching SNOMED CT concepts” but does not have “matching ICD-10 codes” (rank 4). For each inactive term, terminology engineers select a single optimal replacement term from the list of suggestions. Proposed mappings are then reviewed by clinical subject matter experts (SMEs) who are practicing physicians in various specialties.

Results

During the most recent dictionary update, the sum of unique inactive terms queued for replacement in each area was 880. The sum of unique inactive terms replaced in each area was 778. Replacements were made for inactive diagnosis terms associated with the elements listed in Table 2.

In order to limit the work effort, terms associated with fewer than 50 orders and fewer than 50 problems are not replaced. Providers must replace these inactive terms themselves. Currently, term replacements also do not occur in preference lists defined by individual users, or value sets containing manually selected diagnosis terms.
### Table 1 – Criteria for suggesting alternative terms and their ranking order

</tr>
</tbody>
</table>

* Textual similarity is assessed using two separate methods. “Textual match (normalized terms)” are terms that share identical normalized terms, after removal of punctuation and conjunctions, standardizing the word order and substituting words using preferred synonyms, acronyms, and morphological derivations. For example, the terms “Open Fracture of Right Tibia and Fibula, Sequela” and “Tibia and Fibula Open Fracture, Right, Sequela” both normalize to “fibula fracture open right sequela tibia”, so they are considered textual matches. The second method of textual matching determines similarity using a similarity function [1].

### Discussion

The ongoing maintenance of a diagnosis dictionary is not limited to ensuring the appropriateness of terms available for selection. Reference terminologies and code systems associated with diagnosis terms evolve over time, requiring periodic content updates that create important challenges to those responsible for system configuration and data integrity. Diagnosis terms are used in multiple ways within an EHR system, requiring an efficient process to remediate terms and codes that are inactivated and/or superseded by new ones. Inactivated terms with configuration dependencies and inactivated terms that have process dependencies at the time of the update require replacements with semantically equivalent active terms. PHS has developed a process that relies on detailed reports to suggest active replacement terms. Clinical SMEs then approve the semantic equivalence of each suggested term before replacements are made. This process must be repeated with every dictionary update. In the most recent update, for example, the effort required to find replacement terms, obtain SME approval, and implement the replacements was approximately 75 hours, involving 13 people with complementary roles and expertise. Considering 880 inactivated terms were evaluated and 236,863 replacements were made, the relatively modest effort is the result of the efficient process created by PHS, particularly the custom reports that expedite the identification of semantically equivalent terms.

PHS is considering building an application to coordinate and further streamline the process of suggesting alternative terms, obtaining SME approval, and preparing mappings for replacement in various areas. However, replacing terms inactivated by periodic updates of the diagnosis dictionary is just one example of the overall effort to maintain the system configuration and data integrity of an EHR. The costs and resources required for maintenance and support, as well as the ability and expertise needed to handle frequent changes, may be the “Achilles heel” of complex EHR systems.

A Six-Year Follow-Up of Clinical Decision Support System User Acceptability: Practice Makes Progress

Randall W. Grout, MD1, Erika R. Cheng, PhD, MPA1, Aaron E. Carroll, MD, MS2, Stephen M. Downs, MD, MS1, Nerissa S. Bauer, MD, MPH1
1Children’s Health Services Research, Indiana University, Indiana; 2Pediatric and Adolescent Comparative Effectiveness Research, Indiana University, Indiana

Introduction
Clinical decision support systems (CDSS) can improve care, but their efficacy is impacted by clinician acceptance. Prior analyses of user opinions in a pediatric CDSS demonstrated general acceptance. To our knowledge, long-term satisfaction results have not been reported among CDSS users in pediatrics. The current study examines user acceptance patterns over six years of continuous computerized CDSS integration and updates.

Methods
Child Health Improvement through Computer Automation (CHICA) is a CDSS in use for over 12 years at several urban clinics in Indianapolis, IN. CHICA gathers patient pre-visit screening data and computes a prioritized list of recommendations for providers using Arden Syntax medical logic modules (Figure 1). Providers can record responses to prompts to inform future prompts and research. CHICA was used in one health system (HS-E) with 5 clinics. Another health system (HS-U) joined in 2015. The CHICA team implements regular feature upgrades.

We administered anonymous surveys covering user characteristics and 12 core acceptability questions (Table 1). Respondents rated core questions on 5-point Likert scales. Surveys were distributed annually in HS-E between 2011 and 2016, except in 2013 (no funding). HS-U received the survey in 2016 only. We grouped core questions into function and usage domains. We collapsed responses into favorable vs. unfavorable responses with respect to CHICA (e.g., disagreeing with “CHICA makes lots of errors” is favorable). Neutral responses were coded as unfavorable. Providers were physicians or advanced practitioners; all others were non-providers. Frequent users were those who disagreed with “I rarely, if ever, use CHICA.” Intention to use CHICA was reported with “I would rather not use CHICA.” We used survey year, clinic role, part-time status, and CHICA use frequency as independent variables in multiple logistic regressions to predict a favorable response for each core question. Separately, we compared the first and last years of HS-E surveys with the HS-U survey to assess the effects of user experience and system maturity.

Table 1. Core survey questions.

<table>
<thead>
<tr>
<th>Domain</th>
<th>Questions</th>
</tr>
</thead>
<tbody>
<tr>
<td>Function</td>
<td>CHICA sometimes reminds me of things I otherwise would have forgotten. CHICA makes documentation easier. CHICA often makes mistakes. CHICA has uncovered issues with patients that I might not otherwise have found out about. I often disagree with the advice CHICA gives. The handouts CHICA produces are useful. CHICA makes lots of errors.</td>
</tr>
<tr>
<td>Usage</td>
<td>I rarely, if ever, use CHICA. CHICA tends to slow down the clinic. I would rather not use CHICA. CHICA has too many technical problems. Technical support for CHICA is very good.</td>
</tr>
</tbody>
</table>
Results

Of 354 surveys over five waves, 352 were returned. Full data were available for 93.8% (SD 0.8%) of core question responses. Compared to 2011, users responded more favorably for nearly all measures by 2016 (Figure 2); this was more heterogeneous in later years. Frequent CHICA users and providers reported favorable responses more often across several questions. Intention to use CHICA was significantly associated with frequent CHICA use.

Figure 2. Odds ratios of responding favorably to a core question. Transparent overlapping confidence intervals are below values. Reference year is 2011.

Twenty-eight survey responses from HS-U were compared to 71 (2011) and 75 (2016) from HS-E. Users with similar experience levels but a more mature CHICA implementation were more likely to report easier documentation and CHICA identifying missed issues. Users with the same maturity of software but less experience showed more unfavorable opinions in function and usage domains (e.g., worse technical support, rather not use CHICA).

Discussion

CHICA users were more favorable to both function and usage of the system over time. There was heterogeneity of user perspectives and patterns. Favorable opinions were more likely in frequent users, providers, and full-time employees. Dissatisfaction in 2015 may be attributable to the conversion from paper to electronic CHICA interfaces. Analysis with HS-U demonstrated that increasing system maturity was associated with improved CHICA function acceptance, and more user experience was associated with more favorable CDSS function and usage opinions.

These findings are consistent with acceptance models' where perceived usefulness (function domain) and perceived ease-of-use (usage domain) are key factors of behavioral intention and later use. A systematic review reported high short-term provider satisfaction for CDSS that were ambulatory, voluntary, locally developed, and included point of care recommendations – all of which CHICA fulfills. Experience with the CDSS and system quality improvement are both beneficial interventions associated with increased acceptance of clinical decision support systems.

Introduction

Like most health care systems, the VA often has patients who receive some portion of their care outside the VA. Due to the lack of interoperability among electronic health record systems, providers caring for veterans who are receiving services outside the VA may not have timely access to important information about their patients. Health information exchange (HIE) advocates believe that greater interoperability will reduce redundant testing. In this study, measures of overuse were chosen which experts suggest may be sensitive to the effect of HIE.

Methods

Intervention: A regional VA-HIE demonstration program was conducted through a national initiative called the Virtual Lifetime Electronic Record (VLER). The VA-HIE performed secure, bi-directional health information exchange between the VA and community partners organized together through the Indiana Network for Patient Care. Health care providers inside and outside the VA were able to access exchanged data. Patients were enrolled in the VA-HIE program on-site at the Indianapolis VA in outpatient clinics or through the release-of-information office.

Study design: A pre-post cohort evaluation of participants in the VA-HIE program was performed, with a concurrent control group. For the evaluation, data on care received by patients inside and outside the VA were obtained for 1 year before, and 1 year after, the index date of patient enrollment. To allow for program implementation lag time and enable providers to become accustomed to using HIE data, the first study patients were enrolled in the cohort 3 months after VA-HIE implementation. All control patients were enrolled 3 months after VA-HIE implementation.

Population: Patients were included if they had at least 1 clinical encounter at the Indianapolis VA over a 1-year period prior to the index date. Overall, 57,050 patients were included in the cohort: 6,726 who were enrolled in the VA-HIE demonstration program and 50,324 in the concurrent control group. Further, subjects were required to have at least one test record in either the year before or the year after the index enrollment date.

Measures: For each laboratory test ordered over a 1-year period, a test was considered to represent potential overuse if the same test was already performed once within a short time interval before the second test according to the following criteria: 10 days (complete blood count (CBC) and renal profile) and 6 weeks (lipid profile and liver function tests). These time intervals were chosen based upon the prior deliberations of an expert panel.

For each imaging test ordered over a 1-year period, a test was considered to represent potential overuse if the same test was already performed once within 60 days before the second test for the following imaging procedures: computerized tomography (CT) scans, magnetic resonance imaging (MRI), positron emission tomography (PET) scans, and nuclear medicine studies.

Analyses: Multivariable regression models were constructed as a function of VA-HIE intervention status, time, and baseline covariates (age, gender, race/ethnicity, marital status, insurance, service-connected disability, distance traveled to the VA, Charlson comorbidity index, and the number of provider visits in the year before HIE enrollment).
Results

There were statistically significant difference-in-differences between the VA-HIE intervention and control groups in the change in rates of potential overuse, before and after the index enrollment date, across all categories of testing (Table 1). Before and after implementation of the VA-HIE program, there was greater reduction in the rate of overuse in the enrolled versus the control group for CBC and renal profile tests (-1.00% vs. 0.98%), lipid and liver function tests (-3.03% vs. 0.16%), and imaging (-0.77% vs. 0.55%).

Discussion

Participation in VA-HIE reduced the ordering of laboratory and imaging tests at inappropriately short intervals in the ambulatory care setting. This finding is consistent with previous literature, suggesting that one of the positive impacts of health information exchange may be in the reduction of inappropriate or redundant testing. Those enrolled in VA-HIE had higher baseline rates of overuse, perhaps due to higher levels of illness than the control group. Nonetheless, the adjusted models accounted for both comorbidity and degree of outpatient utilization. The effect upon potential overuse was realized early, within the first year of implementation of the VA-HIE. Limitations of this study include our inability to assess the clinical indication for any single lab test. HIE appears to influence the ordering behavior of health care organizations, and future study can explore at whether this influence is exerted at the patient, provider, or system level.

Interactive Machine Learning for Medical Research:  
A Framework to Enhance the Engagement of Clinical Researchers

Bibo Hao, Yiqin Yu, Wen Sun, PhD, Yingxue Li, Guotong Xie, PhD  
IBM Research China, Beijing, China

Introduction

Machine learning (ML) and other big data analytics techniques have evolved increasingly in medical research. By applying ML techniques on various EHR data, data scientists and clinical researchers collaborated to build models to improve prognosis, improve diagnosis accuracy, improve the accuracy of predicting outcomes, etc.  

In the research of ML, considerable attention focused on automatic machine learning (aML), in which researchers try to automatize the whole ML life cycle and build systems that take data as input and generate classification or prediction model as output, with minimum user interaction. Pioneers in medical informatics research developed systems that take advantage of parallel computation to try and to select from different combinations of ML algorithms, strategies, and parameters. Despite the convenience of using these “black-box” aML systems, the ML pipeline and intermediate results are almost inaccessible and invisible to non-ML experts including clinical researchers. As a result, clinical researchers are out-of-loop in these systems and the ML pipelines.  

However, the engagement of clinical researchers plays a key role in medical research. It is essential for clinical researchers to truly understand the data analytics pipelines as well as properly interpret the models built from specific algorithm and data before they develop new methods for diagnosis, treatment, and prevention based on their understanding. In this study, we aim at developing a framework along with a system to support interactive machine learning (iML) that can enhance clinical researchers’ engagement in the ML or data analytics pipelines, contribute their knowledge in the analytics pipeline, and understand the pipeline like a “glass box”.

Methods

First, we break typical ML tasks in medical research into several stages and develop independent and reusable modules as an SDK for each stage, e.g., data loading, data exploration, cohort construction, feature engineering, risk modeling. We develop these modules in Python with open data science packages and including our customized algorithms and strategies. The SDK can then be used in scenarios of both aML and iML.

Second, we introduce and extend Jupyter Notebook, the popular web-based interactive development environment for data scientists, to meet their needs. In this extended Data Scientist View, data scientists can interactively perform analytic tasks by finding and calling the desired APIs of our SDK, and visualize intermediate data and results with pre-defined charts and tables. As designed in our system, a pipeline is defined by a Python class, in which each stage of the pipeline is a method of the class, and the intermediate data and results are member variables of the class. Such design makes it convenient to reuse the pipelines in aML scenario, which can run in a parallel environment with different algorithm and parameter combinations to search the best combination. Furthermore, data scientists can compose iML pipelines based on the Python class, by easily adding customized interactive HTML widgets in the same view and same notebook file. In the iML pipeline, executions of stages are invoked by the interactive HTML widget events.

Third, apart from the extended Data Scientist View, we developed a Clinical Researcher View that allows clinical researchers to use the system with a user-friendly web application like a wizard and does not require users to write code. Given an iML pipeline notebook file developed by data scientists in Data Scientist View, our system will automatically display the pipeline in Clinical Researcher View as a wizard-like user interface. In this view, users can run each step of a pipeline by fill HTML forms and click buttons. What’s more, users can pause at any step of the pipeline execution and inspect the value of intermediate data and results, like inspect the pipeline as a “glass box”.

Results

The screenshots of the Data Scientist View and Clinical Researchers View of a risk prediction pipeline are illustrated in Figure 1 and Figure 2 respectively. After data scientists composing the risk prediction pipeline in a Jupyter Notebook file, our system converts it to an interactive risk prediction task without code in Clinical Researcher View.
Data Scientists View provides an environment for data scientists to compose ML pipelines with tremendous level of flexibility, which 1) gives the data scientists full control to the pipeline, including put the pipeline in an aML use case, 2) allow data scientists to make use of their expertise to define and develop interactions for the clinical researchers.

Clinical Researchers View enhances clinical researchers’ engagement in the iML pipelines, where they can interactively set desired parameters, select or drop desired variables, inspect intermediate results, and of course, go back to previous steps to make a different choice and see the difference in results.

By collaborating in two views of our system, data scientists and clinical researchers can formulate a framework to enhance clinical researchers’ engagement in the ML loop, without sacrificing the pipelines’ use in the aML scenario.

Discussion

We developed a framework along with a system that can enhance clinical researchers’ engagement in the interactive machine learning use case. Meanwhile, data scientists can also use the pipelines in an automatic machine learning scenario. We hope this framework and system can make machine learning more approachable in medical research.

Gene annotation bias impedes biomedical research

Winston A. Haynes¹, Aurelie Tomczak¹, and Purvesh Khatri¹
¹Stanford University, Stanford, California, USA

Introduction

After analyzing samples with a high throughput technology, the de facto first step is to perform pathway or network analysis to identify biological processes that are statistically enriched in the data[1]. Researchers typically form hypotheses for their follow up experiments based on the genes or proteins involved in the enriched processes. Since the annotation resources commonly used for identifying gene functions are created by curation of the scientific literature, they typically only contain functional annotations for genes with published experimental data. Consequently, researchers select those genes or proteins for further validation that have prior experimental evidence, which, in turn, leads to more functional annotations for those genes at the expense of under-studied genes.

We hypothesized that this experimental paradigm has led to a gene-centric disease research bias where hypotheses are confounded by the streetlight effect. To test this hypothesis, we examined the annotation inequality for the human genome across a number of biomedical databases using gini coefficient, a measure of inequality such that high coefficient value indicates higher inequality[2].

Methods

Gene expression data collection and meta-analysis. Gene expression meta-analysis data was compiled from the MetaSignature database [12], which includes over 41,000 samples, 619 studies, and 104 diseases. Cases and controls were manually labeled for each disease and meta-analysis was performed using the MetaIntegrator package [12].

Data collection for disease-gene publications and SNP data. We downloaded the number of publications for each disease-gene relationship from PubPular [5, 6]. From Gene Ontology, we calculated the counts of non-Inferred from Electronic Annotation annotations for each gene [4]. For all correlations, we only considered disease-gene associations with at least 10 publications to limit false positive associations.

Results

Despite the tremendous growth of Gene Ontology (GO) from 20,826 annotations in 2004 for 7,524 human genes to 122,926 annotations for 16,173 genes in 2017, annotation inequality in GO has increased from a gini coefficient of 0.34 in 2004 to 0.50 in 2017. The growth in inequality over time validates that genes with existing annotations continue to receive even more annotations. Pathway databases, including Reactome[7] and CTD[8], have a similarly high level of inequality. Indeed, every gene annotation resource we examined displayed a similarly high level of annotation inequality, including: CTD chemical-gene associations[8]; PDB 3D protein structures[9]; DrugBank druggene associations[10]; GeneRIF gene publication annotations; and Pubpular disease-gene publication associations[5, 6]. We observed that the inequality index for many of the gene resources is higher than income inequality in any nation in the Organisation for Economic Co-operation and Development (OECD)[11].
We explored whether disease research may be affected by the inequality in gene annotation databases. In our manually curated meta-analyses of 104 distinct human conditions, we have integrated transcriptome data from over 41,000 patients and 619 studies to calculate an effect size for disease-gene associations [12]. Our meta-analyses covered diverse classes of human conditions, such as cancer, autoimmune disease, and infectious diseases. Published disease-gene associations exhibited no significant correlation with gene expression false discovery rate (FDR) rank [Fig 2A, cor=-0.005, p=0.7].

Based on these results, we hypothesized that the lack of correlation with molecular evidence may have been an artifact of research bias towards well-characterized genes. Therefore, we examined correspondence between publications about a disease-gene pair and existing knowledge about that gene as indicated by the number of GO annotations. The number of GO annotations for a gene was significantly correlated with the published disease-gene associations [Figure 2B, cor = 0.100, p=8.7e-13], but not with gene expression effect size FDR rank in disease [cor = -0.010, p = 0.136][4].

Discussion

Collectively, our results provide evidence of a strong research bias in literature that focuses on well annotated genes instead of the genes with the most significant disease relationship in terms of both gene expression and genetic variation. Despite the rise of high throughput technologies, annotation inequality has continued to grow over time. While focusing research on the best characterized genes may be natural because it is easy to formulate a mechanistic hypothesis of the gene’s function in disease, we propose that omics-era researchers should instead allow data to drive their hypotheses. To enable researchers to pursue data-driven hypotheses, we have made our gene expression meta-analysis data publicly available at [http://metasignature.stanford.edu]. By focusing on genes with the strongest molecular evidence instead of the most annotations, researchers will break the self-perpetuating annotation inequality cycle that results in research bias.

Implementing Automated Data Reporting to Improve Early Hearing Care

Shan He, PhD\(^1\), Christine Perfili, MBA\(^2\), Darren K. Mann, BS\(^1\), Matt Hoffman, MD\(^3\), Viral Shah\(^1\), Gary Anderson\(^1\), Rishabh Bhatia\(^1\), Sidney N. Thornton, PhD\(^1,4\)

\(^1\)Intermountain Healthcare, Salt Lake City, UT; \(^2\)Utah Department of Health, Salt Lake City, UT; \(^3\)Utah Health Information Network, Salt Lake City, Utah; \(^4\)University of Utah, Salt Lake City, UT

Introduction

With the widespread implementation of Early Hearing Detection and Intervention (EHDI) programs across the United States, more than 97% of newborns were screened for hearing loss, usually before hospital discharge\(^1\). However, screening is only the first step. Diagnostic follow-up testing for infants not passing the screening before discharge is essential to confirm if an infant has hearing loss and to ensure early intervention. Generally, the initial hospital-based newborn hearing screening results are reported to the jurisdictional EHDI program on a consistent basis. However, the reporting of the follow-up diagnostic evaluations is inconsistent\(^2\). In Utah, diagnostic evaluation reporting from healthcare providers to the Utah EHDI program has been manual and paper-based. The process was time consuming with no guarantee that a diagnostic report was received by EHDI. National data indicate about 35% of infants failing the hearing screening were not documented to have received the recommended evaluation. These children are classified as loss to follow-up (LFU) if they did not receive the follow-up diagnostic services, or classified as loss to documentation (LTD) if they received services without the results being reported to the EHDI program\(^2\). The LFU/LTD rate for Utah is about 13% according to the 2013 data. Improving follow-up diagnostic data reporting is considered to have noticeable impact on reducing LFU/LTD rates and achieving optimal newborn hearing care.

Methods

With funding support from the Office of the National Coordinator of Health IT (ONC), the Utah Department of Health collaborated with Intermountain Healthcare and the Utah Health Information Network (UHIN) to implement a solution that enables real-time, automated diagnostic data reporting from Intermountain Healthcare to the state EHDI program.

As shown in Figure 1, three major components comprise our implemented solution. First, event-based triggers were implemented in Intermountain’s Electronic Health Record (EHR) system to monitor infants who received diagnostic hearing testing and evaluation. Two types of events automatically fire the trigger: 1) finalization and storage of any type of diagnostic audiology report; and 2) storage of a cytomegalovirus (CMV) laboratory result. Congenital CMV is the leading non-genetic cause of childhood hearing loss. By working collaboratively with the EHDI professionals and audiologists, a total of twelve diagnostic audiology report types including the most commonly used Audiology Auditory Brainstem Response (ABR) Report and seven CMV laboratory results were identified in the EHR and configured in the trigger code list. Second, when the trigger criteria are met, the system automatically generates a standard C-CDA (Consolidated-Clinical Document Architecture) document. We chose the Progress Note template for this use case because it best suits the clinical scenario and the information need by EHDI without requiring the irrelevant data elements in other templates. Since the audiological reports were stored as free-text notes or scanned
images in the EHR, the C-CDA Progress Note was generated by embedding the entire clinical note as a media object in the “Assessment and Plan” section. Patient demographics and provider information were included in the header section and CMV laboratory results were listed in the “Results” section mapped to standard LOINC codes. Finally, the C-CDA Progress Note was sent securely to the Direct email box for the state EHDI program. Only reports on children under 6 years old are considered relevant and transmitted to the state EHDI.

Results

The automated reporting of newborn hearing diagnostic evaluation from Intermountain to the state EHDI program went live on September 2016. Between October 2016 and February 2017, a total of 1,895 C-CDA Progress Notes on 1,021 distinct patients were sent to EHDI through Direct messages. Among these documents, 1,237 (65%) were triggered by a diagnostic audiology evaluation note such as an ABR report and 658 (35%) were triggered by a CMV laboratory result. About 6% of patients have documents triggered by both types of events.

Since the C-CDA documents were generated and sent in real-time without the need for manual fax, the EHDI professionals were able to review the evaluation results as soon as they were saved in the EHR. The LTD rate for Intermountain infants diminished to zero. With faster access to the diagnostic reports, the EHDI professionals are now able to coordinate with healthcare providers and make early interventions whenever appropriate. For example, during our study period, the EHDI program identified a case where the CMV laboratory test was not ordered with the correct specimen type by the pediatrician. The EHDI staff then contacted the ordering physician to suggest the appropriate test. As a result, the infant received the reliable diagnostic result and proper treatment within a 21-day time frame, which is significantly faster than the 1-3-6 benchmarks recommended by the Joint Committee on Infant Hearing4. The standard-based electronic Progress Note also enhanced the efficiency of the Utah EHDI staff by reducing the processing time of received diagnostic reports from 3 hours per week to 1 hour per week.

Discussion

Our electronic reporting solution provides the opportunity for EHDI professionals to have real-time access to diagnostic evaluation results at Intermountain, which is the largest integrated healthcare delivery system in Utah. The project expects to accurately and timely identify the loss to follow-up patients and to increase the percentage of infants enrolled in early interventions prior to six months of age from the current 77.9% to over 90%. However, getting the data flow automatically from healthcare facilities to the EHDI program is only the first step toward an integrated public health and healthcare system. The current phase of the project requires EHDI staff to manually upload the electronic documents to the newborn hearing surveillance and tracking system (Hi-Track), which manages initial newborn hearing screening results reported by hospitals. The next phase of the project is to collaborate with the CDC EHDI team to develop standard code sets and implement the HL7 CDA standard for Early Hearing Care Plan (EHCP)3. Our early experience working with the state EHDI program to understand their data needs will contribute to the development of the new industry standards. With structured and coded early hearing information, an integration service with Hi-Track will be developed to automatically link the follow-up hearing results and interventions to Hi-Track records. A comprehensive view of a child’s hearing care will be available in the statewide EHDI hearing registry.

Conclusion

Accurate and timely hearing screening and follow-up data reporting from hospitals, audiologists, and other providers to the state or territorial EHDI program is crucial to ensure early detection and intervention for deaf and hard of hearing (DHH) infants. Our automated and standard-based electronic transmission of audiology reports can greatly improve communication and coordination between multiple caregivers. When the solution is implemented statewide, the LTD rate will be significantly reduced to near zero and the LFU can be accurately calculated based on the number of infants who failed newborn hearing screening but did not have a diagnostic evaluation received by EHDI.

Integrating Patient Registries into Enterprise wide Patient-Discovery Strategies

Christopher Herrick MBA¹, Alyssa Goodson MS¹, Wayne Chan¹, Lori Phillips MS¹, Michael Mendis¹, Shawn Murphy MD, Ph.D.¹,²,³

¹Partners Healthcare, ²Massachusetts General Hospital, ³Harvard Medical School, Boston, MA

Abstract: Some of the most valuable patient data that is available for research exists in curated disease registries. Traditionally these registries are not included in enterprise research patient query systems such as Informatics for Integrating Biology and the Bedside (i2b2) (Murphy, Weber et al. 2010). Because the effort involved in systematizing their ontologies and formatting their data into a common information model is very labor intensive Given that a solution to this problem would be a valuable asset, we developed the ability to import registries in a mostly automated fashion such that a registry owner could integrate the registry using a self-serve mechanism, achieving the integration of big and little data.

Introduction: Considerable time is often devoted to creating a set of well characterized patients, characterized by data derived from the electronic medical record or newly collected during an encounter with the patient. When the data is collected in a highly systematized manner, often congruent across multiple sites, this collection is known as a “Registry”. Given the time and effort that go into creating these collections of well characterized patients, it is puzzling why they are usually not included in enterprise research query systems such as i2b2. There appears to be at least three reasons for this absence:

1) They are often not created with standard ontologies and so do not “fit in” to many enterprise query tools.
2) The individuals who create and manage them are often not savvy to how such a database would be integrated into a structured research database such as i2b2.
3) Even if the registry owners were aware of how they could be integrated into research databases, the process of integrating many externally managed, custom collections of patient data would overwhelm the team of engineers who need to extract, transform, and load data into the enterprise research database.

To overcome these obstacles, we developed software in the BD2K Center of Excellence “PIC-SURE” which can manage the integration of patient data registries into a larger i2b2-based enterprise research database, allowing the registry data to be completely interoperable with the data obtained from the electronic medical record data (http://www.pic-sure.org).

Methods: The software solution for integrating patient registries into an enterprise query system was based upon a tool named “BRISSKit” (Butters, Issa et al, 2016) which was developed by a group in the United Kingdom. The BRISSKit software allowed a table of external data to be formatted into the star schema of an i2b2 database and the ontology to be extracted from the data. Integration of the data was then possible through the PIC-SURE distributed query system. Briefly, the overall system is architected to have the software from i2b2 act as a supervisory layer on top of various systems that can be formulated into presenting a structured observation-fact table. A workflow is set up to query and return sets of patients and structured data from the various systems through the i2b2 ontology-driven query system. Administrative and regulatory details regarding use of the data in each Data Repository is governed by the i2b2 privacy layer that constrains the use of the data to comply with HIPAA and HHS regulations (Murphy, Gainer et al. 2011). Permissions for each user are defined as part of a project which governs the access to data across the systems.

Results: A data format that is common to many data registries, or which many registries have ready-made tools to create, is the n x m common table, with rows representing each patient, and columns representing features of a patient. A common variation is to have a time-dependent encounter represented in the rows of the table, and features that the patient had during the encounter represented in the columns. These types of tables can be imported into the enterprise query system in three steps. The first step is to create the proper regulatory environment to publish the data. The data is uploaded with the IRB determination that data was collected with a broad consent or a waiver that allows use within
the enterprise. Although identifiers on the patients must be uploaded with the data to allow proper linkage to enterprise medical record numbers, these identifiers are not exposed to researchers in aggregate queries performed using the i2b2 query tool. With a level of permission in the i2b2 query tool that allows a matrix of patient data to be downloaded, this can be done under a data use agreement (for a limited data set), or an IRB protocol (for an identified data set).

The second step is to allow an ontology to be automatically generated for the registry. This is done by uploading and then analyzing the columns of the registry. The elements in the columns are determined to be values, and they are compiled from each column and determined to be numeric or enumerated. The title of the column is used in the ontology to specify the name of the concept, and if the concept is numeric a summary of high, low, average, etc. is retained to guide a query. If the concept is enumerated the values are determined to be an existing coding system (SNOMED for example), or an invention. Inventions are compiled as new sets of enumerations, and the opportunity is given to map them to existing coding systems. However, they are not forced to map them and they can still be used in queries.

The third step is to create formatted set of data automatically that integrates with enterprise queries. Each transformed table exists independently and may have several different versions, but these are formulated into the query results such that even an enterprise system with 5 billion rows can integrate an almost unlimited number of registries.

Discussion: Data from a healthcare system includes that from the medical record, but also from carefully maintained patient registries. We developed the ability to import registries in a mostly automated fashion such that a registry owner could integrate a registry using a self-serve mechanism into an enterprise wide system that supports research queries for patient cohorts and complex analytics. A significant regulatory problem was that many patient registries have their patients consented such that the data collected in the course of creating the registry cannot be made discoverable across the enterprise. The solution to this problem was to allow registry owners to create projects such that only they could see the registry data but could perform queries across all of the enterprise data. Although more limited in scope, for the registry owners this was extremely valuable because they could easily combine the registry data with all of the Enterprise electronic health care data in this fashion. Furthermore, with specific types of consents, several registries could be combined into one project and queries could be performed across registries. Overall, this allows academic medical centers that implement the open source PIC-SURE i2b2 system to rapidly and flexibly combine data from patient registries with electronic health care data and present it to their investigators in self-serve analytics.

Interpretable Clustering for Prototypical Patient Understanding: A Case Study of Hypertension and Depression Subgroup Behavioral Profiling in National Health and Nutrition Examination Survey Data

Pei-Yun S. Hsueh, PhD1, Subhro Das, PhD2
1IBM Watson Research Center, Yorktown Heights, NY, USA

Introduction

Behavioral factors are the key contributors to morbidity and mental health risk [1]. For cardiovascular diseases alone, behavioral factors have contributed to 41 percent of its global disease burden [2]. In recent years, clinical guidelines (e.g., the 2017 Type II Diabetes management guideline [3]) have established the need to better understand patient behavior and identify patient-centered goals for care plan personalization. However, such guidelines for personalization are usually not formalized and will not grow organically with the increasing knowledge of patients. The key question is, therefore, how to further inform personalized care plan by accurately and reliably quantifying the behavioral patterns from target user-generated health data?

The recent emergence of health consumers and person health IT technologies made available an unprecedented amount of patient-generated health data (PGHD) [4]. To augment the current guideline-based care plan with PGHD insights, we introduce an interpretable clustering method for uncovering outcome-differential behavioral patterns in distinctive patient subcohorts. In addition, to further enable case-based reasoning for subcohort behavioral profiling, the proposed method also explores adding the identification of prototypical users for sense-making explanation and persuasion. Curating the learned subcohort profiles has been expected to facilitate a hybrid approach of PGHD-augmented guideline deployment.

Methods

Using the self-reported outcome survey and sensor measurement data in National Health and Nutrition Examination Survey (NHANES) during 2005 and 2006, we deployed an interpretable clustering method to identify distinctive behavioral profiles related to two types of proxy outcome indicator: blood pressure control (BP) and depression. For the first BP study, we follow [5]'s footstep to use a set of 64 features generated from the accelerometer measurements, blood pressure readings and questionnaire items of 5,695 subjects. The set of features include physical activity intensity, duration, variance of activity, systolic and diastolic BP, and so on. Similarly, for the second Depression study, we use only the set of 38 features generated from the accelerometer sensor readings.

We evaluate the proposed Interpretable Clustering (IC) method that segments subjects into different behavioral segments based on their behavioral patterns and proxy outcomes. Our hypothesis is that although each feature contains only weak behavioral signals for the whole population, when considered collectively in certain sub-cohorts, these features can explain rich behavioral patterns that matter to some proxy health outcome indicator, e.g., whether a user scores less than 4 (minimal depression or none) using the Patient Health Questionnaire (PHQ-9).

In particular, we first apply the Locally Supervised Metric Learner (LSML) [6] of patient similarity analytics to estimate the outcome-adjusted behavioral distances between the users. Then, based on the adjusted behavioral distances, hierarchical clustering is employed to generate sub-cohorts and learn the key features (which contain behavioral signals about implicit user preferences and barriers) that drive the differential outcomes. An automatic tuning algorithm is applied to determine the optimal number of segments. In addition, as we expect it to be easier to interpret patient need from behavior profiles by examples, the proposed method also includes a component to identify prototypical examples (i.e., a set of top 10 subjects who are the closest to the centroid of each behavioral segment in the outcome-adjusted distance space).

Results

For both the BP and Depression datasets, five distinctive sub-cohorts are identified, each appearing in more than 1% of the subjects. Statistical and information theoretic measures are applied to infer cross- and within-subcohort behavioral patterns among subjects and identify 3-10 distinctively informative patterns for each subcohort.

In order to allow for evaluation, both global and personalized predictive models are constructed. While the former is trained on the whole population, the latter is trained for each sub-cohort. In addition, we also compare the outcome-
differentiating Interpretable Clustering (IC) method with K-means clustering and Agglomerative clustering method that do not directly account for outcome differentiation during the clustering process. The evaluation includes clustering quality, i.e. Silhouette score that indicate internal consistency by measuring how similar an object is to its own cluster (cohesion) compared to other clusters (separation), and outcome-differentiating F-statistics and z-scores. Results show that the IC-based personalized prediction model yields significantly better outcome differentiation results in terms of the sub-cohorts it produced. Although the personalized IC models did not produce more accurate risk scores than the general model, it captures more intuitively understandable patterns. Behavioral profile evaluation metrics show that further zooming into the prototypical examples helps identify distinctively more different profiles across the sub-cohorts, as demonstrated in the differences in the top behavioral patterns and those between the individual and global risk factors.

Discussion

The consumer and pervasive health informatics community is increasingly handicapped by the problem of not being able to interpret patient need. Previously, a family of patient phenotyping approaches (including the use of deep learning) has been developed to extract distinctive phenotypes from medical records [7,8] and “digital phenotypes” from digital data (including device/sensor data and self-reported outcomes) [9,10]. One missing key is a behavioral learning mechanism that can sift through user-generated health data to identify outcome-differential patient behavioral patterns.

To address this important problem, this presentation has conducted a 3-fold investigation: First, it has reviewed existing guidelines and data-driven methods of patient subgroup identification and digital phenotyping and identified gaps for realizing the personalization goal of guidelines. Secondly, this presentation also proposed an interpretable clustering approach that adds behavioral response pattern understanding into patient subgroup analysis and informs guideline deployment. Lastly, this presentation provided evaluation by scanning through NHANES data to identify behavioral profiles and prototypical examples related to blood pressure control and depression.

The result demonstrates a large potential for learning methods to derive outcome-differentiating patient behavioral insights, which in turn lend support to better decision tools for care team and facilitate positive changes in patient behavior. In addition, the proposed method also improves on the interpretability of the learning results by providing more distinctively different behavioral patterns and prototypical examples. Finally, by curating the detected sub-cohort and differential behavioral patterns, a natural next step would be to investigate whether we can better deploy guideline-based personalized care plans with better individualized interpretations.

How do physicians read electronic progress notes?

Introduction

Clinical notes are a vital part of the modern electronic health record (EHR). One important type of clinical note is the “progress note“, which typically contains four sections: subjective (S), objective (O), assessment (A), and plan (P)\(^1\). Electronic progress notes are often lengthy and contain information thought to be extraneous, irrelevant or inaccurate\(^2\). While the Assessment and Plan section is often considered most valuable to clinician, finding this information often requires users to scroll through lengthy supporting data\(^3\). There is currently a debate about whether notes should be ordered differently from the traditional SOAP format, placing narrative text earlier in the note (i.e., APSO). In practice, notes often vary in their order, due to the prevalence of customizable EHR note templates. The purpose of this study was to use eye tracking technology to determine the impact of note section order on how clinicians read electronic progress notes. If we can understand how presentation order affects reading, we can better identify strategies for improving clinical note design.

Methods

This study took place at the University of Minnesota and utilized a previously described EHR system prototype\(^4\). Second through fourth year internal medicine resident participants and fellows (n=8) were seated at a desktop computer and asked to review four patient cases as they normally would and provide a brief verbal summary of the case. Each participant reviewed the cases in the same order, but the order in which the sections were presented within the nine notes was randomized across the four patient cases, using the following four orders: all SOAP, all APSO, all SAPO and Mix (3 notes of each specified order). During the session, participants wore eye tracking glasses (SMI, Inc.), calibrated at the beginning of the session, that recorded both audio and video of what the participant said and looked at. We used screen capture software (TURF) to record interactions with the EHR. The eye tracker videos were coded by noting when and for how long participants look at each section (S, O, A, and P). Two researchers coded 25% of the eye tracker videos and resolved all discrepancies, to determine a standard coding process. One researcher coded the remaining videos. Using the coded data, we calculated three metrics for each of the four note orders: 1) the average amount of time into the case when participants first looked at each section (time to first fixation), 2) how long it took participants to read each section, normalized by the number of characters in the section (dwell duration), and 3) how many times participants looked at each section (number of glances).

Results

Figure 1 shows that for all four note orders, time to first fixation was lowest for S, followed by O, and highest for A and P, indicating that participants initially located and read information in the same order. When the sections were in all APSO, however, participants reached the A and P sections much more quickly than in the other note orders. Figure 2 shows the average time per character spent reading each section, noted as the average dwell duration. Patient cases with notes in SOAP format had the lowest dwell duration (in seconds/character), meaning there was more scanning of those notes, or that they were read the most quickly. Across all note orderings, participants read the S section the slowest (largest average dwell duration). Participants read the A section more slowly when the notes were all in APSO or all SAPO. Figure 3 shows the number of total glances at each section. When notes were all in SOAP order, participants had the fewest number of total glances, indicating that participants shifted between sections less frequently in this note order.

Discussion

We found several insights by using an eye tracker to assess how note section order impacted note reading. First, it appears that participants initially looked at the sections in the same general order (S, O, A/P),
regardless of the physical order of the note. This initial reading pattern may be due to participants’ experience reading notes in SOAP format. This implies that simply rearranging notes may not cause individuals to change their initial information search patterns, but that reading patterns may be driven by their existing practices. However, participants skipped to the A/P sections more quickly when they were presented physically at the top of the note. This suggests that APSO format may aid individuals in quickly finding the A/P sections. Participants had fewer overall glances at each section when all notes were presented in SOAP order, perhaps because this ordering is familiar and they do not have to scan back and forth across the note sections. Overall, this study provides preliminary data suggesting that note reading patterns are affected by both individuals’ existing practices, and the physical layout of the information. This study only included one user group at a single institution, and it is possible that other user groups, such as attending physicians, would be affected differently by changes in note section order. Future work should explore whether users from different specialties or with varying levels of experience are impacted differently by note ordering. Future work should also explore the impact of note order in real world settings, where clinicians may be familiar with the patient cases. Research should also explore if giving participants training or a brief “primer” on different note orders impacts their experience reading notes.

Introduction

Social Networking Analysis (SNA) is a discipline rooted in graph theory, sociology and anthropology that allows mathematical analysis of the relationships between actors in a network. SNA is advocated by the Agency for Healthcare Research and Quality (AHRQ) as a way to improve the understanding of behavior in healthcare coordination networks. 1

LOOP is a social networking application that brings together cross-professional, cross-institutional teams of care in the ambulatory environment; patients and caregivers (PtCG), where caregivers in this case are exclusively family members, exist as full participants. LOOP does not allow directed messaging; all messages are visible by all participants within that care team. A LOOP administrator, a research assistant in the study, participates in each team as a technical support resource (other participants are not members of the research team). We used SNA to assess the centrality and roles of PtCGs across 18 teams in the intervention arm of a recently completed, in press, randomized controlled trial of LOOP in patients with advanced malignancy. Teams participated for a maximum of 3 months from enrollment.

The “importance” of an actor can be assessed by centrality, represented by two metrics: degree (the number of outbound and inbound ties) and betweenness (the frequency with which an actor lies on the shortest path between other actors). 3 Actors with high degree are “hubs”, acting as a focal point for interaction, whereas those with high betweenness are “brokers”, acting as key players in the information transmission across the network. Communities of practice, like LOOP, can be defined by four social networking characteristics: density (the percentage of ties relative to the maximum number of ties), distance (the average distance along the shortest path between nodes), fragmentation (the degree to which the graph is a connected whole), and coreness (the extent to which a network has “core” actors who densely participate with each other versus “peripheral” actors who participate only with the core but not with each other). 4 The coreness of a particular actor in a network is the degree to which that actor acts as a member of the core versus the periphery. Based on prior exploratory work during LOOP beta-testing, we hypothesized that PtCGs would be highly central team members; in particular that they would show higher outdegree, betweenness and coreness than other participants, and that teams in which they participated would be more dense and connected than those in which they did not.

Methods

Audit trail messaging data from LOOP was used to create “care” networks for the 18 teams. For each message, a directed tie was considered to exist between actor A and actor B if A’s message either (a) was marked “attention to” B, (b) mentioned B by name in the text, or (c) was a reply to a message from B. Messages could generate ties to multiple actors and messages that were not about patient care (simple salutations, technical support requests from LOOP administrators) were excluded. Ties were weighted, and each additional message meeting criteria would increase the tie strength by one. External actors, i.e. those mentioned but not having an account in the system, were included; these actors were offered participation in the system but were either not contactable or refused. Impossible ties (across teams) were accounted for and not considered in the analysis.

Contingency table analysis is a standard SNA technique that assesses whether the observed patterns of interaction between block-reduced (aggregated) roles in a network differ from the mathematically expected patterns of interaction given the network density and number of actors in each role, assuming equal probabilities of interaction between any two nodes. 5 We conducted a contingency analysis across the aggregate 18-team network to assess
whether the patterns of interaction between PtCGs and healthcare providers (HCPs; predominantly medical/radiation oncologists, palliative care physicians, and home and clinic nursing staff) differed from what would be predicted; LOOP administrators were excluded. To assess the centrality of PtCGs, we compared their mean out-degree, in-degree, betweenness and coreness within their respective teams against all other team members. To assess the impact of PtCG participation on team function, we compared the density, distance, fragmentation and coreness of teams in which patients or caregivers did or did not participate.

All analyses were completed in UCINET 6.587, and comparisons used bootstrapped t-tests over 10000 iterations.

**Results**

Teams had an average of 4.6 non-administrator members, including 1.4 PtCGs and 3.2 HCPs. 74 messages were sent in total, 4.1 per team (range: 0-21). Contingency table analysis shows significant differences in the observed interaction patterns versus what would be expected (p=0.0097, Table 1). PtCGs interact with HCPs more than expected (observed/expected, O/E=1.88), and HCPs interact with patients (O/E=0.92) and with each other (O/E=0.71) less than expected. Patients have a significantly higher out degree (p=0.0071), betweenness (p=0.0037), and coreness (p=0.0004) than other actors in the care teams (Table 2). Teams in which PtCGs participate are more dense (p=0.0015), have lower average distance between actors (p=0.0023), are less fragmented (p=0.0009), and have a higher average coreness (p=0.0007) than those where PtCGs do not participate (Table 3).

**Discussion**

In LOOP, we see a pattern of asymmetric communication between PtCGs and HCPs. PtCG are central, acting in both hub and brokerage capacities, and their participation is significantly related to more tightly interacting and less fragmented teams. Tools like LOOP should consider PtCG to be integral participants. Key limitations of such an analysis are the inability to know from audit trial data whether communication is occurring outside the tool and how these patterns of communication relate to patient oriented outcomes. Further studies should assess the incentive structures for HCP participation in tools like LOOP.

Participatory Design of Probability-Based Decision Support Tools for In-Hospital Nurses

Alvin D. Jeffery, PhD, RN, 1 Laurie L. Novak, PhD,2 Betsy Kennedy, PhD, RN,3 Mary S. Dietrich, PhD,3 Lorraine C. Mion, PhD, RN4

4College of Nursing, The Ohio State University, Columbus, OH, USA

Introduction

The value of clinical decision support tools in general is increasingly recognized; however, gaps still exist in understanding interactions between users and these tools.1, 2 Notably, probability-based clinical decision support (PB-CDS) tools (referred to by some as predictive analytics), with an inherent focus on mathematical probabilities, are increasingly prevalent but have not received adequate attention regarding their influence on clinicians’ behaviors.3, 4 To facilitate the study of these tools, an initial approach would be to study a clinical situation where clinicians’ prompt decisions and actions are warranted, and using currently available data to predict events likely to occur within 24-48 hours would be ideal. In-hospital cardiopulmonary arrest meets these criteria and served as an exemplar by which to study PB-CDS phenomena. Nurses spend more time with hospitalized patients than any other clinician and became the focus of this study. The overall objective of this study was to obtain nurses’ recommendations for the design of a PB-CDS tool. In this presentation, we report our findings on the information preferences of bedside nurses, charge nurses, and rapid response team nurses for the design of a tool assisting cardiopulmonary arrest identification.

Methods

We conducted three separate participatory design sessions, each with different participants. Participatory design is a qualitative method that engages participants as co-investigators in the design process. We recruited a purposive sample (attempting equal representation of bedside nurses, charge nurses, and rapid response team nurses) from an adult teaching hospital, a pediatric teaching hospital, and an adult federal hospital in a large urban city in the mid-South region of the U.S. Each 2-hour session comprised 5-10 end-users currently working as either bedside nurses, charge nurses, or rapid response team nurses. Facilitated by at least two of the researchers, each session contained a priming activity (~20 minutes in length), a designing activity (~60 minutes), and a debriefing activity (~30 minutes).

During the priming activity, all participants watched an 8-minute video vignette in which a patient experienced clinical deterioration warranting activation of a rapid response team. The designing activity engaged nurses in the hands-on creation of a physical representation of an artificial, electronic CDS tool using paper, colored pencils, scissors, rulers, and adhesive note paper. Designing occurred in a simulation laboratory with high and low fidelity manikins and several patient rooms. This setting re-created a clinical environment that mimicked the context in which the PB-CDS tool would realistically be used. During the debriefing activity, researchers used a semi-structured guide to ask participants to share their sketches and provide rationale for their chosen visual and functional elements.

The research team leveraged theme-based content analysis, ongoing aggregation of results, as well as discussion and deliberation of nurse end-user comments and artifacts. After a preliminary analysis was conducted, we consulted with human-computer interaction and design experts to provide an informal evaluation of the tool’s proposed visual and functional elements. We synthesized all recommendations, developed a low-fidelity prototype, and shared the prototype with 14 (70%) of the nurse end-users who participated in the sessions.

Results

Six bedside nurses, eight charge nurses, and six rapid response team nurses (n=20) attended the sessions from 14 unique units. Three major themes emerged from the designing and debriefing activities and represent participants’ goals for the CDS tool: (1) communication of patient status, (2) empowerment, and (3) consistency with context. First, participants reported they wanted a CDS tool that “paints a picture” or “tells the story” of the patient condition over time. They requested the ability for individual users to select which variables become visible and layer those variables’ trends for hypothesis generation and succinct communication. The concepts of advocacy and autonomy surfaced in the second goal. If a CDS tool is designed well, the tool could empower nurses to advocate for the patient and
contribute to treatment decision-making. As an objective assessment of the patient’s condition, the CDS tool has the potential to provide participants with a structured method by which nurses can garner support for their recommendations. In the third goal, nurses agreed that the model had to make sense, and the general perception was that probability-based models are more helpful for confirming what one already thinks rather than identifying unrecognized patient conditions.

Regarding specific design elements, participants frequently expressed a desire to visualize the temporal trend of predicted outcome probabilities with user-selected overlapping depictions of vital signs, laboratory values, and outcome-related treatments and interventions. Charge nurses and rapid response team nurses had a strong request for only viewing a ranked order of the highest risk patients at first; however, when viewing individual patient information, all nurse roles expressed similar preferences. Less notable but fairly commonly-heard requests included alerts only for values exceeding an absolute threshold or high degree of change, a green/yellow/red color scheme, and the ability to view the tool on both a mobile device as well as a dashboard. Participants who reviewed the prototype did not suggest changes. The Figures are screenshots of the prototype produced from these goals and recommendations. The top 2 figures are full-size screenshots; the bottom 4 figures are partial screens demonstrating interactive features.

Discussion and Conclusion
We used the participatory design method to identify important design elements and create a prototype for a PB-CDS tool that predicts cardiopulmonary arrests. Co-creation of the tool via participatory design was beneficial because the active involvement of multiple stakeholders facilitated the identification of novel, integrative design concepts that groups of participants (i.e., researchers and end-users) might not have identified separately. Designers and developers can use and extend the goals and associated recommended design elements to create PB-CDS tools for in-hospital nurses in the future. The information we gained about the preferred design elements of predictive analytics tools that support, rather than interrupt, nurses’ cognitive workflows can benefit future studies in this field as well as nurses’ practice. As these themes and elements undergo additional testing and refinement, we anticipate they can eventually serve as standards for developing PB-CDS tools that are more likely to influence clinician behavior and ultimately patient outcomes.

Building an FHIR Ontology based Data Access Framework with the OHDSI Data Repositories

Guoqian Jiang, MD, PhD¹, Guohui Xiao, PhD², Richard C. Kiefer¹, Eric Prod’hommeaux³, Harold R. Solbrig, MS¹

Introduction

Clinical and translational research increasingly relies on the existence of robust integrated data repositories (IDRs) to combine clinical and “-omics” data. A variety of data models have been developed to provide standardized interfaces to organize research data in a clinical data repository. The Observational Health Data Sciences and Informatics (OHDSI) Common Data Model (CDM) has been increasingly used to build a large-scale international data network in support of observational studies [1]. Other data models include the i2b2 star schema, and the PCORNet CDM. These data models serve well as a layer of standardization for clinical research data within their own research network; however, if investigators want to reuse and integrate applications and accompanying research datasets across different research networks they still face huge challenges. This situation demands a global data model as a reference standard to facilitate data model harmonization and integration.

The HL7 Fast Healthcare Interoperability Resources (FHIR) is emerging as a next generation standards framework for facilitating health care and electronic health records (EHR)-based data exchange [2]. There is a critical need to build the FHIR-based data access and query on existing relational data sources to facilitate standards-based semantic data integration, sharing and discovery in broader scientific research communities [3]. The objective of the study is to develop an FHIR-based data access framework to enable answering semantic queries over the OHDSI CDM-based data repositories. We leverage the FHIR ontology and an open-source Ontology-based Data Access (OBDA) system known as Ontop [4] to demonstrate the feasibility of our approach.

Methods

Figure 1 shows the system architecture, comprising four layers: an input layer, a transformation layer, a semantic query layer and an application layer.

OHDSI CDM and Virtual Machine (VM): The OHDSI CDM 5.0.1 version (https://github.com/OHDSI/CommonDataModel) contains 39 database tables in 6 categories: standardized clinical data, standardized health system data, standardized health economics, standardized metadata, standardized vocabularies and standardized derived elements. We installed an OHDSI VM that is conformant to the OHDSI CDM 5.0.1 version. The VM contains the full OHDSI technology stack and is loaded with both standard vocabularies and sample data. The VM uses a relational database known as PostgreSQL as a storage backend. Ontop and its Protégé 5 Plugin: Ontop is an open-source OBDA system developed for querying relational data sources using an ontology-based approach. We installed the Protégé 5 Ontop Plugin (http://ontop.inf.unibz.it/), comprising 1) the Ontop Mappings tab – managing data source (i.e., database connection), and mapping creation through building an OBDA model (i.e., a specification of how the data in a data source is mapped to the vocabulary in an ontology); and 2) the Ontop SPARQL tab – providing a query editor to allow for editing SPARQL queries and executing a query to test an OBDA model. We at the Mayo Clinic have been collaborating with the FHIR and W3C HCLS community to develop the FHIR Resource Description Framework (RDF) representation specification and associated transformation and validation tools [2]. One of such efforts is to produce the FHIR StructureDefinition resource to OWL transformation, known as the "FHIR Ontology" (http://build.fhir.org/fhir.ttl). The StructureDefinition resource is the metamodel for FHIR resource definitions, meaning that a FHIR resource such as Patient, is formally defined using an instance of StructureDefinition that declares elements like “Patient.name” and “Patient.birthDate” and associated metadata and

Figure 1. System Architecture
constraints (e.g., datatype and cardinality). The FHIR Ontology formally enumerates the classes, predicates, domains, ranges and specific datatypes that are used in describing the FHIR instance data.

We first loaded the FHIR Ontology into a Protégé 5 environment, and used the Datasource manager in the Ontop Mappings tab and established the database connection to the OHDSI VM. And then we used the Mapping manager and Mapping assistant in the same tab and created an OBDA model declaring mappings between the FHIR Ontology and the OHDSI CDM database schema. The consensus of the mappings was achieved through a group discussion among co-authors. We also extended the FHIR Ontology with a number of datatype properties to capture the values of primitive datatypes. Once the datasource is connected and the mappings are defined, the Ontop Core APIs can be invoked and the SPARQL endpoints with reasoning capability (in terms of OWL 2 QL and RDFS) can be established. In this study, we used the Ontop SPARQL plugin that encapsulates both transformation and semantic query layers for the testing purpose. We created a collection of the SPARQL queries representing clinical research data questions, and used the queries to test the system.

Results and Discussion

We created the mappings for 7 OHDSI CDM tables: Person, Condition Occurrence, Drug Exposure, Observation, Concept, Concept Relationship and Concept Ancestor. Out of 7 tables, 5 tables are mapped to the FHIR core resources, i.e., the Person table to fhir:Patient (with 2 properties), the Condition Occurrence table to fhir:Condition (5 properties), the Drug Exposure table to fhir:MedicationAdministration (6 properties), the Observation table to fhir:Observation (7 properties). The rest of tables are from the Vocabulary CDM. The Concept table is mapped to a complex FHIR datatype Coding (3 properties), and the Concept Relationship table and the Concept Ancestor table are mapped to the FHIR resource ConceptMap (3 properties). A total of 418,602,850 virtual triples were produced through the mappings. We successfully created the SPARQL query templates that can identify patient cohorts using a single concept code or its descendants (i.e., demonstrating inference capability) from different domains (i.e., Condition, Medication Administration, and Observation). Table 1 shows the query results of three example concept codes in three domains. We verified that the results are accurate using an OHDSI open source cohort identification tool known as ATLAS (https://github.com/OHDSI/Atlas).

Discussion

In this study, we developed an ontology-based data access framework for enabling FHIR-compliant semantic queries over the OHDSI CDM-based data repositories. We have demonstrated the feasibility of the framework by implementing a prototype leveraging the FHIR ontology and an open-source Ontop system. Our ongoing next steps include: 1) building a set of robust mappings between FHIR and OHDSI CDM through a community-based consensus approach; 2) enhancing the Ontop OBDA model to handle blank nodes which are required for the FHIR canonical RDF representation; 3) producing a library of SPARQL query templates for complex cohort identification logic; and 4) enabling federated queries across the OHDSI data repositories and beyond.

Abstract
This study was designed to develop and validate operational algorithms using healthcare claims and electronic health record (EHR) clinical notes for Relapsing-Remitting Multiple Sclerosis (RRMS) patient identification. Using data from an U.S. Integrated Delivery Network (IDN), algorithms using codes from healthcare claims and unstructured text from EHR clinical notes were constructed and positive predictive values (PPV) were calculated. Both the claims- and EHR clinical notes-based algorithms, with high PPV for identifying RRMS, are promising methods for future research.

Introduction
As the demand for observational studies using real-world data has grown, algorithms to improve case ascertainment have become increasingly critical to ensure the integrity and rigor of outcomes research as well as to help guide clinicians in disease subtype treatment and resource utilization decision-making. This study aimed to develop and validate operational algorithms using healthcare claims and EHR clinical notes for RRMS patient identification in an U.S. IDN healthcare system. These methods may be used to improve RRMS patient identification and to leverage the development and validation of algorithms for case ascertainment of other medical conditions.

Methods
IDN data from 2010-2014 were used to create a cohort of patients aged 18 or older who had at least 1 year of baseline data before a recorded MS diagnosis and no other demyelinating disease diagnoses to address any potential confounding. The claims-based algorithms used only structured/coded data, which were queried for the following combinations: presence of (1) MS ICD-9 diagnosis codes, MS-specific symptom codes recorded as a part of a neurology visit, physician prescribed MS disease modifying therapy (DMT) codes, and codes signifying brain/spinal MRI(s) performed; and (2) ruling out progressive MS (P-MS) through: (option A) medications more commonly used in MS patients with progressive disease; (option B) MS severity/progression from Kurtzke Functional Systems Scores (KFSS) adapted from ICD-9 coding; and (option C) P-MS based on combinations of supportive therapy and resource utilization. Our EHR clinical notes-based algorithm made use of clinical text documents and natural language processing (NLP), where the narrative text of clinical notes was searched electronically using key terms and phrases that potentially indicated MS subtype or progressive MS disease. This provided a comparison of information available via structured claims records vs. narrative text of clinical notes. Terms indicating RRMS subtype such as, ["multiple, sclerosis" or "ms"] and ["relapsing" and/or "remitting"] were used to categorize RRMS patients; terms indicating progressive MS diseases were used to exclude RRMS classification.

Random samples of at least 100 RRMS patients who were identified by each algorithm were manually validated by a single physician review of all available clinical notes, including outpatient clinic notes, inpatient progress reports, and brain/spinal MRI reports. Among the random samples, there were a total of 145 overlapping distinct patients with 1,713 reviewed clinical documents. Through this manual validation, these patients were assigned as Positive, Negative, or Unknown for RRMS subtype based on the information available in the clinical notes. Unknown was assigned to cases where the clinician’s explicit impression of MS subtype was not included in the notes and therefore could not be determined. Positive predictive values with 95% confidence interval (CI), excluding Unknown cases, were calculated for both algorithms. Sensitivity analyses were also conducted.
Results

Of 3,111 MS patients identified from the IDN, the claims-based algorithm identified 2,960, and the EHR clinical notes-based algorithm identified 990 as having positive evidence of RRMS subtype. Of the 2,960 possible RRMS patients identified using the claims-based algorithm, 2,271 (77%) were identified as not having evidence of progressive disease based on the P-MS rule out options A, B or C (98%, 79%, and 98%, respectively), and therefore became our final RRMS patient sample. The PPV (95% CI) for the claims-based algorithm compared to the clinical note-based manual validation was 0.89 (0.75-0.95) overall, and 0.87 (0.78-0.93), 0.89 (0.79-0.95) and 0.88 (0.79-0.93), respectively for the three P-MS rule out options. One third of patients identified using the claims-based algorithms were classified as Unknown cases, which were included in sensitivity analyses. The Unknown determination in validation review most often reflects the lack of explicit indication of MS subtype in the physician’s clinical notes.

Of the 990 possible RRMS patients identified using the NLP-based EHR clinical notes algorithm (i.e. MS patients who had a term for RRMS in their EHR), 837 (85%) were identified as not having evidence of progressive MS mentioned in a clinical note until 90 days after the index date. These patients were characterized as our final RRMS patients from the NLP-based EHR clinical notes algorithm. The PPV (95% CI) for the EHR clinical notes-based algorithm compared to the clinical note-based manual validation was 0.99 (0.94-1.00) when excluding Unknown cases and 0.96 (0.91-0.99) when Unknown cases were assumed negative for RRMS.

Conclusion

Both the claims- and EHR clinical notes-based algorithms had high PPV for identifying RRMS among patients with documented MS. Thus, they produced a cohort of RRMS patients that can be studied in clinical research with confidence. High PPV may be expected due to the high prevalence of RRMS among MS patients. We chose an approach using multiple criteria and several options to assess the contributions of each factor towards positively distinguishing RRMS patients from primary progressive MS (PPMS) and secondary progressive MS (SPMS) patients. Traditional medical chart reviews can support the clinical note-based manual validation, particularly for patients without clinical notes of MS subtypes. Our study assigned a high number of patients as Unknown during the manual validation because there was insufficient evidence of MS subtype documented in the clinical notes. Our validation required clear or explicit documentation by a clinician of the subtype. Often symptoms and course of care were well documented, but no clear or explicit indication of RRMS subtype was found. At times, this occurred when the precise MS subtype had not been clinically determined or when more time was required for the patient’s pattern of MS symptoms to present. Another scenario encountered was when patients were in a relatively stable clinical state with their MS, and the MS subtype may not have seemed relevant to the patient’s continued clinical care; therefore, it was not documented. This particular scenario helps explain why a much smaller number of RRMS patients were identified by EHR clinical notes only compared to the claims-based algorithm.

With the growing number of available disease modifying therapies indicated for relapsing forms of MS, better documentation of subtype will aid future clinical research as well as medical decision making for improved patient care and health outcomes. In the meantime, these claims- and EHR clinical notes-based algorithms to identify RRMS are promising methods for future MS research using real-world data.

A Comparison of Using Full and Partial Information from Administrative Claims Data to Predict Future Health Care Costs

Hong J. Kan, PhD, MPP, MA\(^1\), Hadi Kharrazi, MHI, MD, PhD\(^1\), Hsien-Yen Chang, PhD\(^1\), Jonathan Weiner, DrPh\(^1\)

\(^1\)Center for Population Health IT, Department of Health Policy and Management, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD

Introduction
In the last several decades, research has focused on modeling health care cost and utilization using statistical and econometric approaches, with much effort spent on explaining their variation and adjusting for underlying differences in risk for payment purposes\(^1\). Those models were typically developed with substantial domain knowledge (eg, a good understanding of the distribution of health care cost and utilization). Recently, an emerging literature started to apply machine learning methods to predicting health care cost and utilization\(^2\,3\). This study used lasso regularized regression to focus on important variables from a large pool of variables in the past year and longitudinal patterns of disease development in the past 4 years in predicting future health care costs under the scenarios of having complete claims data, simulated complete electronic medical records (EMR) data, and simulated incomplete EMR data. Since the linear regression model is still widely used as the de facto standard modeling framework for risk adjustment, predictors selected by lasso regression were also evaluated with linear regression to isolate the effects of variable selection for cost prediction.

Methods
This retrospective cohort study used IMS LifeLink\(^\circledast\) database\(^4\) comprised of commercial health plan claims in the United States. Patients born between 1949 and 1953 from a large health plan with 5 years of continuous enrollment from 2009 to 2013 were included for the study. Standard linear regression and lasso regression models were used to predict 2013 total cost with predictors from 2012 and clusters of longitudinal disease development patterns from 2009 to 2012. Many predictors were constructed using the Johns Hopkins ACG\(^\circledast\) system\(^2\) and used in the following scenarios (see Table 1 for a full list of variables in each scenario):

- Scenario 1: A user (such as a health plan) has complete claims data including cost, utilization, diagnoses, procedures, and medications over multiple years.
- Scenario 2: Simulating a user (such as an integrated health care delivery system) with complete EMR data including inpatient and outpatient care over multiple years. We used the same claims data but excluded cost.
- Scenario 3: Simulating a user (such as a small primary care practice) with incomplete EMR data. We assumed that the only complete data available was diagnoses, and thus only included diagnoses from claims data and grouped them into Expanded Diagnosis Clusters (EDCs, aggregate disease groups based on diagnosis codes) and Aggregated Diagnosis Groups (ADGs, an even higher level aggregation of diagnosed conditions).

Lasso regression was used to select variables and predict cost in each scenario. In addition, the variables selected by lasso plus age, sex squared and gender were included as predictors in linear regression models. Model performance was assessed using cross-validated \(R^2\) and cross-validated root mean square error (RMSE). We also tested the importance of longitudinal disease development clusters based on yearly EDC counts and yearly major ADG counts from 2009 to 2012 formed by k-means clustering.

Results
A total of 64,258 patients were identified with mean (SD) age of 60.9 (1.4) years old and 49.9% being female. Mean (SD) total allowed cost in 2013 was $10,380 ($30,232). Twenty clusters of yearly major ADG counts and 21 clusters of yearly EDC counts from 2009 to 2012 were identified. Using linear regression models, we found: (1) Cross-validated \(R^2\) with lasso-selected predictors was only slightly lower than that with the full set of predictors in scenarios 2 and 3, and was even slightly higher in scenario 1; (2) Cross-validated RMSE were essentially the same between the full and reduced sets; (3) Some of the longitudinal major ADG count clusters and EDC count clusters are important predictors in scenario 3. Relative to linear regression, lasso regression performed better with slightly higher \(R^2\) and lower RMSE in all scenarios (Table 1).

a. 408 predictors: Age, age squared, female; allowed cost: inpatient, outpatient and pharmacy; total number of claims: inpatient, outpatient and pharmacy; 34 ADG indicators; frailty, generalist, coordination_LCI, coordination_PCI, resource utilization band 1-5, hospital dominant morbidity, chronic condition count, major ADG count, active ingredient count, majority of source of care, unique provider count, specialty count, management visit count, 280 EDC indicators, 67 RxMG indicators. b. 11 predictors: Age, age squared, female; allowed cost: inpatient, outpatient and pharmacy; total number of claims: inpatient, outpatient and pharmacy; major ADG count, REN06. c. 405 predictors: same as except for no allowed cost. d. 11 predictors: Age, age squared, female; total number of claims: inpatient, outpatient and pharmacy; hospital dominant morbidity, major ADG count, REN06, MAL03, and rxmgGURx020. e. 317 predictors: Age, age squared, female, 280 EDC indicators, 34 ADG indicators. f. 35 predictors: Age, age squared, female, ADG3, ADG4, ADG7, ADG9, ADG10, ADG11, ADG16, ADG22, ADG26, ADG27, ADG28, ADG32, ADM02, TOX04, MUS01, CAR05, NUR21, REN02, CAR16, HEM02, REN01, REN06, RES01, ALL06, HEM08, RES12, MAL12, MAL03, NUR12, REN03, NUR08, NUR10, REN12, REN03, MAL03, MAL12, MAL03, NUR12, REN03, NUR08, MAL10, cluster0. g. 34 predictors: Age, age squared, female, ADG3, ADG4, ADG7, ADG9, ADG10, ADG11, ADG16, ADG22, ADG27, ADG28, ADG32, ADM02, TOX04, MUS01, CAR05, REN02, CAR16, HEM02, REN01, REN06, RES01, ALL06, HEM08, RES12, MAL12, MAL03, NUR12, REN03, NUR03, MAL08, MAL10, cluster3, cluster4, cluster5, cluster7.

Conclusion
Using high-dimensional data to develop a linear prediction model may risk overfitting and inclusion of irrelevant variables. This study demonstrated that reducing the number of input variables in a linear regression through a lasso-based variable selection procedure preserved most of the prediction power, potentially meaningful to users with limited EMR data. Longitudinal disease development patterns based on EDCs and major ADGs were important when only disease diagnoses were available. However, their contribution to model performance was minimal. In addition, lasso regression showed slightly better performance in terms of R² and RMSE relative to linear regression. Although complete cost and utilization data from claims data maximized prediction of future costs, limited EMR data with diagnosis information only could still explain ~14% of variation of future cost in a liner regression model.

Agile Clinical Decision Support Development

Vaishnavi Kannan, MS, Mujeeb Basit, MD, MMSc, DuWayne Willett, MD, MS
University of Texas Southwestern Health System, Dallas, Texas

Abstract

Designing effective Clinical Decision Support (CDS) tools in an Electronic Health Record (EHR) can prove challenging, due to complex real-world scenarios and newly-discovered requirements. As such, deploying new CDS EHR tools shares much in common with new product development, where “agile” principles and practices consistently prove more effective than traditional project management. Typical agile principles and practices can thus prove helpful on CDS projects, including time-boxed “sprints” and lightweight requirements gathering with User Stories and acceptance criteria. Modeling CDS behavior removes ambiguity and promotes shared understanding of desired behavior, but risks analysis paralysis: an Agile Modeling approach can foster effective rapid-cycle CDS design and optimization. The agile practice of automated testing for test-driven design and regression testing can be applied to CDS development in EHRs using open-source tools. Ongoing monitoring of CDS behavior once released to production can identify anomalies and prompt rapid-cycle redesign to further enhance CDS effectiveness.

Introduction

Despite years of seeking portable clinical decision support (CDS), most CDS development remains local. The concept of shareable CDS tools—designed, constructed, and tested once, then re-used at other sites—holds intuitive appeal. Adopting what's proven, avoiding re-inventing the wheel—the concept is compelling. But now that most healthcare organizations are on an EHR, what is actually happening "on the ground" with CDS? Today, most CDS tools (alerts, rules, banners, etc.) still are developed locally within a single institution. While successful novel designs may be presented, the volume of actual record-sharing appears low. Cycle times for delivery of a new CDS tool are generally felt to be long. Defects in CDS tools delivered to production are perceived to be common. How then can we deliver to our own production environments CDS tools of higher quality, faster, and with less wasted effort? Much foundational groundwork has been laid and progress made in CDS logic design, user interface design, workflow context evaluation, and evaluation: we deal here with methods for implementing CDS in a production EHR, employing these established concepts. New CDS development shares characteristics with new product development, including creating something that did not exist before, and a complex environment where solutions may not be initially obvious but emerge from frequent feedback. In new product development, agile principles and practices have proven superior. Our core tenet is that certain of these approaches (agile project management, agile modeling, test-driven development, and rapid-cycle monitoring) will improve the effectiveness of clinical decision support development.

Methods

From the Agile Project Management (APM) domain, we employed Scrum (iterative development), "user stories" for lightweight requirements gathering, and a use-case driven development approach. Agile modeling methods included principles such as "use the simplest tools possible", "model together", and employed a combination of standard, rigorously-defined diagram types, both Unified Modeling Language (UML) and non-UML diagrams. Automated acceptance testing was accomplished with FitNesse, an open-source wiki-based testing framework, with the dbFit extension allowing queries against the EMR database. Monitoring to-date has been semi-automated, with construction of data cubes (Microsoft Analysis Services) and interactive dashboards and reports (Excel, PowerBI, Microsoft) for multidimensional analysis of CDS behavior in production, looking for anomalies and opportunities for iterative improvement.

Results

Agile Project Management: User stories were employed in the typical format of "As a <role>, I want <some CDS tool>, so that <value to be achieved>. We found writing these in the voice of the user who would be exposed to the CDS tool—not the requestor—was instructive. This helped clarify the who, what, and why of the CDS "5 rights" before beginning detailed design. The use of time-boxed 2-week iterations with demonstration of working CDS product at end-iteration proved feasible, and provided the opportunity for early feedback and iterative refinement.
Agile Modeling: A subset of modeling techniques and diagrams proved most consistently useful:

- Use case diagrams to depict all the user activities in a system and actors/roles involved, including which roles would use which CDS tools.
- Swimlane workflow (UML Activity) diagrams, to show a defined sequence of activities across multiple roles.
- Decision trees, to unambiguously describe the logic for when an alert should and should not appear.
- User interface storyboarding and Use Case Text (the latter in the form of “user does this”, “system does that”): to visualize how the user would interact with the CDS user interface, and how exactly the system should respond to any given user action.
- Object diagrams: to depict both the business objects and their relationships in the "problem domain", and the EHR objects and their relationships in the "solution domain".

Test-Driven Development and Monitoring: Employing the open-source testing framework Fitnesse with an add-in (dbFit) that allows writing and running SQL database queries enabled writing of acceptance tests to specify the structure and behavior of a CDS rule/alert, even before it was built. The test would be "red" or fail until the CDS alert was constructed, then the test would turn green if the build matched the original specifications. Suites of these tests were also developed.

A multidimensional data model for user interaction with CDS alerts was extended and provided both time-series analyses and snapshot comparison graphs of subgroups to evaluate CDS behavior, in terms of both triggering events and user responses.

Conclusion

Typical agile principles and practices can prove helpful on CDS projects, including time-boxed “sprints” and lightweight requirements gathering with User Stories and acceptance criteria. Modeling CDS behavior removes ambiguity and promotes shared understanding of desired behavior, but risks analysis paralysis: an Agile Modeling approach can foster effective rapid-cycle CDS design and optimization. Modeling using standard rigorous model types (UML and non-UML) provides one mechanism for sharing designs between organizations for faster replicability, and potentially to evolution of re-usable design patterns. The agile practice of automated testing for test-driven design and regression testing can be applied to CDS development in EHRs using open-source tools. Ongoing monitoring of CDS behavior once released to production can identify anomalies and prompt rapid-cycle redesign to further enhance CDS effectiveness.

Analyzing Prevalence of Obesity among VHA Patients Using Clinical, Temporal, and Geographical Data Extracted from a Nationwide EHR

Hadi Kharrazi1, Tamara Box2, Stephen Fihn2, Jonathan Weiner1
1 Johns Hopkins University, Baltimore, MD, USA
2 U.S. Veterans Health Administration, Washington DC, USA

Abstract

This study evaluates the use of EHR data to measure the prevalence of obesity among 9,389,909 male veterans seeking care at one of the VHA facilities in the continental US between 2000 and 2015. Data is extracted from VHA’s national Clinical Data Warehouse representing VHA’s nationwide EHR. Obesity prevalence using EHR-extracted BMI, data quality issues, and various geographical and temporal analyses of data are discussed.

Introduction

Obesity is one of the most prevalent adverse health outcomes in the U.S. population (1). Obesity rates among veterans seeking care at the VHA is higher than the general population (2). Understanding obesity trends in the VHA population is important to prevent obesity and obesity related diseases and to control future costs (3). Similarly, geographic areas of excess obesity will be essential to target interventions and services to address obesity among the VHA population.

Methods and Study Design

The VHA’s Corporate Data Warehouse (CDW), a data repository of VHA’s VistA EHR that archives clinical records of 21+ million veterans daily (4), was utilized to identify and track the BMI (body mass index) level of individual veterans over an extended timespan (2000 to 2015) and on a national scale (50 US states; excluding territories). BMI levels were adjusted and/or stratified based on age (18-30, 30-40, 40-50, 50-60, 60-70, 70-80, 80+) and stratified based on gender. Patient’s addresses were translated to latitudes and longitudes and mapped with Census shape files (5). Geographical aggregate BMIs (e.g., county level BMIs) were calculated after adjusting/controlling for age and stratifying for gender using multi-level modelling approach.

The initial denominator included 21,470,625 patients. Patients with missing age/sex, invalid veteran status, or a death record before 2000 were excluded (4,392,183). In addition, patients who did not have at least one weight or height were excluded (6,712,870) as well as veterans without a US address (252,645). An analysis of the excluded patients did not reveal a significant difference in demographics, comorbidities, and/or geographical distribution from patients included in the study (10,112,927). Only male patients (9,389,909) are reported in this abstract.

Findings

Average BMI of male veteran patients has increasing across all age-groups from 2000 to 2015 (after adjusting for age). Smallest BMI increase from 2000 to 2015 has been for the 18 to 30 age group with .87 points. In the same timeframe, the largest BMI increase has been for the 40 to 50 age group with 2.45 points (Table 1). Other age groups have had a consistent increase in BMI ranging from 1.18 points to 1.65 (Table 1).

BMI has increased in some geographical boundaries more than other (Figure 1). Certain counties showed a higher increase in adjusted BMI for the male patient population of VHA over time than others.
Figure 1. Geographical distribution of average BMI of male VHA patient population

Geographical unit of analysis: Census defined county; Years: 2000 [top-left] to 2015 [bottom-right];
BMI scale/ranges (same for all maps): 27.5 [green] to 32.5 [red]

Conclusion

EHR data can be utilized to track BMI levels on a temporal and spatial basis for population-health management purposes at the VHA. VHA uses considerable resources to tackle obesity and its consequences. Findings of this study can guide policy makers and local clinical program managers to allocate and guide existing resources, such as VHA’s national MOVE weight management program (6), to areas of excess obesity.

Learning Objectives:
1. Explain the use of EHR data (e.g., data quality) in analyzing geographically-bound population health outcomes
2. Compare the obesity rates in the VHA’s male population with the general population

Consumer Views of Electronic Health and Genetic Data Sharing: Findings of a National Survey

Katherine K. Kim, PhD, MPH, MBA1, Lucila Ohno-Machado, PhD, MD, MBA2
1University of California Davis, Sacramento, CA; 2University of California San Diego, La Jolla, CA

Abstract
Networks have emerged to provide infrastructure including technology and data access to support person-centered care and precision health. Consumers are willing to electronically share genetic and health data but factors such as trust and purpose may moderate their willingness. This national, random digit-dial survey (n=1504) showed greater trust in healthcare and educational organizations accessing health data than national health agencies or companies. Respondents are more willing to share health data for research than genetic data.

Introduction
Networked health systems have emerged to provide infrastructure including network technology, access to data, and governance mechanisms to support national priorities of enabling person-centered care and delivering precision health. Several national programs have recently been initiated to spur innovation in these areas. The Patient-Centered Outcomes Research Institute (PCORI) has made a major investment in distributed research networks (DRNs) to enable efficient, large-scale person-centered clinical research that leverages secondary use of clinical data.1,2 The All of Us Precision Medicine Research Program aims to build a cohort of 1 million Americans with collection of genetic and longitudinal clinical data from EHRs.3 Recent studies show that consumers are willing to participate in research, contribute genetic data4 and electronic health data.5 However, this willingness may be moderated by factors such as trust, the purpose for data access, and type of data accessed. The purpose of this study was to explore these factors related to sharing of electronic health data and genetic data.

Methods
A survey was developed that included new questions and existing questions from the literature. New questions were pretested for clarity with six individuals prior to fielding the survey. A random-digit dial telephone survey was conducted using a national sample of phone numbers, 68% landline and 32% mobile representing the national distribution.6 The survey was conducted in English and Spanish by bilingual interviewers and lasted an average of 20 min. Organizational trust was assessed with the question: I would be comfortable if [organization] had electronic access to my anonymous health information for research from1=strongly agree to 5=strongly disagree. Willingness to share electronic data was assessed via the following survey questions all rated from 1=very likely to 4=very unlikely. 1) If health researchers asked to use your anonymous health information and to send it electronically to other researchers, how likely or unlikely would you be to agree to that?; 2) If health researchers asked to use your genetic information and to send it electronically to other researchers, how likely or unlikely would you be to agree to that?; and 3) If you were offered the choice to have your health information automatically shared electronically (without requiring any action by you) with the different places where you receive health care, how likely would you be to agree to it?

Results
The survey concluded with 1504 responses, representing a 9.95% response rate. 28 interviews were conducted in Spanish. The mean age of respondents was 53.5 years (SD = 17.7, range 18-99). Respondents were representative of the US population in terms of gender, but the sample is less diverse (78.0% white, non-Hispanic/Latino vs. US proportion of 63.0%) and more highly educated (34.5% college educated vs. US proportion of 28.2%).7 Respondents’ trust differs by organization type although the differences are small. They were most comfortable with healthcare and educational organizations accessing their health information: hospital (M = 2.34, SD = 1.17), doctor’s office (M = 2.35, SD = 1.19), college/university (M = 2.89, SD = 1.31), and state/local government health agency (M = 2.97, SD = 1.37). They were less comfortable with national agencies and companies: national government health agency (M = 3.16, SD = 1.45), pharmaceutical company (M = 3.16, SD = 1.36), biotechnology company (M = 3.22, SD = 1.31), and insurance company (M = 3.40, SD = 1.33).
There were significant differences in willingness to share health and genetic data (paired sample t-tests, p < .001). Two-thirds of respondents were likely to share health data for research, while less than half were likely to share health data for healthcare or genetic data for research.

![Electronic Data Sharing*](image)

**Figure 1.** Willingness to share data electronically by type of data and purpose

**Discussion and Conclusion**

Consumers have different concerns and expectations for use of genetic data vs. health data, and for the purpose of healthcare vs. research. Since genetic data and health data used in delivery healthcare rely on identified data, the public may be more concerned about disclosure and lack of privacy. A recent study on consent for data sharing in California found that patients are more likely to share de-identified health information for research purposes than to share identified information for healthcare purposes. Person-centered care and precision health both rely on these data. Programs such as PCORI and *All of Us* must pay close attention to the views of consumers if they are to build the public trust necessary for success.

This study was limited by a low response rate which raises concerns about potential non-response bias. However, the response rate was in line with the declining rates seen in other national surveys which currently averages 9%. Respondents were also not fully representative of the US population.

Networks are emerging to fill the needs of large-scale data collection and secure data access for healthcare and research. Understanding of consumers' expectations can inform the construction of national and network-specific policies that support the laudable aims and protect public trust.

**Acknowledgements:** The study was funded by AHRQ 1R01HS019913-01.

Examining the Coverage of Nursing Content in the UMLS-CORE Problem List

Tae Youn Kim, PhD, RN¹, Nicholas Hardiker, PhD, RN, FACMI²
¹University of California Davis, Sacramento, CA, USA
²University of Salford, Salford, UK

Introduction
The meaningful use of electronic health records (EHR) requires maintenance of an up-to-date patient problem list which is coded in a principled way.¹ This problem list should include clinical diagnoses and patient problems (or findings and complaints) that are relevant to the current care of an individual regardless of specialties and disciplines.² Nursing problems identified by nurses through their clinical judgment should also be integrated into a patient problem list to ensure continuity of care and drive patient-centered treatment plans.³,⁴ The standardization of coded problem lists has many potential benefits, such as support for clinicians’ decision-making⁴ through patient-centered alerts or reminders that could be triggered for disease management, follow-up care, health promotion, and/or early detection and prevention of an adverse outcome in the EHR. Yet maintaining a standardized list of patient problems that are sharable within and across settings is challenging for a range of reasons, including variations in clinical work flow, documentation practice, and administrative and technical support at the organizational level. As part of an effort to promote the implementation of a standardized problem list, the U.S. National Library of Medicine (NLM) and the International Health Terminology Standards Development Organisation (IHTSDO) have released Systematized Nomenclature of Medicine—Clinical Terms (SNOMED CT) Subsets that cover selected patient problems.²,⁴,⁵ The purpose of this study was to examine the extent to which the Clinical Observations Recordings and Encoding (CORE) Problem List² can serve as a multi-disciplinary problem list, especially in coding patient problems addressed by the nursing profession. Specifically this study aimed to create a primary nursing problem subset coded with SNOMED CT and determine the coverage of nursing problems in the CORE.

Methods
This study involved a 4-step process from data acquisition to analysis. First, two existing sets of nursing problems were obtained from the NLM and IHTSDO.⁶,⁷ The NLM Nursing Problem List (201411 Version) is a set of nursing diagnoses created using the Unified Medical Language System (UMLS) Metathesaurus⁴,⁶ while the IHTSDO Nursing Reference Set (201607 release) refers to a product developed through a collaboration agreement between the International Council of Nurses and IHTSDO.⁷ Second, a dataset was then created by merging these two sets of nursing problems, which is named as the Nursing Core Problem List (or Nursing CPL) in this study. Third, the content of the Nursing CPL was compared with that of the CORE Problem List including 6,159 SNOMED CT concepts derived from the UMLS 2016AB.⁸ In other words, the coverage of nursing problems in the CORE Problem List was determined by examining the proportion of nursing content in the UMLS-CORE. Lastly, all SNOMED CT codes were verified against the SNOMED CT 20160731 release and then linked to concept unique identifiers in UMLS 2016AB for identifying semantic types or high-level categories in the semantic network.⁹,¹⁰

Results
The NLM Nursing Problem List (201411 Version) and the IHTSDO Nursing Reference Set (201607 release) comprised 506 and 492 SNOMED CT-encoded patient problems respectively. There was overlapping content between the two nursing subsets (i.e., 261 concepts were identical). After removing duplicates, a total of 723 unique problems made up the experimental Nursing CPL for this study. According to the SNOMED CT hierarchy, all but six problems were located in the Clinical Finding hierarchy. The outliers were classified as either Situation (e.g., family grieving) or Event (e.g., elderly person maltreatment) concepts in the hierarchy. When examining further the semantic types of the 723 nursing problems in UMLS, the majority were classified as Finding (³ 80%) and Biologic Function (³ 16%). The semantic type ‘Finding’ includes problems discovered by direct observations or measurements, such as signs and symptoms while ‘Biologic Function’ consists of concepts associated with mental or behavioral dysfunction, disease or syndrome, and mental process.⁹,¹⁰ When querying the 723 nursing problems against the CORE Problem List, approximately half of the nursing problems (343 problems or 47.4%) were found, accounting for 5.6% of the CORE concepts. Table 1 presents a summary of example concepts appearing in the Nursing CPL and CORE subsets.

Discussion and Conclusion
Nursing problems appear across a range of terminologies. The NLM Nursing Problem List has been developed through the identification of nursing problems that exist within the U.S. healthcare environment.⁴ In contrast, the IHTSDO Nursing Reference Set was developed through an exploration of nursing practice worldwide.⁵,⁷ In an effort
to create a primary set of nursing problems, this study combined the two nursing subsets into a Nursing CPL, yielding a total of 732 concepts relevant to the nursing profession. Although this list is not exhaustive, it provides a useful starting point and can serve as a foundation for future research. With regard to semantic locations of nursing content in the SNOMED CT and UMLS Metathesaurus, the discrepancy was somewhat expected as each organization employs a different modeling and integration process of clinical concepts. While the study findings indicate that the nursing CPL is only partially represented in the UMLS-CORE Problem List, this study illuminates potential for research to enhance this nursing CPL and the CORE. Interestingly, the UMLS-CORE Problem List contains additional concepts that could be seen as having relevance to nursing, as shown in Table 1. Further examination is needed to improve the semantic locality of nursing content in UMLS and explore the applicability of this nursing CPL to clinical practice in order to promote data collection, retrieval and exchange across healthcare settings where various EHR systems have been implemented along with different standards of care. While just over half of the nursing problems within the nursing CPL were not found in the CORE, with some enhancement to nursing content, the CORE has the potential to serve as a multi-disciplinary problem list.

Reuse of PCORnet Data to Support the Precision Medicine Initiative: Data Model Harmonization

Jeffrey G. Klann, PhD1,2,3; Matthew A. H. Joss2; Kevin Embree2; Shawn N. Murphy, MD, PhD1,2,3

1Harvard Medical School, Boston, MA; 2Partners Healthcare, Boston, MA; 3Massachusetts General Hospital, Boston, MA

Introduction
The proliferation of research repository systems, which are increasingly used for secondary analysis of electronic health record data, has brought data interoperability to the forefront of medical informatics. Several contrasting data models for clinical research are emerging, such as the PCORNet Common Data Model (CDM), Informatics for Integrating Biology in the Bedside (i2b2), and the Observational Medical Outcomes Partnership (OMOP) CDM. To maximize participation in clinical research initiatives, it is increasingly important for systems to be compatible with multiple data models.

The Precision Medicine Initiative, now known as the All Of Us Research Program, presents a current practical data interoperability challenge. AllOfUs is an NIH-sponsored, “participant-engaged, data-driven enterprise supporting research at the intersection of lifestyle, environment, and genetics to produce new knowledge with the goal of developing more effective ways to prolong health and treat disease.”[1] AllOfUs will be collecting electronic health record data from consented participants using the OMOP data model, and AllOfUs is presently requiring its partner organizations to implement OMOP data export. Our partnership, the New England Precision Medicine Consortium, comprises two sites which have already invested significantly in the PCORNet Common Data Model through the Scalable Collaborative Infrastructure for a Learning Health System (SCILHS) network: Boston Medical Center and Partners Healthcare. Therefore, we explored whether some of their investment could be reused to prepare data for AllOfUs.

We previously published a methodology that allows i2b2 data to be transformed into a PCORNet conformant data model using "information models", which are modeled as i2b2 “ontologies,” or hierarchies of terminology. [2] By developing a PCORNet information model in i2b2 and implementing a robust methodology for mapping data into it, we technologically enabled the transformation of i2b2 data into the PCORNet CDM. This was practically important because we presently run a PCORNet network that internally uses i2b2 but externally must support PCORNet's initiatives. We found that the PCORNet CDM supported a comprehensive information model for network interoperability.

We hypothesized that the similarities between the PCORNet common data model and the OMOP common data model would allow significant reuse of our existing investment. Partners Healthcare has data for 3.5 million patient lives mapped to the PCORNet information model and Boston Medical Center (BMC) has 1.5 million. Together, they could potentially bring 5 million patient lives to the OMOP CDM.

Here we describe our unique solution, which utilizes the PCORNet information model in i2b2 to transform directly into OMOP. This has also given us a detailed understanding of the differences and similarities in these data models.

Methods
Our existing methodology consists of two components: an information model which exactly mimics the fields and permissible values in the PCORNet CDM; and, a SQL program which transforms data using the mappings in the information model into the PCORNet CDM. We sought to modify only the latter component, so that sites with their data mapped to the PCORNet data model could produce an OMOP data set without any additional work.

We did ultimately make one change to our information model, but one that does not require remapping. OMOP version 5 assigns its own unique "OMOP numbers" to every standard term that is in its concept dictionary. Therefore, we added an OMOP code column to our information model that had a direct cross-reference to the OMOP number in the concept dictionary.

AllOfUs chose the tables in OMOP that the leadership believed were the most clinically relevant domains and excluded the fields that were deemed to be too obscure from the data model. The domains included: Person, Visit, Condition, Procedure, Measurement, and Drug. Our task was to provide data in OMOP format covering as many of the remaining fields as possible. To accomplish this, we analyzed differences in: a) the data model and b) terminology design between PCORNet and OMOP. We then implemented changes to the SQL transform to transform i2b2 data mapped to our PCORnet ontology into OMOP format.

Results
Data model analysis
Our analysis found five categories of field relationships between PCORnet and OMOP:

- **The field exists in OMOP and PCORnet** but with different names, and the field does not use a structured terminology. These cases were trivial renamings of the field names in the transformation. This included mostly dates and pseudo-identifiers. \((52/89 = 58\%)\)

- **The field does not exist in PCORnet.** (ex. drug lot #, procedure quantity) These were impossible to transform without modifying the information model. None of the fields in which this occurred were available in our source data, so at our site, this did not affect the output. \((14/89 = 16\%)\)

- **The field does not exist in OMOP.** (ex lab result priority, data source type) These could not be transformed into OMOP, which resulted in an implicit information loss in the transformed data. \((na/denominator\%\) is OMOP; comparison is PCORnet)

- **OMOP and PCORnet represent the same information in different ways.** (ex. drug type, normal ranges) Though PCORnet valuesets often mapped directly into OMOP, sometimes incompatibilities arose, yielding mapping with information loss. For example, PCORnet distinguishes between prescribed, dispensed, and administered drugs, but not subtler variations supported by OMOP, such as “dispensed through mail order” or “Physician administered drug, identified from referral record.” \((7/89 = 8\%)\)

- **The field exists in both OMOP and PCORnet, but with different structured terminologies.** (ex. condition & procedure codes) The subtleties of this process were the most challenging element of creating the new transform. OMOP’s concept dictionary defines terms’ domain in a nonstandard way. There are thousands of cases in which, e.g., a procedure code is assigned to the diagnosis table and vice-versa. Furthermore, OMOP’s mappings to their preferred terminologies split single source terms into multiple target terms, sometimes spanning multiple destination tables. Finally, although OMOP’s mappings do include retired codes, many codes in our ontology were missing from one or both mappings. For this version, we chose to support only the straightforward use case: the term is mapped and the target terms all fall into the same table as they appear in the PCORnet ontology. \((16/89 = 18\%)\)

(Percentages are % of fields in the OMOP data model selected for AllOfUs.)

### Pilot Transformation

We successfully transformed a subset of our PCORnet datamart at Partners Healthcare into OMOP format and ran it against a suite of validations provided to us by AllOfUs. These validations are based on standard OMOP analytical tools, Achilles and Achilles Heel. The validation tools are available for download at [https://github.com/cumc-dbmi/pmi_sprint_reporter](https://github.com/cumc-dbmi/pmi_sprint_reporter). Both a set of test data and our production data on real patients passed all tests.

### Discussion

With relative ease, we leveraged our previous work in transforming i2b2 data into PCORNet CDM. When the source data is i2b2, we now have a methodology and a common ontology to transform this data into two popular analytical data models, PCORNet and OMOP CDM.

We do not at present support terms that map to a different domain than their source domain, terms that bifurcate into terms in multiple domains, and several optional columns. However, the current transform is sufficient for initial data analysis in the AllOfUs research project. Our tool is open source and is being made available in the SCILHS GitHub repository as components are finalized. [3]

Our analysis of these two data models revealed that, among their common domains, there are far more similarities than differences. The most significant differences were in terminology; most of the data fields were represented similarly between the two models. Terminological differences are, in our experience, the most daunting and challenging aspect of data transformations in medical informatics, which has continued to prove true in this endeavor despite the similarity of preferred terminologies between PCORNet and OMOP. A relatively small number of OMOP fields are not present in PCORNet, and designing a harmonized PCORNet/OMOP ontology (terminology differences aside) would be relatively straightforward.

Our work will allow for considerably easier participation in a variety of initiatives even if they use different data models for their analytics.

Evaluation of Text Mining Methods to Support Reporting Public Health Notifiable Diseases Using Real-World Clinical Data

Matthias Kochmann, MD1,2, Jiachen Wang, MS1, Brian E. Dixon, MPA, PhD1,3, Suranga N. Kasthurirathne, BEng4, Shaun J. Grannis MD, MS1,2
1Regenstrief Institute, Indianapolis, IN, USA; 2Indiana University School of Medicine, Indianapolis, IN, USA; 3Indiana University Richard M. Fairbanks School of Public Health, Indianapolis, IN, USA; 4Indiana University School of Informatics and Computing, Indianapolis, IN, USA

Abstract:
Accurately and automatically identifying conditions reportable to public health is an ongoing challenge. Machine learning approaches may be more effective and efficient at reporting of public health notifiable diseases when compared to existing rules-based approaches. Using real-world transactional clinical laboratory data from multiple health systems, we trained four machine learning algorithms, analyzed their performance, and compared the results. Machine learning models exhibited high accuracy suggesting they could be used for operational purposes.

Introduction
Accurately and automatically identifying conditions reportable to public health authorities is an ongoing challenge (1). Despite the increasingly ubiquitous use and promising published performance measures for machine learning in this decade, their potential for accurately and automatically identifying and reporting diseases to public health authorities has previously only been hypothesized (2). To assess whether broad adoption of these methods is practical, we sought to assess the feasibility of implementation and performance characteristics of these approaches. Such results have the potential to contribute to emerging evidence-based best-practice guidelines for using machine learning methods that support reporting of public health notifiable diseases. To generate such evidence, this study determines the performance of machine learning algorithms using routinely available clinical data.

Materials and Methods
We extracted 12 months of HL7 v2 laboratory transactions for four infectious diseases: hepatitis C, hepatitis B, chlamydia, and gonorrhea; from the Indiana Health Information Exchange (IHIE), the nation’s largest and longest-running health information exchange (3). These transactions contained both negative and positive notifiable disease cases. We created a gold standard training and test datasets for each disease by manually reviewing and labelling the HL7 laboratory transactions as positive (reportable) or negative (non-reportable). We preprocessed the transactions by removing formatting (e.g., punctuation and HL7 formatting), stop words, stemming, and identifying words in negated context using the Negex algorithm (4). Each laboratory transaction was then transformed into a feature vector containing counts for each token in the negated and non-negated context.

Using these feature vectors, we selected four machine learning models implemented in R, which included a 3-layer neural network, random forest, support vector machine, and logistic regression. Two of the algorithms were selected based on our prior experience with random forest and logistic regression (2), and the remaining two based on their wide use and prevalence in the literature. We trained the models using varying combinations of parameters: four feature set sizes (5, 10, 15, and 20 features); three ngram sizes (1, 2, and 3-grams); and four diseases (chlamydia, gonorrhea, hepatitis B, and hepatitis C). Therefore, we had (4 x 3 x 4 x 4) combinations of parameters for 192 analytical units. For each of the analytical units, we calculated sensitivity, specificity, positive predictive value, accuracy, F-score and area under the receiver operator characteristic curve (AUC).

Results
Manual review of 16,834 HL7 v2 messages identified N=2,441 Chlamydia reports (56% positive), N=3,432 gonorrhea reports (82% positive), N=2,500 hepatitis B reports (50% positive), and N=8,461 hepatitis C reports (11% positive). Across all four diseases and four algorithms, feature vectors using 1-grams and 20 features the range for the various performance characteristics revealed: accuracy 98-100% (p<0.0001), sensitivity 98-100% (p<0.0001), specificity 85-100% (p<0.0001), PPV 97-100% (p<0.0001), F- score 98-100% and AUC 97-100% (p<0.0001). There was no
significant difference between use of 1-grams and 2-grams. For hepatitis B using 3-grams and only 5 features, accuracy decreased to 80%. Results and specific trends for all 192 analytical units will be described during the presentation.

Discussion

Results for the 192 analytical units revealed no statistically significant differences among the four machine learning algorithms. Using feature vectors that contained 1-grams and 20 features, three of four algorithms achieved an accuracy, sensitivity, specificity, PPV, F-score and AUC of 96-100%. Calibrating the model further by choosing individual algorithms, at 1-grams and different feature sizes, performance measures increased to >98% for all diseases.

Regarding overall trends, we noted that model performance decreased when the total number of features decreased. Further, 1-grams were overall associated with improved performance when compared to models trained with 2- and 3-grams. We also noted that laboratory results for hepatitis B and C contained more complex results: they often included combinations of structured numeric and nominal values, as well as unstructured free-text interpretations. These more complex laboratory results required both 1) a larger feature set and 2) higher granularity 1-grams to achieve similar performance metrics when compared to less complex diseases like chlamydia and gonorrhea, which typically contained structured numeric or nominal values.

Conclusion

Machine learning models trained using feature vectors derived from real-world ("in-vivo") HL7 v2 transactions can feasibly and accurately identify notifiable diseases that should be reported to public health authorities in nearly every U.S. state. All four tested machine learning methods performed equally well. To attain highest performance, calibration of an algorithm to a specific disease is necessary. These results represent early evidence suggesting that machine learning algorithms can be feasibly implemented in operational systems to support automated detection of public health notifiable diseases. Our future work will evaluate machine learning performance for an expanded number of notifiable conditions and test their use in lieu of existing rules-based approaches like those in use currently within the IHIE (5).

Cardioprotective Drugs and Incident Dementias in Medicare’s Big Data

Fabricio S. P. Kury, MD1, Seo Hyon Baik, PhD1, Clement J. McDonald, MD1
1U.S. National Library of Medicine, Bethesda, MD

Introduction

Studies to assess a possible protective effect of cardioprotective drugs – antihypertensives and statins – on incidence of dementias demand large cohorts, detailed information about medication usage, and long follow-up because these diseases mostly occur late in life and only in a subset of patients. Among 17 studies of antihypertensives and dementias reviewed by Rouch et al., 2015,1 most had relatively limited cohorts and/or limited follow-up, leading to scarce events (new diagnoses of dementia during follow-up). In the context of statins, the 2015 review by Power et al.2 found that several secondary analyses of data from small randomized trials (≤ 6 months of duration) reported mixed conclusions, while the only two much larger ones failed to detect such protective effect.

As of mid-2017, the CMS Virtual Research Data Center (VRDC) provided exhaustive longitudinal data for up to 57 million beneficiaries ever enrolled in Medicare Part D, and up to 10 complete years of follow-up. It is a good example of big medical data. Most (96%) of dementia cases occur in Medicare-age patients (≥ 65 years), therefore the VRDC provides a prime dataset for assessing the potential effect of cardioprotective drugs on incident dementia. Here we report such an investigation using this dataset.

Methods

We analyzed all claims from a 20% random cohort of beneficiaries who originally joined Medicare based on old age criteria (≥ 65 years). To filter out prevalent cases, we excluded individuals with diagnosis of dementia within 2 years of their enrolment (washout period). We defined dementia according to the algorithm of the CMS Chronic Conditions Data Warehouse (CCW), which includes Alzheimer’s disease and other dementias. We used Part D prescription data from 2007, the first full year of Part D existence, until 2015, the last year available at the time. We only included patients who: a) were fully enrolled in Medicare Parts A, B and D; b) were never enrolled in managed care (Part C – for which claims data is not available); c) had at least 6 months of follow-up; and d) were exactly 65 years old at the end of 2007 (to filter out the important effect of age on risk of dementia). Given our large cohort size, we were able to analyze potential effects separated by drug classes. We also included proton pump inhibitors (PPIs) as a negative control. We quantified drug use by the sum of days of supply of the drugs. Our statistical analysis consisted of a competing risk regression (death is the competing risk) with time-varying covariates. The dependent variable was onset of dementia. Independent variables included all 57 chronic conditions recognized by the CCW’s algorithms, Medicaid eligibility status (as a surrogate for socioeconomic status), rural area residence, race and gender. We performed sensitivity analyses using only some of the aforementioned covariates. All source code we used, and the full set of results it produced, are available for free download from GitHub at https://github.com/fabkury/rxad.

† Not statistically significant at 95% confidence level. All others are significant.

Results

From the 600,315 beneficiaries who met our eligibility criteria, 29,695 (5.0%) died, 13,444 (2.2%) developed dementia, and the remainder (92.8%) reached December 31st, 2015 and were censored. Follow-up time averaged 4 ± 2.5 years per beneficiary. In comparison to no statin use at all, continuous use of any statin was not significantly associated with risk of dementia (HR: 1.01, 95% CI: 0.95—1.07). Calcium channel blockers (HR: 0.98, 95% CI: 0.92—1.04) and proton pump inhibitors (HR: 0.98, 95% CI: 0.92—1.05) were also non-significant. Beta blockers, diuretics, and inhibitors of the renin-angiotensin-aldosterone system (RAAS) were significantly associated with reduced risk by
6%, 14% and 9% respectively. Female gender (HR: 0.91) and lung cancer (HR: 0.85) were associated with decreased risk. On the other hand, the following are some of the covariates that were significantly associated with increased risk: Black (HR: 1.31) and Hispanic (HR: 1.19) races, Medicaid eligibility (HR: 2.86), depression (HR: 2.06), stroke or TIA (HR: 2.11), hypertension (HR: 2.22), traumatic brain injury (HR: 2.28), schizophrenia (HR: 2.96). The hazard ratios and confidence intervals for the drug classes are presented in Table 1. In sensitivity analyses, when not including any covariate besides drug use, proton pump inhibitors (HR: 1.75), as well as beta blockers (HR: 1.34) and calcium channel blockers (HR: 1.25), were significantly associated with increased risk, while statins and diuretics were non-significant. When adjusting for race and socioeconomic status, statistical significance remained the same, but with less expressive hazard ratios: 1.47, 1.25 and 1.13 respectively. When adjusting for all covariates we had, PPIs became non-significant, diuretics became significantly protective (HR: 0.86, 95% CI: 0.81—0.91), and beta blockers became borderline-significantly protective (HR: 0.94, 95% CI: 0.89—0.99). Statins were non-significant in all models.

Discussion

The crude sensitivity analyses (without any covariates beside drug use) showed significant associations of drug use with increased risk. However, as we added more covariates the hazard ratios become smaller, then non-significant, and changed direction (decreased risk instead of increased) in the case of beta blockers. Diuretics, which were non-significant in sensitivity analyses, were significantly “protective” in our main analysis. Notably, statins were non-significant in all analyses we performed, in contrast to the two large observational studies that showed risk reductions by as much as 20%, but in agreement with the few randomized trials on this topic.2

In the context of antihypertensives, diuretics exhibited the largest risk reduction (-14%), which was similar in magnitude to the risk reduction found for angiotensin receptor blockers in the only other study (about antihypertensives & dementia) of size comparable to ours (Li et al., 2010). The other antihypertensives were also significantly protective, except for calcium channel blockers, albeit with less expressive hazard ratios.

We had originally included proton pump inhibitors as a negative control. Contradicting our expectations, after we started our work an observational study was published reporting increased risk of dementia due to use of proton pump inhibitors.3 In our analyses we found that such effect was absorbed by confounders to the point of becoming statistically non-significant. The large size of our cohorts increase the noteworthiness of statistical non-significance in our results.

In spite of using death as a competing risk, we still found death rates to be seemingly influential over the hazard ratios for dementia. For example, lung cancer had hazard ratio of 0.85 for dementia but 7.0 for death, suggesting that this disease looks protective against dementia because these beneficiaries die before having the “chance” of acquiring dementia. Conversely, other conditions such as other cancers, heart failure, atrial fibrillation, hypertension, among others, were associated with increased risk of both death and dementia. Therefore, understanding the influence of death over the hazard ratios for dementias remains challenging.

Conclusion

We were unable to find statistically significant associations between use of statins or proton pump inhibitors and incident dementias. Antihypertensives, except for calcium channel blockers, exhibited protective effect. Further study is needed to establish whether cardioprotective drugs prevent dementia and whether proton pump inhibitors cause it, with particular interest in comprehensive analyses and the potential influence of death rates.

Generating a Test of Electronic Health Record Narrative Comprehension with Item Response Theory

John Lalor, MS¹, Hao Wu, PhD², Li Chen, MS², Kathleen Mazor, EdD³, Hong Yu, PhD FACMI ³, ⁴
¹College of Information and Computer Sciences, University of Massachusetts, Amherst, MA; ²Psychology Department, Boston College, Chestnut Hill, MA; ³Department of Quantitative Health Sciences, University of Massachusetts Medical School, Worcester, MA; ⁴Bedford Veterans Affairs Medical Center, Center for Healthcare Organization and Implementation Research, Bedford, MA

Introduction

Allowing patients direct access to their electronic health record (EHR) notes has been shown to enhance medical understanding and improve healthcare outcomes. However, EHR notes contain complex medical terms, abbreviations, and domain specific jargon which patients have difficulty comprehending1–3. Health illiteracy is associated with a number of adverse health outcomes, including repeat health problems, insufficient follow up, and failure to follow post-visit instructions4, 5.

Instruments exist to evaluate health literacy in individuals6–8, but many focus on single term comprehension or word pronunciation. Existing instruments also have a number of problems that affect their ability to measure health literacy⁸, ⁹. EHR note comprehension requires knowledge that goes beyond terms. For example, one needs to comprehend relations between terms and clinical scenarios that incorporate complex relations and multiple events.

In this work, we report on the development of a new instrument to test patients’ ability to comprehend EHR notes. Our instrument consists of a test set of question-answer pairs that are based on the semantic content of EHR notes and selected using the psychometrics method Item Response Theory (IRT)¹⁰.

Methods

Our framework for question generation and validation consists of three steps. First, we developed a hybrid model integrating topic models and hierarchical clustering to automatically select representative EHR notes from a large hospital EHR system. Second, we developed a protocol to have researchers and medical doctors generate questionns from those notes. Finally, we used the crowdsourcing platform Amazon Mechanical Turk (AMT) to obtain responses for the generated questions and fit a model of ability using IRT to validate the questions.

We selected six conditions according to ICD-9 diagnostic codes to retrieve EHR notes from the University of Massachusetts Memorial Hospital EHR system. For each condition we randomly selected 1000 notes and annotated each note with MetaMap¹¹ to map the notes to Unified Medical Language System¹² (UMLS) concepts. We ran topic modeling on the notes according to the UMLS concepts and hierarchically clustered the notes according to topic similarities. One representative note was selected from each cluster, resulting in 30 notes (5 per condition). Our assumption is that the representative notes contain information that would be present in other similar notes.

Notes were presented to a group of researchers and medical doctors, who were asked to identify key sections of the note (a sentence or phrase from the EHR) and generate three statements about the section: (i) a paraphrase, (ii) a meaning change, and (iii) a distractor. 154 questions were created, 83 of which were selected for inclusion in the AMT task after manual inspection. Questions that were too specific for a single patient or dealt exclusively with lab results were removed.

AMT workers were given questions related to one of the 6 conditions and asked to select the correct definition of the concept from the three choices generated by the researchers. We collected responses from 1000 AMT workers to fit the IRT models. These responses were then used to fit an IRT model of latent ability and identify the subset of questions that can model ability. The subset of questions was subsequently used in a follow-up AMT task to confirm the validity of the model.
Results

Of the 83 questions used in the first AMT task, 55 were retained as good questions for evaluating latent ability. All 55 were retained after the subsequent confirmatory analysis. Retained questions were significantly more likely to be parsed as full sentences as opposed to noun phrases ($\chi^2 = 17.44, p < 0.001$). Question difficulty parameters range from -2.5 to 0, which is an appropriate range for evaluating low health literacy. The question set can be used to discriminate between low levels of ability in patients EHR note comprehension.

Discussion

In this work we identified a set of questions that can be used in a test of EHR note comprehension by applying the psychometric method of IRT. Using crowdsourced responses we model question difficulty and discriminatory ability to identify those questions that can discriminate between levels of ability across the normal human scale. We found that questions that consist of full sentences and not just noun phrases are more likely to be retained as good questions. This question set was generated directly from EHR notes, meaning that the questions have direct relevance to patients with the same condition. The questions are specific enough to a single topic that they can benefit a specific set of patients, but general enough that they are not unique to a single patient’s care and therefore not useful for other patients. Together they consist of a test to measure a patient’s latent ability to comprehend concepts from EHR notes.

These questions can be used as-is as a test of EHR note comprehension. The test can be administered to patients in preparation for receiving their own EHR notes. In addition, the framework we presented can be replicated to extract notes and questions for other diseases and conditions. Future work will evaluate existing tools for improving comprehension of EHRs to determine if they have a significant effect on the latent ability trait of test-takers. Finally, this question set can be used as a comparison set for systems that automatically generate questions from EHR notes.

Comorbidity Miner: An Open Source Interactive Tool for Mining Disparate Electronic Health Data Sources

Ashley S. Lee, MS1,2, Indra Neil Sarkar, PhD, MLIS2, Genevieve B. Melton, MD, PhD4, Yuanqing Liu, MA2,3, Vivekanand Sharma, PhD2, Elizabeth S. Chen, PhD2

1Data Science Practice, 2Center for Biomedical Informatics, 3Department of Biostatistics, Brown University, Providence, RI, USA; 4Department of Surgery and Institute for Health Informatics, University of Minnesota, Minneapolis, MN, USA

Introduction
The explosion of resources available to healthcare researchers — machine learning libraries, publicly accessible health data, and the pervasiveness of electronic health record (EHR) systems — has resulted in many studies and open source software for mining clinically actionable knowledge from patient data. However, a challenge persists in integrating knowledge from disparate data sources that use different coding systems and terminologies to represent diseases or conditions at varying levels of abstraction. This feasibility study aimed to develop an open source interactive tool for performing comorbidity analyses and demonstrate use for EHR and public health data in the context of anxiety disorders. This tool aims to address the knowledge integration challenge at multiple steps in the underlying pipeline by introducing: (1) versatility in the data ingestion step, (2) automated mapping of diagnosis codes to clinically significant groupings in the cohort selection and data mining steps, and (3) interactive visualization of comorbidities.

Methods
Comorbidity Miner is a web app built in R Shiny (v0.14.1) that performs data preprocessing, terminology mapping, cohort selection, data mining, and visualization. Preprocessing is customized to each data source, with subsequent steps standardized to work with generic data formats. The International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM) was initially selected as the terminology standard for the generic format, which can be mapped to other terminologies such as the Systematized Nomenclature of Medicine Clinical Terms (SNOMED CT) and grouped by Clinical Classifications Software (CCS) as single- and multi-level categories or ICD-9-CM chapters. Apriori and SPADE algorithms implemented in arules (v1.5-0) and arulesSequences (v0.2-16) R packages are used to generate associations and sequences for co-occurring conditions at different levels of support and abstraction. Interactive visualization of results is done using the arulesViz (v1.2-0) and googleVis (v0.6.1) R packages.

Figure 1 shows the interface for data, cohort, and terminology selection, as well as some data mining parameters (e.g., support, confidence, lift, and maximum length) and filters (e.g., sequences containing “Anxiety”). To demonstrate the tool’s versatility, data representing clinical and public health perspectives were instantiated in the app: (1) Medical Information Mart for Intensive Care III (MIMIC-III; v1.3) database, which contains EHR data including ICD-9-CM diagnosis codes from Beth Israel Deaconess Medical Center from 2001 to 2012, and (2) Adverse Event Open Learning through Universal Standardization (AEOLUS; v1.0) database, which includes normalized data about SNOMED CT encoded drug reactions from case reports contained in the FDA Adverse Event Reporting System Database (FAERS).

Results
A cohort with any ICD-9-CM code in the CCS multi-level category 5.2 for Anxiety Disorders, was selected from each data set. Association rules and sequential patterns were generated at four levels of abstraction (ICD-9-CM codes, CCS for ICD-9-CM single- and multi-level categories, and ICD-9-CM chapters) and at varying levels of support, lift, and confidence for each cohort. Figure 2 shows a graph visualization of a subset of sequences with various filters and post-processing steps for MIMIC-III and AEOLUS. Source code at: https://github.com/bcbi/comorbidity-miner.

Discussion
Preliminary findings suggest that public health data may be complementary to clinical data, highlighting the potential value of Comorbidity Miner for facilitating knowledge integration for any disease or condition. The conditions found in AEOLUS are limited to drug adverse events, but are similar to those identified in MIMIC-III when abstracted to CCS categories (e.g., anxiety disorders associated with other psychiatric conditions, cardiovascular and urinary diseases, diabetes, and gastrointestinal disorders established in medical literature). Comorbidity Miner is being actively enhanced to add functionality such as incorporating other types of data (e.g., medications, procedures, and labs), accommodating data sources that use other terminologies (e.g., ICD-10-CM) and groupings (e.g., CCS for ICD-10-CM, PheWAS, and Unified Medical Language System hierarchies), and enhancing visualization capabilities.
Figure 1. Comorbidity Miner interface (left) and sequential pattern mining tab (right).

Figure 2. Graph visualization for association rules for Anxiety Disorders in: MIMIC-III (439 patients, support>0.02, sort statistic=lift, node size=lift, node color=lift) (left) and AEOLUS (1069 cases, support>0.01, sort statistic=confidence, node size=confidence, node color=lift) depicting adverse event co-occurrences (right).

Usability and Feasibility of a Mobile App for Nursing Student Handoff Education

Mikyoung Lee, PhD, RN1, Catherine Bailey, PhD, RN, CNE2, Peggy Mancuso, PhD, RN, CNM, CNE1, & Patti Hamilton, PhD, RN1

1Texas Woman's University College of Nursing, Denton; 2Texas Woman's University College of Nursing, Dallas, TX, USA

Abstract

This study examines the usability and feasibility of a mobile nursing handoff reporting app (ON-SHARE) as an educational tool for baccalaureate senior nursing students to enhance handoff communication skills. The study uses a randomized pretest-posttest design. The usability of the ON-SHARE app is measured by 'think-aloud' comments, user-performance, duration of handoff reporting, and a usability questionnaire. Changes in students' confidence in handoff communication are compared within and between the experimental and control groups.

Introduction

Handoff is defined as the communication process that transfers essential patient information among healthcare providers during patient transitions in care. For decades, the importance of effective handoff communication has been highlighted through research findings of its relationships with patient safety and quality of care. In 2016, however, the Joint Commission1 reported communication failure as the second and third leading cause of serious unexpected, but preventable events (“sentinel events”) in U.S. healthcare settings with “handoff” documented explicitly as a contributing factor. With an increasing focus on strategies to improve handoff communication, studies on nursing handoff communications have accrued considerably2. Nevertheless, few studies have addressed educational designs and the effects of handoff training on clinical nursing education. The need for handoff education in pre-licensure nursing programs is certainly recognized by research findings that handoff failures have been implicated in seven out of eight novice nurses’ near miss and adverse events3.

Current literature reviews indicate that nursing students reported limited opportunities to develop and enhance handoff communication. The process of learning handoff communication in pre-licensure nursing programs is often unpredictable and dependent on clinical experiences4. Students remarked that they were unclear about communication components that constitute best practices5, 6, and they felt disorganized, anxious, and fragmented during change-of-shift interactions5, 7. Various omissions related to patient safety (e.g., missing patient names, incorrect infusion pump settings, and erroneous parameters) appeared in handoff during the clinical rotation of students8. The American Association of Colleges of Nursing's Baccalaureate Essentials9 includes appropriate and safe handoff communication skills as an essential competency of baccalaureate nursing students. Concurrently, there is increased attention towards innovations that integrate health information technology (HIT) to enhance patient safety. However, in many health care organizations, students and faculty have limited or no access to electronic health records because of logistics, security, and privacy issues10.

Students need opportunities to practice the handoff process to increase their confidence, promote teamwork, and enhance critical thinking skills. It is hypothesized that the use of the mObile Nursing Synergy HAndoff REporting (ON-SHARE)11, 12 provides a solution to these challenges in handoff education in a pre-license nursing program. The ON-SHARE app offers an innovative tool that students and faculty can use to document patient assessments, report patient conditions, plan care, and review practice performances during handoff simulations with it. This study aims to examine the usability and feasibility of a mobile nursing handoff reporting app (ON-SHARE) as an educational tool for baccalaureate senior nursing students to enhance handoff communication skills and to ultimately contribute to patient safety and quality of care in clinical learning experiences.

Method

The study uses mixed-methods, incorporating a randomized pretest-posttest design. The ON-SHARE app was developed by integrating the American Association of Critical-Care Nurses’ Synergy Model into the interface design11, 12. A convenience sample of 68 senior nursing students is randomly assigned into experimental and control groups (34 each). Prior to any handoff education and practice, all students complete the confidence in handoff communication skill questionnaire, which consists of 13 questions using a 5-point Likert scale (‘Most Confident’ (=5) to ‘Least
Confident’ (=1)) and an open-ended question for student feedback about the helpfulness of the simulated-handoff practice. With two simulated patient scenarios, the experimental group uses the ON-SHARE app for handoff practices and provides usability data measured by “think-aloud” comments, user-performance screen captures, duration of handoff reporting, and a user satisfaction questionnaire. The control group experiences standard handoff procedures using a paper-based template; the duration of handoff reporting is measured. Students in both groups complete the post measurements of handoff communication skills. The accuracy score is measured by checking if 25 items that correspond to patient condition changes are updated and reported in students’ handoff reports. Total accuracy scores are generated from each correctly captured/updated patient information item (‘Accurate’ (=1) and ‘Inaccurate’ (=0)).

**Results**

The following findings are reported: 1) differences in the accuracy scores associated with capturing patient condition information on handoff reports between the students in the experimental group and the students in the control group, 2) differences in confidence in handoff communication skills of the students within the experimental group between pre- and post-handoff practices, 3) differences in confidence in handoff communication skills after handoff practices between the students in the experimental group and the students in control group, and 4) usability evaluations from the analyses of ‘think-aloud’ comments, user-performances, duration of handoff reporting, and usability questionnaires collected with the use of the ON-SHARE app for handoff practices.

**Discussion/Conclusion**

The senior students’ clinical practices require well-thought out assessments and syntheses of the care rendered to patients. The handoff training via the ON-SHARE app will help students learn how to collect/synthesize patient data, promote an understanding of patient problems and situations, plan interventions, and communicate patient condition information to other healthcare providers while facilitating the application of theory to practice through the opportunity to use/review the HIT app. Strategies for an adoption/implementation of the ON-SHARE app for handoff education in a nursing program will be planned considering lessons from the process of this study and students’ comments.

Clustering Vital Sign Observations Using Unsupervised Random Forest

Dae Hyun Lee¹, Meliha Yetisgen, Ph.D.¹,²
¹Biomedical & Health Informatics, ²Linguistics, University of Washington, Seattle, WA, USA

Introduction

Vital signs are the primary observation in clinical practice. Compared to lab test values, they do not alter subtly due to the compensatory reflex. If altered, those vital signs tend not to be sustained for a long period because aggressive first-line interventions are applied in most cases to prevent further life-threatening deterioration. In addition, vital signs are measured at least once a shift, so they can be ideal features when illustrating a patient’s baseline physiology throughout their hospital stay. In this work, we conducted a clustering analysis using an unsupervised random forest (URF) dissimilarity matrix and k-means clustering to identify vital sign patterns over intensive care unit patients.

Method

MIMIC-II¹ demo dataset was used for the analysis. The dataset includes 4,000 patients with 34,828 intensive care unit (ICU) patient-days. In total, 41.33% of patients died in hospital. Regarding patient demographics, the average age was 72.20 years old (standard deviation: 16.28). For hospital admission, 4,438 emergency, 408 elective, 201 urgency and 27 newborn admission were presented among 5,074 hospital admissions. There were 5,844 ICU admissions among those patients with an average length of stay of 5.46 days (standard deviation: 9.00).

The proposed clustering analysis was based on the hypothesis that abnormal vital sign patterns would be observed frequently among expired patients. We considered systolic blood pressure, diastolic blood pressure, heart rate, respiratory rate, and body temperature to be vital signs, although consensus varies in this regard. As the dataset presented the vital signs as time-series observations, proper abstraction was needed to conduct a clustering analysis. The observations were grouped based on the same hospital day for each patient, and calculated summary statistics (minimum, maximum, average) for each variable. In addition, we introduced sustainment and instability quantifiers from our previous study². Sustainment quantifiers aimed to quantify the atypia of variables using the p-value from t-test and instability quantifiers aimed to quantify instability using the p-value from f-test. Both statistical tests compared population and the sampled observations.

URF³ is a method used to calculate dissimilarities between instances. The technique introduces synthetic data generated from original data, with the objective of the random forest model being to distinguish the former from the latter. Synthetic data is generated by shuffling features by columns, which will introduce a new dataset that ignores inherent feature correlations with the new class label while preserving the distribution of each feature with the same number of instances. In our study, a similarity matrix was calculated using terminal node assignment from random forest sub-trees. The similarity between two instances Iᵢ and Iⱼ, similarityᵢⱼ, was calculated by dividing the number of subtrees that assign the same terminal node on two instances with the total number of subtrees. The dissimilarity matrix was derived by the following: dissimilarityᵢⱼ = √1 − similarityᵢⱼ. K-means clustering was used to cluster instances using the resulting dissimilarity matrix.

Result

To find a URF model for the dissimilarity calculation, various model complexity was considered by changing hyper-parameters, and we chose the one with the lowest skewness (negatively skewed) on the probability of original instances. In an ideal case, we would expect the ideal URF model to assign a low probability of original instance to synthetic instances (positively skewed) and a high probability of original data to original instances (negatively skewed). In addition, we defined cluster mortality as the proportion of the instances from expired patients within the cluster to evaluate the quality of k-means clustering results. For choosing the number of clusters, k, we choose the smallest k that achieves two-fold difference between the highest cluster mortality and the lowest cluster mortality.

We used 34,420 day-level abstracted instances for the cluster analysis after excluding instances with missing values and instances of newborns. The selected URF model resulted in -0.5333 Pearson’s skewness for the assigned probabilities on original instances. We selected k as 20 where the highest cluster mortality (76.73%) was 2.58 times higher than the lowest cluster mortality (29.72%) to generalize our findings although higher k will achieve higher inter-cluster mortality difference.
**Discussion**

Figure 1a presents the cluster mortality for each cluster after k-means clustering, \( k = 20 \). As can be seen from the figure, cluster 16 included more vital signs from expired patients, and observed heart rate and respiratory rate in the cluster tends to be comparably lower while other variables followed population distribution (Figure 1b). For cluster 0, on the other hand, instances with lower heart rate and higher systolic blood pressure were gathered compared to population distribution. In addition, Cluster 3 included the majority of instances (76.73%), while other clusters included the remaining instances (29.72%), which were distributed with minor variations. The k-means clustering approach, using dissimilarity, first aggregated instances that deviated from population distribution, while instances wherein all vital signs followed population distribution were assigned a lower priority in clustering tasks.

The information gain from the selected URF model showed that it assigned different weights to features when classifying original and synthetic instances, thereby indicating that feature contribution would also be different when calculating dissimilarity between instances (Figure 1c). Unweighted Euclidean distance is a common way to calculate the distance between instances when conducting k-means clustering. However, it assumes the contribution of features equally when calculating distances. On the other hand, the URF dissimilarity considers the feature relationships represented in the original dataset. Therefore, URF dissimilarity is more feasible compared to Euclidian distance for the clustering task on clinical variables because the features are known to interact each other.

**Conclusion**

Due to the magnitude of EHRs, it is hard to review all patient vital signs manually to verify potential abnormalities. Therefore, we provided a clustering analysis using patient-day abstraction to identify the groups of potentially abnormal patient day-level vital signs, which could present during patient deterioration.

We are currently in the process of creating a comprehensive clinical dataset from University of Washington Medical Center and Harborview Medical Center. This new dataset will include structured clinical observations, unstructured clinical notes, and time-stamped clinical events created during hospitals stays of a large population of patients. We are planning to conduct the clustering analysis using a broader feature space.

Patient-Reported Outcomes in Clinical Use: Clinician Perspectives
Cynthia LeRouge, PhD1, Andrea Hartzler, PhD 2, Liz Kellogg, MPH1, Mary Beth Hasselquist, MD1, Danielle Lavallee, PhD, PharmD1
1: University of Washington, Seattle WA; 2: Kaiser Permanente Washington Health Research Institute, Seattle WA

Introduction
Patient-Reported Outcomes (PROs) such as functional health, quality of life (QoL), and well-being represent a patient’s perspective about their health without interpretation or filtering from clinicians or caregivers. Growing evidence demonstrates that collecting PROs increases clinician awareness of patients’ concerns1, reduces symptom distress2, and enhances patient-clinician communication without increasing visit length2,3. When patients share PROs with their healthcare team, patient satisfaction, perceptions of QoL, and clinical outcomes improve3. Thus, shifts towards patient-centered healthcare and payment reform initiatives call for the inclusion of PROs in clinical practice. Given this environment, evolving healthcare systems are increasingly exploring the use and integration of PROs into routine clinical care.

Although there is promise in clinical use of PROs, most clinicians and care teams do not routinely or systematically capture such metrics. Rather, clinicians generally gather informal assessments of patient outcomes, often based on their own impressions. Many clinicians remain skeptical about using PROs in clinical care and uncertain of how to incorporate this data into routine practice. Although clinicians express concern that adding PRO displays to clinical workflow could add complexity, some studies highlight the increased efficiency and usability of PRO measures that are integrated with existing EHR systems. The development of meaningful and sustainable PRO capture and reporting systems for clinical practice requires further study of the perspectives, needs, and characteristics of clinicians.

Pilot work that informed the current study through interviews with a diverse sample of clinical stakeholders (n=12) across specialties revealed the following clinician perspectives: a) the need for long-term collection of PRO to achieve value; b) the need for new tools to both capture and report PROs as part of practice workflow; c) concerns about data visualization tools that may slow or impede workflow; d) concerns over what PRO data might show and how their practice might change as a result of sharing and having to explain such data; and e) concerns about how to interpret data of questionable validity or accuracy, and f) lack of clarity regarding how to manage missing data or data that conflicts with clinical findings. Despite those obstacles, pilot participants voiced enthusiasm for leveraging PRO data for enhancing healthcare practice and outcomes.

Funded by the Agency for Healthcare Research and Quality (AHRQ), we are expanding on pilot findings by further exploring the design, implementation, and workflow for use of PROs in clinical care at University of Washington Medicine. UW Medicine is performing a system-wide deployment of the EPIC PRO module. The context provides an opportunity to extend early pilot interviews to more deeply discern clinician perceptions of PRO use and workflow, the challenges and affordances resulting from integration of PROs with electronic health record (EHR), and visual preferences for PRO displays. The clinician network from which we recruited participants includes both novices to PRO systems as well as seasoned PRO users with experience using homegrown and other commercial systems.

Methods
We are conducting in-depth interviews with clinicians engaged in implementing the EPIC PRO module to explore their perceptions about clinical use of PROs. The 19 participants interviewed to date represent the following specialties: orthopedics, cardiology, urology, and general surgery. The semi-structured interview protocol contains two sections. The first section explores perceptions of PRO use and workflow and both challenges and affordances associated with integration of PROs with an EHR. The second section of the protocol asks participants to react to various graphical PRO visualizations (i.e., line graphs, bar charts, and scatterplots) and detailed aspects of each visualization. The protocol includes coverage for three types of PRO visualizations: 1) longitudinal PROs for a specific patient; 2) comparative PROs for one patient relative to other patients; and 3) performance information that compares PROs for a clinician’s or practice’s patients to other patients.
Interviews are recorded, transcribed, and checked for accuracy. Two independent coders perform open coding with periodic reconciliation of general themes aided by a third reviewer who also performs a detailed review of all coded quotes post-reconciliation. This procedure aligns with other published open coding reconciliation procedures.

**Results**

**PRO Use:** Interest and enthusiasm for the use of PROs in patient care was greater when PROs provided information that participants felt they could not obtain by conventional means (e.g., clinical tests and general conversation). Participants indicated that they would most frequently use PRO data to discern longitudinal trends of PROs as a check of patient status and would use PRO visualizations that compared their patient to other patients to assist with shared decision making. Even when probed, none of the clinicians interviewed indicated that they would ordinarily review PROs data outside of encounters with patients, barring situations where they may be conducting a research study and using PRO data to support that study.

Regarding the use of PROs for quality improvement and practice performance, participants’ reactions varied widely between strong support and strong opposition. Mirroring results from our pilot related to using PRO data to make comparisons among clinicians, several participants expressed concerns over data ownership and unintended consequences of making PROs available outside the clinic, whether accessed by system administrators or the public.

**PRO Workflow:** Although electronic PRO capture from patients outside of clinic visits was perceived to be vastly more efficient for staff workflow, participants recognized this would not be feasible for all patients and that electronic means of capturing data from patients in waiting rooms (e.g., tablet, kiosk) and paper back-ups would be required. Data capture outside of clinic visits was preferred to ensure that the most recent points of data were included. Regarding review of PRO data captured, most participants reflected time constraints and indicated that they would “glance” at PRO data to check patient status prior to entering the exam room and possibly again during an encounter to share with a patient, particularly if PRO trends were favorable after a procedure or to assist with shared decision making. Although all participants expressed the preference for integration of PROs in the EHR to facilitate workflow by avoiding the need to connect with an external system, there were mixed perspectives regarding the actual need to integrate clinical data with PRO data.

**PRO Visualization:** Participants universally preferred simple graphs (e.g., line and bar graphs) to other graphical options (e.g., box plots and scatter plots) and referenced pictographs as being useful to share with patients. The preference for illustrating benchmarks or minimally clinically important difference scores on PRO visualizations varied widely among specialties. For PROs involving an intervention (e.g., surgery, new medication), participants preferred a clear indication of the point in time of the intervention indicated on longitudinal graphs.

**Discussion**

Overall, our findings suggest that many clinicians perceive a PRO system as a potentially valuable addition to augment their patient care process if preferences for use and visualizations are met and if PRO workflow is streamlined. Our findings reveal many commonalities among clinician perspectives of PROs as well as a few nuances among specialties. This suggests that a moderate degree of customization may be needed for a system-wide deployment of PROs to meet clinician expectations of PRO usefulness and ease of use. In addition, our findings reveal both the opportunity to share PRO data across specialties as well as the challenge of defining a systemwide scale for common measures of interest (e.g., quality of life or depression) to avoid redundancy. Our work to date provides referential data regarding patient process and preferences; future work will integrate these findings with patient perspectives or PRO systems.

When to re-order laboratory tests? Learning lab shelf-life

Gal Levy-Fix, MA1, Sharon Lipsky Gorman, MS1, Noémie Elhadad, Phd1
1Department of Biomedical Informatics, Columbia University, 622 W. 168th Street, New York, NY, USA

Introduction

A lab test result reflects the health state of a patient for only a certain time period, after which the test is outdated and needs to be re-administered. We refer to this duration as the lab shelf-life. Currently this information is not centrally available anywhere and largely depends on implicit knowledge of doctors. In this work we propose an automated method to learn lab-specific shelf-life or shelf-lives (if there are several) by mining lab orders patterns reflected in patients’ electronic health record (EHR). Lab shelf-life information has multiple use cases including encoding in decision support tools such as those aimed to prevent over-testing or those reminding to test as well as determining the informational utility of available data for modeling tasks.

Previous work have utilized occurrence of lab orders as inputs for probabilistic phenotyping and clinical order recommendations.1–3 Manually identified patterns in the time between lab orders have been used to identify guideline adherence, emergence of new practices, and order context.4, 5 By contrast to previous work, our proposed method automates the identification of prevalent order patterns using time between orders across many patients.

To identify lab shelf-life we utilize an anomaly detection method originally developed for the analysis of long-term time series. We implement this method on patient EHR data from New York-Presbyterian Hospital (NYPH) for 69 lab types and evaluate our findings based on the method’s ability to identify common gap lengths in the data (internal validity), clinical interpretability, and its utility in modeling phenotypes (external validity). The method was found to perform well on all three tasks.

Methods

To identify prevalent patterns in the time between lab orders we calculated the time gaps for each lab in the records of about 14,000 patients (Figure 1(a)). The frequency of each gap length was then aggregated for each lab over all patients in the studied cohort. We then applied an anomaly detection method called Seasonal Hybrid ESD (S-H-ESD)6 on each lab series (Figure 1(b)). S-H-ESD combines seasonal time-series decomposition7 and the generalized Extreme Studentized Deviate (ESD) test.8 The method removes any seasonal and trend detected in the data before implementing the ESD estimation, since anomalies are more difficult to detect in data with such forces at play. To make identified peaks robust and clinically relevant we excluded all identified gap lengths longer than 365 days and which were exhibited in the records of less than 40 patients.

Figure 1: Method approach for a specific lab (A1c). Given all patients’ A1c measurement gaps the method finds gaps at about 3 months and 6 months; consistent with clinical guidelines for A1c testing.
Experimental Setup

To evaluate the performance of the proposed method we designed three complimentary evaluation tasks. In Task 1 we set out to assess the **internal validity** of the anomaly detection method to find peaks in lab-gap frequencies. We do this by comparing gap lengths found by the method to those found by visual inspection of histogram graphs of the data as a sort of sanity check. Task 2 evaluates the **clinical interpretability** of the identified gap lengths by a review of a domain expert. The domain expert was to assess whether the identified gap-lengths correspond to clinically meaningful shelf-lives. Task 3 focuses on task-based evaluation, where the task is to learn high-throughput phenotypes at scale (K=250 phenotypes). The Phenome model was used and its standard metrics for quality were used to assess the learned phenotypes qualitatively and quantitatively.\(^1\) We compare the output of Phenome to one that incorporates gap lengths.

Results

In Task 1, the average precision at K across the labs was found to be 90% and the average recall at K was 89%. Hence, a large majority of the identified gap lengths were confirmed visually in the lab histograms, while some manually identified gap lengths were missed by the method. Before the post-processing steps the average precision at K was 79% and average recall at K was 86%. Hence the post processing steps removed several false positive gap lengths according to the manual review. In Task 2, the results for 96% of the labs were found to be largely consistent with the medical opinion of the expert (such as that of Hemoglobin A1c seen in Figure 1(b)) while a few lab- gaps identified in the data remained unexplained by medical guidelines. Finally, in Task 3, the Phenome model using the alternative lab feature was found to preform as well as the original Phenome model in terms of log-likelihood of unseen patients and in terms of the qualitative assessment of the clinical expert.

Discussion

We show that contextual anomaly detection method can be used to identify laboratory shelf-life lengths from patients’ lab order histories. Identified shelf-lives using this method were found to be highly consistent with a visual evaluation of the lab order patterns and clinical knowledge, with few exceptions. Most of the analyzed labs were found to have more than one shelf-life, pointing to multiple context of use. The shelf-lives were shown to be useful in categorizing patient lab data into gap-length types for phenotype modeling.

User-Centered Design of a Collaborative Genetic Variant Interpretation Tool

Wayne H Liang, MD MS¹, Bas de Veer, MSc², Diane M Korngiebel, DPhil², Annie T Chen, MSIS PhD², Gail P Jarvik, MD PhD², Peter Tarczy-Hornoch, MD², David R Crosslin, PhD²
¹University of Alabama at Birmingham, Birmingham, Alabama,
²University of Washington, Seattle, Washington

Introduction

Precision genomic medicine is reliant upon accurate genetic variant interpretation knowledge¹. However, multiple studies have reported high levels of inter-rater discordance in variant interpretation²⁻⁵. Contributing factors include heterogeneity in sequencing pipelines, inadequate knowledge sharing, and institution-specific variant interpretation criteria⁶. In 2015, the American College of Medical Genetics and Genomics (ACMG) and the Association for Molecular Pathology (AMP) published joint guidelines standardizing variant interpretation⁷. The Clinical Sequencing Exploratory Research (CSER) consortium evaluated the guidelines with 97 test variants across nine laboratories and found inadequate inter-laboratory concordance (K alpha = 0.76, 66% discordance rate⁸). Contributing factors include calculation errors, differing guidelines interpretation, and information siloing. Concordance improved significantly after a collaborative consensus process with inter-rater discussion and knowledge sharing.

Computerized tools supporting collaborative variant interpretation may improve consistency in genetic variant interpretation⁹⁻¹¹. We report on a user-centered design of an openly available computerized tool that supports role-based collaboration, knowledge sharing, and consensus-making in variant interpretation.

Methods

Part A. We used literature review and informal expert input to a) characterize the existing variant interpretation workflow; and b) create initial designs for a collaborative workflow, web-based graphical user interface (GUI), and technology architecture for a collaborative variant interpretation tool. Part B. We used user-centered design methodology, including user interviews and design feedback sessions with molecular geneticists, to a) further characterize the existing workflow; b) define user requirements and desired functionality; and c) refine designs for the collaborative workflow, GUI, and technology architecture. User sessions were audio-recorded, transcribed, and coded for themes using an analysis methodology based on Grounded Theory.

Results

Part A. We characterized the existing workflow and developed a proposed collaborative workflow based on the Delphi Method, an established structured communication process to facilitate consensus among multiple experts¹². We developed an initial GUI and REDCap-based technology architecture to support this workflow (Figure 1C).

Part B. Four faculty molecular geneticists representing different laboratories at the University of Washington enrolled in the user-centered design process (six invited, response rate = 67%). We conducted four 45-60 minute interviews, which were transcribed and coded for thematic content. User feedback data were used to further characterize the existing workflow, define user requirements, define desired functionality, and refine designs.

In our revised design, MEGA (MEdicine Gene Annotation) is a tool integrated within the existing workflow to support role-base collaboration, knowledge management, and knowledge sharing for variant classification (Figure 1A). MEGA consolidates all clinical, phenotypic, and variant annotation data required for variant interpretation. InterVar, an open-source guidelines-based pathogenicity classification calculator, is used to perform semi-automated classification predictions⁸. MEGA consolidates interpretation opinions from collaborating geneticists and external consultants. The Delphi Method-based workflow was removed based on user feedback. MEGA supports the report author in finalizing the variant interpretation. Variant data is saved in an internal knowledge base and can be exported to external systems (e.g. ClinVar).

The GUI was revised to support the revised workflow (Figure 1B). The Interpretation Panel is designed to resemble the ACMG/AMP Guidelines evidence table. This interface captures and displays the evidence and interpretation assignments entered by the predictive rules engine, all collaborators, and the user, to enable collaboration. The
Evidence Panel displays all necessary phenotypic and annotation data for classification. The technology architecture is unchanged (Figure 1C).

Figure 1. Final Design. (A) Workflow. (B) Graphical user interface. (C) Technology architecture.

Discussion

We report on a user-centered design of an openly available tool supporting role-based collaboration, consensus-making, and knowledge sharing in variant interpretation. We used user-centered design methodology, which is not commonly used in bioinformatics, to design this tool. Our experience demonstrates that user-centered methodology uncovers rich user data that can significant change the direction of the design process. The Delphi Method-based workflow was eliminated based on user feedback. Future direction include conducting additional user interviews and design sessions across multiple sites, building a working prototype, conducting usability testing with the working prototype, and testing within an actual laboratory workflow.

Promoting Adoption and Effective Use of Continuous Patient Monitoring Technology in the Acute Care Setting

Graham Lowenthal1, Stuart R. Lipsitz, ScD1, Catherine S. Yoon, MS1, Perry G. An, MD2, Suzanne Salvucci, RN2, Christine Shaughnessy, RN2, Sharon Keogh, RN2, David W. Bates, MD, MSc1,3, Patricia C. Dykes, PhD, RN1,3

Introduction
In the acute care setting, patients often exhibit physiological signs of deterioration, such as adverse changes in heart and respiratory rates, hours before experiencing critical events.1,2 Continuous patient monitoring systems have demonstrated potential to aid clinical staff in detecting these early physiological warning signs and taking appropriate actions sooner to prevent patient deterioration before conditions become too severe.1,3 In January of 2013, a continuous monitoring system was implemented on all adult medical-surgical beds in an Eastern Massachusetts acute care hospital. This particular system uses contact-free sensors under the patient’s mattress to continuously measure heart rate, respiratory rate, and motion. Through real-time analysis of its collected measurements, the system can accurately recognize trends, identify clinical deterioration, and deploy audible and visual alerts to influence earlier care team intervention.3 Controlled trials had linked use of this system to improved quality of care, length of stay, and cost outcomes.1,3 However, observation of real-world staff workflow at the implementation site revealed much resistance to system adoption and to adherence to practice guidelines, limiting projected benefits. This podcast presentation will describe the process our team used for identifying and overcoming barriers to adoption and effective use of the continuous monitoring system.

Methods
We established a committee of key stakeholders: physicians, clinical champions (nurses, managers, educators, and patient care assistants) from all study units, researchers, and vendor partners. Our committee hosted regular meetings to identify barriers to adoption and effective use of the continuous monitoring system. We then designed practical solutions based on staff and unit needs using a cyclical Plan Do Study Act (PDSA) framework. We developed strategies and tactics for addressing each discovered barrier (PLAN), executed the intervention (DO), evaluated effectiveness of our methods (STUDY), and revised then redeployed our approach (ACT). Our desired outcome was improved system adoption and adherence to practice guidelines. We measured the success of our PDSA interventions toward achieving this outcome through observed changes in staff alert response times: the interval between the triggering of an alert from the continuous monitoring system, patient assessment at bedside, administration of treatment, and electronic dismissal of the alert on the patient’s bedside monitor. The smallest response times were considered the most ideal.

Results
Working with hospital staff, we identified and addressed several barriers to adoption and effective use of the continuous patient monitoring system. Barriers, as well as the strategies and tactics we developed to overcome those barriers, are detailed in Table 1. Using our PDSA solutions, staff produced statistically-significant improvements (trend P-value < 0.001) to response times between January 2014 and January 2017. During this period, monthly mean cardiac alert response times improved from 105 (range: 17 to 312) minutes to 21 (range: 5 to 43) minutes. Mean respiratory alert responses improved from 91 (range: 26 to 360) minutes to 26 (range: 8 to 61) minutes. Mean combined (cardiac and respiratory) alert responses also improved, from 92 (range: 17 to 360) minutes to 25 (range: 5 to 61) minutes.

Discussion
Using our PDSA framework allowed us to effectively address barriers to adoption and support proper use of the continuous monitoring technology in the acute care setting. We chose to employ a PDSA because its cyclical nature enables users to continuously adapt improvement approaches to changing needs. This allowed us to facilitate consistent progress in an often hectic and constantly changing environment. Involving hospital staff, the system’s end-users, was imperative for the implementation to succeed. Empowering staff to voice their own concerns and observations allowed for much more effective identification of barriers. Likewise, permitting staff to contribute directly to development of practical solutions and workarounds facilitated greater unit engagement in improvement
efforts. We used response times as the unit for measuring progress toward outcomes because in order to maximize the benefits of continuous monitoring systems staff must respond to alerts as quickly as possible. Therefore, the response time improvements that we facilitated may indicate greater opportunities for staff to recognize, act appropriately on, and prevent patient deterioration earlier. To test this, future research will focus on measuring the impact of our documented improvements with the continuous monitoring system on clinical outcomes.

Recurrent Neural Networks for Classifying Relations in Clinical Notes

Yuan Luo

1Department of Preventive Medicine, Northwestern University, Chicago, IL, US

Introduction

Relation extraction from text documents is an important task in knowledge representation and inference in order to create or augment structured knowledge bases and in turn support question answering and decision making. In the clinical domain, extracting relations from clinical narratives has been gaining attraction over the past decade. Part of the advances in the state-of-the-art specialized clinical NLP systems for identifying medical relations have been documented in the 2010 i2b2/VA challenge workshop, which attracted international teams to address successive shared classification tasks. The challenge focused in part on identifying the relations that may hold between medical problems and treatments, between medical problems and tests, as well as between pairs of medical problems. Support Vector Machines (SVMs) were a common theme among the systems that tackled the relation extraction task in the challenge. All challenge participating systems involved heavy feature engineering; they explored lexical, semantic, syntactic, general domain and medical domain ontology features etc.

Systems that use many human engineered features often do not generalize well to new datasets. Recent progress on applying recurrent neural networks (e.g., Long Short Term Memory, LSTM) to clinical datasets aims to minimize the amount of engineered features and has achieved some success on specific tasks such as early detection of heart failure onset using structured clinical data and de-identification of patient notes. In this work, we use recurrent neural networks to classify the semantic relations from the 2010 i2b2/VA challenge, which include relations from the following three categories. The medical problem-treatment relations include: treatment administered for medical problem (TrAP), treatment is not administered because of the medical problem (TrNAP), treatment improves medical problem (TrIP), treatment causes medical problem (TrCP), a patient’s medical problem has deteriorated or worsened because of or in spite of a treatment being administered (TrWP), and no relation. The medical problem-test relations include: test has revealed some medical problem (TeRP), test was performed to investigate a medical problem (TeCP), and no relation. The medical problem-medical problem relations include: two problems are related to each other (PIP) and no relation.

Methods

Word embedding

For NLP applications, recurrent neural network models are most used together with word embeddings. The word embedding is designed to capture semantic similarity of words. Neural language modeling tools such as word2vec can learn embedding vectors from an unlabeled large text corpus, based on the word’s contexts in different sentences. We trained word vector on clinical notes from MIMIC-III database using word2vec tool. Of note, the MIMIC-III dataset contains clinical notes for over 46,000 patients with a total of 100 million words.

Segment level LSTM for relation classification

Some of the top performers in the i2b2/VA relation classification challenge reported that distinguishing the concepts vs. context text, and further subdividing the context text into text preceding the first concept, between the concepts, and succeeding the second concept. To explicitly model the concept and context text, we construct segment level LSTM architecture for relation classification, as shown in Figure 1. We divide the concept and context text into five segments: before the first concept (preceding), of the first concept (concept 1), between the two concepts (middle), of the second concept (concept 2), and after the second concept (succeeding). For each segment, we feed the sequence into a LSTM layer then a pooling layer to learn the \( n_{hu} \)-dimensional hidden feature representation. We then concatenate the hidden features from the five segments into one \( 5n_{hu} \)-dimensional feature vector, input the feature vector to a softmax layer to produce the relation class labels. In our input data from the i2b2/VA challenge, some of the concepts are annotated on the head word, while others are annotated including preceding and succeeding modifiers. To more consistently capture concept characteristics, we allow the text of the concepts to be padded before and after by neighboring words.

Experiments and Results

In order to fairly compare our models with those from the i2b2/VA challenge participants, we used the same split of the training and test datasets by the challenge organizers. To optimize the parameters for our models, we further randomly selected 10% of training dataset as the validation set and used it to tune the parameters. For segment level LSTM models, we experimented with a series of padding sizes (from 3 to 10) for padding the concept text with their...
context. We experimented with multiple numbers of hidden units (100, 150, and 200 in this work). For regularization on the LSTM models, we used dropout technique in the output of the pooling layer. We compared our systems’ performance with the top four teams from the i2b2/VA challenge participants, as shown in Table 1. From the comparison of the micro-averaged f-measure, we see that segment LSTM model ranks the second in classifying the TrP relations, the third in TeP relation classification, and the third in PP relation classification. Overall segment LSTM achieved good performance that are comparable to state-of-the-art systems from i2b2/VA challenge participants with heavily engineered features, even though segment LSTM uses only the basic word embedding as features.

Table 1 Performance of the LSTM models. Performance of top four i2b2/VA challenge participating systems are also included for comparison. Best micro-averaged f-measures are in bold. R = Recall, P=Precision, F=F-measure.

Conclusion

In this work, we proposed the first system based on LSTM for classifying relations from clinical notes. We showed that our segment LSTM models achieved a micro-average f-measure of 0.661 for classifying medical problem-treatment relations, 0.800 for medical problem-test relations, and 0.683 for medical problem-medical problem relations. These results support the use of LSTMs for classifying relations between medical concepts, as they show comparable performance to state-of-the-art systems from the i2b2/VA relation classification challenge while requiring no manual feature engineering.

A Pilot Randomized Trial to Train Vulnerable Primary Care Patients to Use an Online Patient Portal Website

Courtney Lyles PhD, Lina Tieu MPH, Stephen Kiyoi MLIS, MS-HAIL, Shobha Sadasivaiah MD, Mekhala Hoskote, Neda Ratanawongsa MD MPH, Urmimala Sarkar MD MPH, and Dean Schillinger MD

University of California San Francisco, Department of Medicine at Zuckerberg San Francisco General Hospital and Trauma Center, San Francisco, CA

Introduction
Patient portals, websites that provide patients and caregivers access to personal health information, are becoming ubiquitous in the US, especially with the support of Meaningful Use financial incentives. Previous research has documented substantial usability barriers, especially among patients with limited health literacy. We conducted a randomized pilot trial to determine the effectiveness of a scalable online video-based training program to increase use of a portal website among patients in a safety net healthcare setting. We further explored whether training outcomes varied by mode of delivery (administered in person vs. distributed via a link) or by patient characteristics.

Methods
Based on our previous work documenting usability barriers to portal use, we created a curriculum with simple instructions and 11 how-to videos for accessing features of the patient portal available in the public healthcare system in San Francisco (videos available at http://www.sfhealthnetwork.org/about-myshealth), distributed through a link to an online learning platform, Learnerweb. These videos were developed in close consultation with both a patient advisory board (members included primary care patients from the system with varying experience with technology) and project advisory board (members included experts on health information technology research, adult education, and clinical operations) to ensure that the content was appropriate in terms of digital and health literacy levels of the target population.

We then randomized 93 patients to receive either: 1) an in-person tutorial with a trained research assistant versus 2) a link to watch the videos on their own. To identify eligible individuals, we identified English-speaking patients with at least 1 chronic condition (heart disease, diabetes, hypertension, heart failure, asthma, kidney disease, anxiety, depression) through a chart review of patients with recent clinic visits, as the portal website was only available in English. Through phone screening, we excluded individuals with no previous email use. We also excluded those who reported use of the portal website in our setting in the previous year. We assessed health literacy status using a screening item, categorizing participants noting any lack of “confidence filling out forms” as having limited health literacy.” Follow-up measures were collected via phone after participants had a clinic visit ≥3 months post-baseline, or at 6 months if they had no visit.

The primary outcome was portal use (proportion of patients who signed on to the portal website and number of log-ins) between 3 and 6 months post-training, assessed through electronic chart review. Data on use of specific portal features was not available through the electronic health record. We collected baseline and follow-up survey measures regarding participants’ perceptions of the importance of the portal website, experiences with their chronic illness healthcare (using the Self-Efficacy for Managing Chronic Disease Scale,2 and Morisky Patient Medication Adherence Scale3), and digital health literacy ratings (using 4 questions from the eHealth Literacy Scale4). Using the tracking capabilities of the online training platform, we also measured whether participants viewed the training videos over the course of the study.

Results
The trial enrollment was completed in September 2016. From a list of 833 provider-referred patients, we contacted 377 via phone, of whom 52 declined and 186 were ineligible primarily due to lack of email use (108, 58%). Of the remaining 139 individuals, 93 participants were enrolled. The mean age of the sample was 54 years, and 51% had self-reported limited health literacy; 60% were non-white, 52% were female, 45% were in fair or poor health, 25% reported speaking English less than very well. While the majority of participants used the Internet and email daily (76% and 65%, respectively) and reported that it was very important to access their medical information
electronically (75%), at baseline over a quarter (27%) reported that they believed they lacked the skills to use a portal website to manage their healthcare.

By design, everyone in the in-person training arm watched the videos at least once, compared to 44% of those in the take-home arm (p<0.01). Overall, among the 93 enrolled, 35 participants (41%) logged into the portal at least once at follow-up (including the 17 those who had logged into the portal before the study); 18 participants (21%) logged into the portal website during the 3 to 6 months post-training. These proportions did not differ by the in-person vs. take-home training assignment (37% vs. 45% (p=0.41) for having ever logged in and 21% vs 20% (p=0.91) for logging in 3 to 6 months post-training). The mean number of log-ins to the portal website in the 3 to 6 months post-training was 1.4 (s.d.=3.2). Number of log-ins did not differ by study arm (average 1.2 for take-home, 1.6 for in-person, p=0.57). Overall, we found significant improvements in ratings of digital literacy (p<0.01) and medication adherence (p<0.01) from baseline to follow-up, and a trend toward an increase in self-efficacy for managing chronic disease from baseline to follow-up (p=0.09).

When we analyzed rates of portal login during the follow-up period, we found significant differences in portal use by age, health literacy status, and number of chronic conditions. Participants who were 60 or older were more likely to log in to the portal than their younger counterparts (33% vs. 13%, p=0.03). In addition, participants with adequate health literacy were more likely to log in than those with limited health literacy (35% vs. 7%, p<0.01). Participants with only 1 chronic condition were significantly more likely to log in than those with 2 or more conditions (35% vs. 15%, p=0.04).

To measure per-protocol outcomes, we examined the subgroup of participants in either arm exposed to the training videos at least once (n=60): 23% logged into the portal in the follow-up period, which was not statistically higher than the 15% among those who did not watch the videos (p=0.41). However, there was a significant improvement in patients’ self-reported skills in using the portal website: 65% agreed or strongly agreed that they had the skills to use the website at baseline, and this improved to 80% at follow-up (p=0.04). There was also a trend toward higher patient ratings of the Internet being useful for their health needs (58% at baseline to 74% at follow-up, p=0.09). Notably, we found that interest in using the portal among those who accessed the training decreased significantly: 91% reported moderate to high interest in using the portal at baseline versus 75% at follow-up (p=0.02).

Of note, 58% (n=26) of those in the take-home arm and 49% (n=20) of those in the in-person arm had been registered for portal access prior to enrolling in our study but did not have self-reported experience in using the website. Among this subsample of already registered patients, 12% (n=3) in the take-home arm and 25% (n=5) in the in-person arm logged into the portal following training, but this trend did not reach significance among this limited sub-sample (p=0.23).

Conclusion

Patients receiving care in safety net health care settings are interested in using a portal to help manage their healthcare. An online training program appeared successful in improving patients’ confidence in their skills to use the website, motivating subsequent 6-month portal use among about 1/5 of the patients regardless of the training vehicle (i.e., in-person vs. take-home link). While this moderate rate of portal use is likely higher than the secular trends in portal use we have observed in this safety net healthcare system, there is room for improvement in patient engagement in this and similar settings. In particular, a one-time training session may be insufficient for patient activation, particularly for patients with limited health literacy. More research is needed to determine what additional patient-level and provider-level interventions are needed, as well as to determine how to make portal interfaces more engaging and user-friendly.

Leveraging SNOMED CT Relationships for Mapping Disease Codes with Different Levels of Abstraction between EHR Systems

Sina Madani, MD, PhD, Shari Just, RN, BSN, Scott D. Nelson, PharmD, MS
S. Trent Rosenbloom, MD, MPH, Asli Weitkamp, PhD
Vanderbilt University Medical Center, Nashville, TN

Abstract
There is an increasing demand for rapid and consistent mapping of data elements to terminology standards to support data migration between clinical information systems. However, the level of detail used for representing clinical concepts in the source and target systems may not be the same. Furthermore, such translation relies heavily on domain experts’ knowledge and consistency in mapping. We have developed a framework for efficient mapping between two clinical data sets within two EMR systems using SNOMED CT hierarchical relationship.

Introduction
Mapping clinical concepts to standard terminologies like SNOMED CT leads to numerous benefits, including unambiguous data capture and support for semantic interoperability in clinical and research domains. Migrating between Electronic Health Record (EHR) systems requires rapid and coherent translation of clinical data into the new system. To support the integrity of such data during EHR migration, mapping between source and target concepts should be kept consistent and semantically meaningful. Such mappings can maintain the quality of patient data for health care providers during the implementation and data migration to a new EHR system.

Vanderbilt University Medical Center (VUMC) is in the process of data conversion from various modules of the its home grown EHR, such as Family Medical History (FMH), to a commercial EHR system. Although clinical concepts used for family medical history in our legacy and target EHR systems were both bound to SNOMED codes, FMH data migration process underwent an additional mapping procedure due to the differences in the granularities of the concepts represented in the source and target data sets. To improve the pace and consistency of the mapping between the two systems we used existing SNOMED CT hierarchical relationships, such as the is-a relationship. The main objective of this study is to evaluate a framework for identifying equivalent concepts between two data sets that represent family medical history findings with different levels of abstraction in two EHR systems. We have used structural resemblance of the concepts within SNOMED CT hierarchy in order to find the best match based on the closeness of the parent concepts from the source to the target concepts.

Methods
We identified all Family Medical History (FMH) concepts represented by SNOMED CT codes within the current VUMC EHR system that have no direct match to SNOMED CT concepts in the target EHR system. All retired SNOMED concepts were excluded or replaced with an active concept based on the 2016 version of SNOMED CT. We used a graph version of SNOMED CT (v2016AA) to identify all hierarchical parents, grandparents, and ancestors of FMH concepts in our legacy system by using SNOMED CT is-a relationships. During the query process, we calculated the distance of each extracted parent concept to its child FMH concept. We then compared SNOMED CT codes associated with parent concepts to the existing SNOMED CT codes in the target EHR system to find possible matches based on the closest distance. Subject matter experts (SMEs) evaluated the mapping to validate whether the suggested closest parent concept was the best match among the target data set repository (Figure 1).

Figure 1. Mapping schema between VUMC and target EHR concepts
Results

We identified 2,014 unique SNOMED CT codes associated with Family Medical History (FMH) context in patient records within our legacy system without any direct equivalency to SNOMED CT codes bound to the target EHR FMH concepts. However, one or more parent concept(s) of the source FMH concepts in our system had a direct match to the limited set of 637 SNOMED CT codes within the target EHR system (Figure 1).

The SMEs confirmed 88.6% of the mappings of the nearest parent concept as appropriate (Table 1). For 34 VUMC FMH concepts, with more than 1 parent with matching target EHR concepts, another parent concept other than the nearest concept was considered as the best map to a target EHR concept. For example, for Myoclonic Seizure two parent concepts identified as Movement Disorder and Seizure Disorder with a distance of 2 and 6 to Myoclonic Seizure respectively. Despite the fact that Movement Disorder is the closest concept to Myoclonic Seizure (based on SNOMED CT hierarchy) the domain expert decided to select Seizure as the best match within the target EHR. Moreover, in 124 cases where there was only 1 suggested parent match to a target EHR concept, the SMEs decided to reject the map and pick another concept from the target EHR concept that seemed more relevant. For example, there were 44 instances of different types of Arrhythmias in FMH (like Tachyarrhythmia) where the nearest parent with a map to a target EHR concept, Heart Disease, was replaced with Conductive Disorder of Heart by SMEs. The reason for this and similar cases (like cancer related concepts) were due to the fact that less granular concepts can be located at the same hierarchical level as their semantically related concept with more granularities under the same axiom or other axioms in SNOMED CT. There were 72 VUMC FMH concepts that SMEs couldn’t find any direct match between their parent concepts and the target EHR concepts or any other relevant concepts in the target list.

Discussion

Standard clinical terminologies, such as SNOMED CT, that tend to cover medical domain are often used in EHR systems. These terminologies, with different levels of granularities, may overlap with other terminological sources that are used in different applications. Identification of equivalent clinical concepts with lexical and semantic similarities between terminologies is an important contributory factor in interoperability and re-usage of data of the underlying clinical data repositories. Therefore, during the migration process between clinical information systems, ad hoc mapping between existing and new terminologies becomes an important and often arduous task.

Conclusion

The successful automatic mapping of family medical history concepts based on SNOMED CT hierarchies has facilitated the migration and reuse of patient data from our legacy system into the new EHR system. The results of this study can be used as a framework in similar environments where concepts with higher granularities can be mapped to the relevant but less-granular concepts based on SNOMED CT is-a relationship. We have also used lexical matching method for mapping the concepts that were not bound to SNOMED CT codes in the source and target data repositories. However, additional evaluation of this method was beyond the scope of this study.

Development of a Wrist-Worn Sensor to Improve Medication Adherence:
Designing for Diverse User Behaviors and Technology Preferences

Jenna Marquard PhD1, Barry Saver MD MPH2, Swaminathan Kandaswamy MS1, Vanessa Martinez1, Jane Simoni PhD3, Joanne Stekler MD MPH3, Deepak Ganesan PhD1, Sean Noran1, James Scanlan PhD2,
1University of Massachusetts, Amherst, MA, 2Swedish Medical Center, Seattle, WA, 3University of Washington, Seattle, WA

Introduction

Studies have demonstrated that, for optimal outcomes of antiretroviral therapy (ART), both high (at least 95%) and consistent levels of adherence are necessary for continuously suppressing HIV replication1,2. For preventing new HIV infection with pre-exposure prophylaxis (PrEP), daily dosing is currently the only recommended regimen3. These required adherence levels are substantially higher than the 80% typically used for other health conditions, and maintaining such high levels of adherence is a challenge. For providers, lack of reliable, real-time information about ART and PrEP adherence makes it difficult to identify patients struggling with adherence until adverse outcomes, such treatment resistance, have already occurred. Current medication adherence-promotion devices, for this and other patient populations, do not capitalize on advances in wearable sensors. We are developing “USE-MI” (Unobtrusive Sensing of Medication Intake), a low-cost and innovative system designed to improve measurement and adherence. USE-MI uses a wrist-worn device and a tagged medication container to unobtrusively sense individuals’ gestures related to opening a pill bottle followed by hand-to-mouth arm movement, using this data to determine pill-taking behaviors, trigger pill-taking reminders to the wrist-worn device and a smartphone app, and to generate summative data on individuals’ adherence levels. To guide the design of this device, we conducted patient interviews, questionnaires, and observations to understand their current medication-taking practices and technology preferences. Our approach and findings provide generalizable guidance for similar devices and interventions.

Methods

Participants (n=17) were current patients at clinics providing medical care and social services for persons living with HIV/AIDS. In an interview, we asked participants questions about how they store, take, and remember to take their medications and 2) their feedback about how two candidate devices (MS Band, Android Wear Watch) could support this routine. We observed participants wearing a wrist device while taking placebo pills. Participants also completed a questionnaire asking about their perceived adherences, additional medication-taking practices, and preferences for gaining feedback about their medication-taking patterns, and general demographic measures. Interview responses were coded and reviewed by two team members. Questionnaire responses were analyzed using descriptive statistics.

Results

Almost all participants were male and HIV+ taking ART, but were relatively diverse in age and race (Table 1). Participants reported taking a mean of 88% (36%-100%) of their medications over the previous 4 weeks. Participants reported taking medications once (82%) or twice (18%) per day, split between the morning (41%) and night (53%); one participant took medications at lunch. Participants reported taking their medications from pill bottles (35%), blister packs (12%), and rolls with pills heat-sealed into bags labeled with date/time of intended administration (53%); 3 participants reported deviating from this method five or more days a month (e.g., transferring containers because of travel). Participants used a range of medication reminder approaches, including placing the medications in visible locations (e.g., by the coffeepot), aspects of the storage method itself (e.g., time and date on pill roll), annotating calendars, self-motivation, and reminders from others.

Participants exhibited varied handedness, with 12 right-handed (RH), 4 left-handed (LH) and 1 ambidextrous participant. When asked to wear the wrist device and take a placebo pill from a bottle (even if they typically take pills a different way), there was significant variation in which hands participants used to perform medication-taking tasks. Figure 1 shows what percent of participants used their right hand for each task; 1 RH individual did not have a video. Over 75% of all participants used their right hand to turn the pill bottle cap, regardless of their handedness. Participants were evenly split on which hand they used to put the pill in their mouth. Most participants (82% RH, 75% LH) used their dominant hand to drink the liquid.
After testing the devices, when asked for their preference for the devices, two participants (12%) stated they would only wear the MS Band and two (12%) stated they would only wear the Android Wear Watch. Most participants (76%) had no preference between the MS Band or Android Wear Watch, though 77% of this group preferred the MS Band over the Android Wear Watch. These preferences related to a variety of criteria, including size, comfort, fashionability, other functionality, battery life, and the charging mechanism. Two preferences related to drug use arose; one participant did not want a valuable device that might be sold or stolen, another wanted a waterproof device that could withstand sweating and showering at bathhouses.

Most participants (65%) stated that they would like to use the system. Those who said no (18%) felt the feedback would be helpful, but in the end did not want to wear the device. Two participants (12%) were unsure as to whether they would use the system. Participants were most interested in receiving medication reminders via a mobile app (67% extremely/very interested), the wrist-worn device (59%), or text message (53%); phone calls and emails were not of interest. Most participants (86%) wanted to receive feedback on their pill taking over time; most (86%) also wanted to share that information with their doctor. Mobile apps (58%) and email (33%) were the preferred mechanisms for receiving this summative feedback.

Discussion

While most participants were interested in using the proposed device, our results highlighted diverse user behaviors and preferences. First, our initial design required users to store their medications in pill bottles; we are working to determine how the system could accommodate pill rolls. Second, we are working to improve medication-taking gesture recognition, given the variation in which hand users perform tasks with. Third, we will allow some flexibility in the method for sending users reminder alters and summative reports. Finally, we are developing the system to work with multiple Android Wear watches, allowing user choice in wrist device style. While we focused on designing an intervention for individuals with HIV/AIDS, the aforementioned findings may align with the preferences and behaviors of other patient populations. Our findings are limited by a fairly small sample size.

Turning Off Medication Alerts to Reduce Clinical Decision Support Overrides

Allison B. McCoy, PhD¹, Eric J. Thomas, MD, MPH², Marie Krousel-Wood, MD, MSPH¹,³, Ryan P. Walsh, MD, MMM²,⁴, Adam Wright, PhD⁵, Dean F. Sittig, PhD⁴

¹Tulane University School of Public Health and Tropical Medicine, New Orleans, LA, ²McGovern Medical School, Houston, TX, ³Tulane University School of Medicine, New Orleans, LA, ⁴The University of Texas School of Biomedical Informatics at Houston, Houston, TX, ⁵Brigham and Women’s Hospital, Partners HealthCare, Harvard Medical School, Boston, MA

Introduction
Computerized alerts that warn clinicians about drug interactions or provide dosing guidance are commonly implemented forms of clinical decision support (CDS) to improve patient safety. However, high rates of inappropriate alerts and alert overrides prevent healthcare providers and the settings in which they work from realizing the desired improvement in clinical processes and patient care and can create additional work for already busy clinicians.¹,² Evaluation and improvement of alert implementations, and turning off inappropriate alerts, may help reduce overrides and subsequently increase patient safety.³,⁴

Methods
We previously developed an interactive dashboard that allows informatics personnel to review CDS alerts and provider responses (InSPECt: Interactive Surveillance Portal for Evaluation Clinical decision supporT).⁵ We used InSPECt to review medication interaction alerts in a large multi-specialty, ambulatory practice that provides care for all ages throughout the Houston community. During this process, we identified high override rates for a large number of alerts displayed that were deemed to rarely require a change in clinical care. As a result, we changed the alerting criteria from displaying alerts for all severities to only the highest severities (i.e., the lowest setting).

To evaluate the effect of the intervention, we extracted log data from the electronic health record (Allscripts Enterprise EHR) for 20 weeks before and 20 weeks after the intervention. We reviewed the number of alerts displayed to providers and the number of alerts overridden versus accepted, and we compared these outcomes across alert type before and after the intervention, and by week. We performed a chi-square test to identify whether there was a significant difference in the override rate between the pre-intervention and post-intervention periods.

Results
Providers received 532,672 alerts during the pre-intervention period and 191,836 alerts during the post-intervention period. Despite receiving 64.0% fewer alerts, override rates persisted at 69.2% pre-intervention and 70.1% post-intervention (p<0.0001). Figure 1 depicts overridden and accepted alerts for pre-intervention and post-intervention by alert type. Drug-condition alerts were the most frequent, with 333,204 pre-intervention alerts and 9,840 post-intervention alerts; 66.5% and 66.2% were overridden for pre-intervention and post-intervention, respectively.

Figure 1. Intervention results by alert type.
We observed the largest change in the override rate for drug-dose error alerts, with 78.1% of 85,417 pre-intervention alerts and 67.6% of post-intervention alerts overridden (p<0.0001). Changes were also significant for drug-drug (p=0.047), duplicate therapy (p<0.0001), and drug-dose alerts (p<0.0001); however, the change in override rates was not clinically significant.

Figures 2, 3, and 4 depict overridden and accepted alerts by week for all alerts, drug-condition alerts, and drug-dose error alerts. The override rates remain similar across weeks in the pre-intervention and post-intervention periods for all alerts combined and drug-condition alerts, and lower in the post-intervention period for drug-dose error alerts. We observed no other temporal trends.

**Conclusion**
Through use of a previously developed dashboard for evaluating CDS alerts, we identified high rates of overrides and inappropriate alerts. After implementing an intervention to turn off low severity alerts, we reduced the alerting rate by 64.0% compared to the pre-intervention period. Despite a statistically significant change, there was no clinically significant change in override rates (69.2% pre-intervention to 70.1% post-intervention). Additional research is necessary to further improve CDS alerts to reduce overrides and improve patient safety.

Introduction
Smartphone apps for self-tracking of chronic disease hold promise both for patients trying to manage their condition and researchers aiming to characterize diseases and behavior patterns at scale. In 2015, Apple introduced ResearchKit, a platform to facilitate app-enabled research through streamlined survey functionality and wide recruitment of study participants through electronic consent. Studies that use ResearchKit have been successful over traditional studies in enrolling a large number of participants, but opportunities remain to overcome the limitations of passive recruitment, in which a ResearchKit app is released but not actively marketed, and for app engagement via active contribution of data consistently over the study period. For example, the mPower study on Parkinson’s disease had 48,104 app downloads but only 898 study participants, of which 150 were patients (0.3%), used the app for at least 5 days within the 6-month study. Fostering engagement (broadly defined as the quality of experience in using a technology that makes it appealing to continuous use) is critical for realizing the full potential of research and general tracking apps. In this study, we explore the impact of active recruitment strategies as well as the use of specific app functionalities on user engagement. The context for this work is Phendo, an app-based study to capture and characterize endometriosis, a prevalent disease (estimated to affect 10% of women) and systemic chronic condition with a high burden on quality of life, from the standpoint of patients.

Methods
Phendo aims to capture directly from patients a wide range of variables about endometriosis through time. It was developed as a ResearchKit-based tracking app. The design of the app, in particular, identifying the range of variables to track, along with determining their temporal granularity for patients to track (e.g., momentary assessment vs. day-level) was carried out through a user-centered, participatory process with endometriosis patients via 5 focus groups with 27 adult women with the disease. We incorporated a number of features beyond the vanilla ResearchKit capabilities: customized user interface of surveys to allow users to enter multiple responses to a survey question; smart notifications triggered only when a user has not tracked any data as well as “positive” notifications to encourage returning users, calendar-based review and insights screen that provide a personalized timeline of tracked data; and a Citizen screen showing how much their individual data contributed to the overall study. For this study, we explore three novel functionalities and their traction with study participants: (i) customizable surveys to track medications, hormones, supplements, foods, and exercises; (ii) ability to track specific variables on a moment-by-moment basis (repeatedly if needed) throughout the day and other variables at the day-level; and (iii) ability to track all variables retroactively. The app is available on the iTunes Store for use on iPhone, and as such passive recruitment is available. For active recruitment, we created a website (citizenendo.org) and a social media presence, maintained a blog, and engaged with patient advocacy groups and celebrities who advocate for the disease to promote Phendo. We focus on the first 100 days of the app since its launch (11/13/2016-2/20/2017).

Results
1,184 women with self-reported endometriosis diagnosis from 39 countries consented to the Phendo study, during which time no participants opted out. Participant demographics follow the adult US female population who use apps: 56.7% have at least a college degree, live in suburban (46.4%) or urban (38.1%) areas, and are White non-Hispanic (82.5%). Their median age is 29 years old, and their age at endometriosis diagnosis was consistent with epidemiological characterization of the disease. Fig. 1 shows the impact of active recruitment efforts on enrollment. In the first 100 days since the launch of the app, participants each tracked 1 to 80 days, and 50% of them tracked 6 days at least. Participants made use of the customizable surveys: 84.5% used at least 1 customized variable, and on average created 6 variables across the food, exercise, medications, supplements, and hormones categories. Overall, participants tracked both day-level (e.g., “Do you have your period today?” and “What did you do to self-manage today?”) and moment-level variables (e.g., “Are you experiencing any GI/urinary issues now?”) (Fig. 2). We note the variability in amount of tracking both at the moment- and day-level, indicating that participants made sure to track only what is relevant to them or what they deem useful to let researchers know (e.g., menstrual periods were tracked more than sexual activity). Fig. 3 shows the times at which participants engaged with the app.
to track (i.e., local time at which participant used their phone). They used the app throughout the day for momentary tracking, whereas they answered day-level questions at the end of the day (7pm is default notification time). 53% of actively tracking participants made use of retroactive tracking. Within the same day, they tracked retroactively primarily for moments (graph not shown) (e.g., tracked a moment that occurred in the morning at 4pm). But they also tracked retroactively up to several days in the past (Fig. 4), mostly for day-level questions.

Discussion
Beyond ResearchKit’s many benefits, ways to retain and engage patients are needed. We found that active recruiting was critical to not only gather interest but also to target the right population of study participants (in our case, women with endometriosis). Aligning tracking functionalities with the way in which participants experience the disease showed promise in engaging participants: they made heavy use of customized tracking and both moment and day-level surveys, with specific patterns of tracking throughout the day. Furthermore, ability to track retroactively was shown convenient and useful to participants. When used retroactively, moment-level tracking was done within the same day, while day-level tracking went back 1-2 days in time, suggesting users are reasonable in their recall. These patterns are encouraging: these functionalities enable more data points to be tracked, and there is likely validity to them given the short retroactive tracking times. Although we focus on a specific condition, engagement functionalities are applicable to other chronic disease populations that experience a wide range of symptoms dynamically over time.

Usability Testing to Guide Development of a Clinical Decision Support System for Substance Use Screening and Interventions in Primary Care

Jennifer McNeely, MD, MS1, Andre Kushniruk, PhD2, Sarah Farkas1, Aida Vega, MD3, Eva A. Waite, MD3, Lauren Peccoralo, MD3, Melanie Harris1, Christine Chollak1, Richard N. Rosenthal3, John Rotrosen, MD1, Joseph L. Kannry, MD3

Introduction
Alcohol and drug use are significant drivers of preventable morbidity and mortality that are not routinely identified or treated in medical settings.1 Screening, brief intervention, and referral to treatment (SBIRT) to address substance use in primary care is widely promoted, but has proven challenging to implement.2 Validated screening tools that can quickly and accurately identify substance use have been designated common data elements (CDEs),3 but are not widely integrated into electronic health records (EHRs). As part of a study of the NIDA National Drug Abuse Treatment Clinical Trials Network, we developed a clinical decision support system (CDSS) to support the delivery of substance use screening and interventions in primary care, and thereby facilitate data capture of the CDEs.

The four-phase study began by conducting qualitative interviews with key clinical stakeholders to identify barriers and facilitators to substance use screening, and to inform a clinical workflow for implementing SBIRT. In Phase Two, results of which are reported here, we conducted multiple rounds of usability testing to iteratively develop the content and delivery of a substance use CDSS. The later study phases will examine the performance of the CDSS in capturing the CDEs and facilitating substance use interventions, in two large health systems. This work is significant because it provides a CDSS to support the integration of behavioral health in primary care, and addresses a significant knowledge gap among medical providers, who receive little education on substance use treatment. To enhance generalizability, we developed the CDSS in a widely used EHR (Epic™) using standard functionality.3

Methods
We employed the ‘Framework for Usable and Effective Clinical Decision Support’ to guide our CDSS development, usability testing, and implementation approach.4 We had previously applied this framework in a study to develop a CDSS for antibiotic prescribing that achieved high levels of adoption and acceptance in primary care.4 Key features of the framework are 1) active and actionable decision support; 2) multiple rounds of usability testing with iterative development to increase user acceptance; 3) numerous context sensitive triggers; 4) dedicated training and support for users of the CDSS to foster adoption; and 5) support from clinical and administrative leadership.

Prior to usability testing, we drew upon findings from the stakeholder interviews to build an initial prototype CDSS in the Epic test environment. We then conducted 3 rounds (total of 27 sessions) of usability testing in June-August 2016, with 19 end-users in one primary care clinic. Participants were medical assistants and primary care providers (PCPs), including both faculty and resident physicians. Some PCPs from the initial round were invited to repeat testing in subsequent rounds, to provide feedback on whether changes made were responsive to their suggestions.

During usability testing, participants were given a clinical scenario of a patient with moderate- or high-risk alcohol or drug use, and were led through the scenario by the facilitator and asked to ‘think aloud’ as they used the EHR tools. The medical assistants used the EHR tool to enter screening results, while the PCP users reacted to the data and alerts and were asked to complete a patient progress note. Alerts notified providers that screening is due, and alerted them to a high-risk screening result. Use of the system during a medical visit was simulated by having the participant interact with a simulated patient (i.e. one of the investigators playing the role of a patient using a script). Data was collected using Camtasia™ screen capture software, audio and video recordings, and written notes.

For analysis, first all of the audio data was transcribed to create a log file. The video data was then reviewed, and usability problems were identified and annotated in the log file. Problems were classified as being either ‘human-computer interaction’ findings (e.g. number of mouse clicks) or ‘workflow’ findings (e.g. context and timing of the information delivered). Following each round of testing, the investigators met with the medical informatics team to review the results and make decisions on how to implement changes. Once the changes were completed, the subsequent round of testing was performed.
Results
Participants were medical assistants (n=3), faculty physicians (n=10), and resident physicians (n=6). The main problems identified and changes made to the CDSS in each round of usability testing are summarized in Table 1. This presentation focuses on workflow findings, which proved more challenging to solve than the human-computer interactions findings. For example, we found that participants were sensitive to the timing of alerts, which in some cases were triggered before having had a conversation with a patient. The majority of problems were identified in the first round of usability testing, after which significant changes to the CDSS were made. By the third round of testing the number of identified problems had decreased considerably and solutions focused on training issues.

Discussion
Usability testing identified important problems with the substance use CDSS, many of which we were able to address during the development process. Similar to observations of the CDSS development framework paper, triggers and workflow proved challenging in a commercial EHR. Standard EHR functionality was not optimal for collecting the substance use CDEs because it did not support the reconciliation of the CDE data with the social work and drug fields in the social history section. We found it difficult to use the EHR to facilitate team-based behavioral health interventions in primary care; a problem that has also been reported in other studies. Notably, usability testing of our EHR-integrated substance use CDSS revealed issues related to the tool’s content, in addition to identifying more basic human-computer interaction issues. Limitations of our study include (1) the decision to include some repeat participants, which reduced our sample size and potentially complicates our analyses; and (2) having a member of the study team play the role of simulated patient, which could bias our findings. Despite these limitations, our iterative process of usability testing and content adaptation allowed us to successfully modify the EHR to support a complex behavioral intervention for substance use, though some limitations to its functionality remain. Future phases of this study will examine adoption of our CDSS in multiple primary care clinics.

Identification of Clinically Meaningful Clusters of Multi-morbidity in a National Cohort of Adults Using Unsupervised Learning

Che Ngufor, Ph.D., Rozalina G. McCoy, M.D., Lixia Yao, Ph.D., Lindsey R. Sangaralingham, M.P.H, Shannon M. Dunlay M.D., Nilay D. Shah, Ph.D.
Mayo Clinic, Rochester

Introduction

The number of individuals in the U.S. and around the world affected by multiple chronic conditions (MCC) has increased substantially and continue to rise.¹ Patients with MCCs require significantly more health care resources, incur high cost of care, and face greater mortality, functional decline, and worse quality of life.²³ However, identifying, treating, and improving the care and health outcomes of patients with MCCs have been hindered by the marked complexity and heterogeneity of this population. Current Comparative Effectiveness Research and Evidence Based Practices (EBP) focus on one disease at a time, or on highly prevalent co-occurring two-way or three-way combinations of conditions, thus leaving a large gap in our knowledge about how to optimally manage individuals with complex MCC. Alternatively, comorbidities are treated as being equal; with risk stratification based on weighted or unweighted comorbidity counts. Yet not all comorbidities, affect patients the same way. Nor do they incur the same burden or pose the same risk to the patient and the healthcare system. Information about the interactions and subgroups of MCC can facilitate diagnosis, enhance preventive strategies, improve quality of life, and help create smart EBP guidelines.

To address this critical knowledge gap, we use data driven unsupervised learning methods to identify clinically meaningful homogeneous groups of MCC from a large observational data and to characterize frequent disease combinations, relationships, and phenotypes of patients within subgroups.

Methods

Study population: We used data for 604,712 adults, age ≥ 18 years, included in OptumLabs Data Warehouse (OLDW), a national administrative claims database of commercially insured and Medicare Advantage beneficiaries across the U.S. A two-year sample of Medicaid beneficiaries with at least 12 months of continuous medical coverage and affected by at least two chronic conditions was used for the analysis.

Clustering and Association Rule Mining: We propose a two-stage method that allows the discovery of stable, robust, and clinically meaningful homogeneous multimorbid subgroups. First, we applied the agglomerative hierarchical clustering algorithm with the Ward’s minimum variance criterion to cluster patients based on similar multimorbid patterns. Similarity between patients was measured by the Jaccard index.⁴ Agglomerative hierarchical clustering starts by assuming that each patient was a cluster, and successively merge similar clusters to form larger clusters. Because of the hierarchical tree structure, different number of clusters can be obtained by restricting the tree at specific heights. The Ward’s method minimizes the sums of squares between clusters and merges similar clusters. To evaluate the goodness of the clustering results and select the optimal number of clusters, we apply a validation technique that makes use of external information not used to generate the clusters. Specifically, based on an assumption that individuals with similar MCC combinations are expected to consume about the same amount of healthcare resources, we validated the clustering by measuring the area under the ROC curve (AUC) for a logistic regression model predicting health utilization (Frequent ED Visits and Readmission) based on cluster memberships. By the assumption, the more homogeneous the clusters, the higher the AUCs, which implies that the AUC increases with the number of clusters. We selected the optimal number of clusters by plotting the AUC against the number of clusters and applied the elbow criterion. The elbow is the point on the graph where addition of a cluster does not lead to a significant gain in AUC and corresponds to the optimal number of clusters. As the elbow method can be ambiguous, we also applied the principle of parsimony when selecting the number of clusters.

In the second step, we applied association rule mining in each cluster to characterize frequent disease combinations (3 or more) and disease-disease association rules. A disease-disease rule is a statistically meaningful pattern identified in the data, such as "patients with {Cardiac Dysrhythmia, Cardiomyopathy, Chronic renal Failure and Asthma} tend to have {Congestive Heart Failure}". Mining frequent disease combinations can generate large number of frequent comorbidity sets, most of which might contain a small number of high prevalence conditions (e.g., hypertension, hyperlipidemia, and dementia), while missing out the low prevalence but more important rare MCCs. To address this problem, we weighted the conditions by dividing by their frequency of occurrence in the data to reflect their importance. This strategy is a reflection that not all chronic conditions affect patients equally.
Results

The median age of the study population was 66 years, with 55.51% female, and mean number of conditions per patient was 3. Based on the Wards criterion and the external validation technique, we identified 14 optimal clusters of patients with 69 chronic conditions defined by the Agency for Healthcare Research and Quality (AHRQ [https://www.hipxchange.org/Comorbidities] and 5 demographic variables (age, gender, race, and region). We also tried other merging algorithms such as the single, complete, and average linkage methods, but they all produced unstable and sparse clusters. The Wards method produced stabled, dense, and approximately equal sized clusters. Figure 1 (a) shows that the AUC for predicting health utilization increases gradually as the number of clusters increases (solid lines) compared to the poor and all flat-out performance of randomly generated clusters (dotted lines). There is a big jump in performance from the 12 and 13 clusters to 14, but after the 14th, no observed gain in AUC can be seen. Thus, 14 clusters correspond to the turning point or elbow of the curve and was selected. Clusters beyond the 14th did not add much clinical value and some were sparse (with respect to the outcome) and unstable.

Figure 1 (b) shows the distribution of the top frequent disease combinations in each cluster by the support (fraction of patients with the combination). The mean age (A) and percentage of females (F) are shown above each group. Several clusters described patient groups with the common and high prevalent conditions, however, our weighting scheme revealed some of the less prevalent conditions compared to when no weighting was used. Cluster 8 can be described as the Mental Subgroup, characterizing young female adults (18-34 years) with primarily mental illness (top disease-disease rule: \{anxiety, depression, substance-use disorder\} \rightarrow \text{bipolar}), while cluster 14 can be considered as the Hypertensive Heart Disease Subgroup, describing older male (70+ years) with top frequent disease combinations: \{Hypertension, Coronary artery atherosclerosis, and CHF\}.

Conclusion

In this study, we combined two data driven unsupervised learning techniques: hierarchical clustering and association rule mining to discover clinically meaningful clusters of patients with multiple chronic conditions. Based on the assumption that similar MCC patients tend to consume the same amount of health care resources, we were able to select 14 optimal clusters by measuring the predictive ability of cluster memberships in discriminating patients with high health care utilization. These clusters can help in comparative effectiveness research in identifying patients who are more likely to benefit from certain interventions.

Designing and Evaluating an Automated System for Real-time Medication Administration Error Detection in a Neonatal Intensive Care Unit

Yizhao Ni, Todd Lingren, Eric Hall, Matthew Leonard, Kristin Melton*, Eric Kirkendall*
Cincinnati Children’s Hospital Medical Center, Cincinnati, OH *Equal contribution

Introduction

Medication administration errors (MAEs) are the most common medical errors experienced by patients. Neonates are particularly vulnerable to MAEs due to medication dosing that is influenced by weight, gestational age and postnatal age. Previous efforts to reduce MAEs, including voluntary incident reporting and trigger tools, rely heavily on manual vigilance and detect only a fraction of errors. Sustaining effective and accurate detection of MAEs remains a challenging issue among pediatric healthcare institutions. Our objective is to develop an automated system that utilizes comprehensive Electronic Health Record (EHR) information to detect dosing-related MAEs in real-time and to facilitate mitigation of medication safety events in neonatal patients.

Methods

We focus on automating detection of MAEs among 11 high-alert medications prescribed to inpatients in the neonatal intensive care unit at Cincinnati Children’s Hospital Medical Center. The medications include total parenteral nutrition (TPN), lipid, intravenous fluids (IVF), insulin, morphine, fentanyl, milrinone, vasopressin, dopamine, dobutamine, and epinephrine. Our study consists of three phases: 1) development of the MAE detection system, 2) observation and evaluation of system performance without intervention (i.e., without step 4 in Figure 1), and 3) intervention and system deployment into clinical practice. This work reports results of the pilot system at the observation phase (November 2016 through February 2017).

Figure 1 diagrams the piloted MAE detection system. The system extracts medication use information from the EHR (step 1), including medication orders and modifications, medication administration records (MARs) that document doses (or infusion rates) administered to patients, and free-text physician to nurse communications that describe dose/rate changes. By utilizing logic-rules and natural language processing (NLP) techniques, the system’s detector identifies discrepant doses/rates between MARs and other extracted information (step 2). The detector builds on MAE detection algorithms from our earlier work1,2. If a discrepancy is identified, the notifier will send a MAE message to clinicians in real-time (step 3). The clinicians will investigate the notification and take appropriate action (e.g., communicating with bedside nurses; step 4). Clinician feedback will be sent to the reporter (step 5), which generates case reports for system evaluation and improvement (step 6). Using the case reports, study investigators will periodically evaluate system performance and calculate the time window after a MAE event during which a patient is potentially at risk for harm (step 7). Their feedback will be fed into the learner module to adjust system parameters (e.g., modifying regular expressions in NLP to improve dose detection from clinical narratives; step 8).

During the observation phase, study team physicians (Drs. Kirkendall and Melton) double-reviewed MARs for the targeted medications and identified all MAEs. We reviewed two months of orders for high frequency medications (TPN, IVF, lipid, morphine and epinephrine) and four months of orders for the others. Two medications (dobutamine and dopamine) had no orders during the observation period and were excluded from this evaluation. Adjudicated MAEs were used as a gold standard to assess system performance, where positive predictive value (PPV), sensitivity (SEN), negative predictive value (NPV), and specificity (SP) were calculated in aggregate and for
each medication. We also evaluated expected mitigation of exposure to potential harm following a MAE event with the implemented system. Without the system the time of exposure was calculated between the MAR time of erroneous dose/rate administration and time of documented clinician correction. With the system it was calculated between the MAR time and time of MAE notification, assuming a clinician could respond immediately upon receiving a MAE message. If a MAE was missed by the system (false negative), the time of exposure was identical to that without the system.

Results and Discussion

Table 1 presents descriptive statistics of the medication use data. The physicians reviewed 5,333 MARs for 3,124 medication orders and identified 80 MAEs (Cohen’s kappa of inter-annotator agreement: 87.8%). Both the physicians and the system identified a notable number of insulin dose discrepancies. However, the retrospective analysis suggested that many discrepancies were documentation errors rather than true MAEs. Eighteen errors resulted from non-standard documentation for specifying insulin dose change were excluded from the subsequent time window evaluation. Table 2 shows the system performance in aggregate and for each medication. The MAE detection system achieved an overall PPV of 85.5% and SEN of 81.3%. The PPV was over 95% for the majority of the medications and over 75% for medications with frequent dose adjustments via physician to nurse communication (TPN and IVF). The system achieved similar SENs across medications except lipid and morphine, where two lipid and one morphine MAEs were missed. Finally, the automated system had potential to reduce the median time window for exposure to harm, from 298 minutes to 35 minutes (p<0.001 with paired t-test). In particular, the time windows were reduced substantially for long-time intravenous medications such as TPN and lipid.

The high PPV and sensitivity suggest that the implemented system has capacity for identifying MAEs while guarding against alert fatigue. Furthermore, the system could significantly reduce a patient’s exposure to potential harm following a MAE event. Consequently, we hypothesize that the automated MAE detection system, once fully deployed, has great potential to significantly mitigate medication safety events among neonatal patients.

Reducing Variation in Core Measures data through Automation

Matthew A. Oberhardt, PhD¹, Hojjat Salmasian, MD PhD,¹,² Dena Goffman, MD³, David Vawdrey, PhD¹,²
¹: Value Institute, NewYork-Presbyterian Hospital, New York, ²: Division of Quality & Patient Safety, NewYork-Presbyterian Hospital; ³: Department of Obstetrics & Gynecology, Columbia University Medical Center

Introduction

The Centers for Medicare & Medicaid Services (CMS) defines a set of “Core Measures,” key metrics that hospitals are required to track in order to benchmark and improve quality outcomes. The OB-GYN core measure named “PC-02” assesses the rate of Cesarean sections (C-section) among NSTV women -- Nulliparous, Full-Term women who delivered a Singleton baby in Vertex position (i.e., numerator = C-sections, denominator = women who had NSTV deliveries) ¹. This rate is traditionally determined manually by nurse abstractors who, in our study setting, randomly assess ~40-120 delivering women per quarter (approximately 10% of deliveries) and determine who among those are NSTV (typically ~10-50 women). They then pull the C-section rate among this NSTV subsample, and extrapolate that rate to the hospital as a whole. This manual abstraction process may be hindered by lack of consistency and also by high intrinsic variance due to the small number of patients sampled each quarter. Automating data abstraction has potential to reduce costs and improve consistency in reporting, but must be done carefully to ensure quality ².

For these reasons, an effort has been underway to develop electronic Clinical Quality Metrics (eCQMs) to automate abstraction of quality metrics. A preliminary eCQM was developed for PC-02, but it has yet to be officially reported ³ or assessed to our knowledge. Here, we develop an automated algorithm for determining PC-02 C-section rates that is functional within our healthcare setting. We evaluated whether this method significantly tightened the confidence intervals on PC-02 rates and increased data consistency.

Methods

We implemented a rules-based automated method for determining PC-02 rates across four hospitals in the New York City area (see Table 1).

Table 1: Pseudocode for automation of PC-02 measure. Note, when measures appear in multiple notes for a patient (e.g., parity), we take the maximum value.

Identifying appropriate rules required detailed conversations and shadowing of clinicians about how the data is entered into the EHR as well as conversations with data abstractors about how they obtain the measures. Conversations with leading clinicians and physicians assistants led, for example, to the use of the ‘living children’ field instead of the ‘parity’ field for determining that a woman is Nulliparous, as this was deemed more reliable in our records. The rules-definition process was iterative with intensive

involvement of both the data abstractors and clinicians. After automating the measure, NTSV determinations were compared directly against determinations from manual abstraction. We found that the automated methods were able to identify approximately 10x as many NTSV women as the sample examined manually by abstractors, giving NTSV rates with significantly tighter confidence intervals (Figure 1).

We performed a comparative analysis of the patients determined to be NTSV through the automated vs manual methods, and found strong overlap (average precision = 0.9, recall=0.79 across 4 hospitals for the automatic method to identify the same NTSV women from the subset manually abstracted).

**Results**

The rates for both automated and manual extraction were found to be consistent, both drawn from the same population for three of the hospitals (1, 2, and 4). However, the last hospital (number 3) was inconsistent (Table 2). The inconsistency is found in patients assessed only by the automated algorithm, in that they showed a different NTSV rate than patients assessed by both the abstractors and the manual abstractors. In contrast, the patients identified by both methods have a high overlap. i.e., for the patients that the automated method was able to judge, it often accurately assessed NSTV status (precision=0.95, recall=0.87 for NTSV identification of manually abstracted women in hospital 3). To further understand this, we looked into factors contributing to PC-02, and found that they are not always recorded consistently by the abstractors. An analysis of the ‘nulliparous’ status revealed that 9% of patients have discrepancies in their parity scores based on the data in medical notes, and 7% of abstractor parity determinations conflicted with at least one note. To address this, we worked with the abstractors to define a priority ranked list of notes that should determine parity labeling, thus improving consistency and hopefully accuracy of the manual method.

**Conclusions**

Automation of core measures and other manually abstracted metrics is a major priority for hospitals across the country, as it can liberate hospital human resources for other tasks. Here we find that a rules-based automated process can indeed improve consistency, but care must be taken to ensure the accuracy of the methods and generalizability. The effort was helped by strong communication between clinicians (data enterers), abstractors (data pullers), and technical quality analysts (data analyzers) to get appropriate feedback and develop a working model. Knowledge of how to achieve this kind of effort is highly generalizable to many other data metrics, which require multiple types of input to be successfully automated.
The Impact of Simulation on Electronic Health Record Use Patterns among Pediatric Residents

Introduction:
As electronic health record (EHR) adoption has grown, training clinicians to efficiently and effectively use the EHR has become increasingly important to provide safe, high-quality patient care. While most formal EHR training occurs in classroom and lab settings,1 simulation with realistic, clinically rich test patients has improved recognition of safety concerns on subsequent simulation2,3 as well as outpatient provider self-efficacy ratings.4 However there is a paucity of data on how simulation changes EHR use in real clinical encounters. In this study, we aimed to determine if exposure to an EHR simulation that exhibited specific tools was associated with enduring changes in EHR use patterns.

Methods:
We created an informatics simulation curriculum for first-year pediatric residents at the Children’s Hospital of Philadelphia aimed at increasing their capacity to detect patient safety concerns using the EHR. Once a month on the General Pediatrics/Hematology team, 4-6 residents participated in a 1 hour teaching session focused on a simulated case in the EHR aimed at increasing awareness during emergency department (ED) to inpatient handoffs. In this case of an infant with hyperbilirubinemia, exploration in the EHR beyond the ED note revealed vital sign instability suggestive of neonatal sepsis and evidence of hemolytic anemia. During the debrief session, we emphasized the utility of specific data visualization and information retrieval tools in the EHR to detect these safety issues. While the curriculum is intended for all first-year residents, in the first 16 months of the program some first-year residents never participated because their clinical rotations did not overlap with scheduled simulation administrations.

Using EHR access logs, we assessed the frequency with which these tools were accessed by residents who did and did not participate in the simulation. We combined these data with resident schedules and simulation schedules to identify additional potential predictors including class year and weeks of inpatient experience. We restricted the analysis to inpatient weeks scheduled at the Children’s Hospital of Philadelphia. Among those who had participated in the simulation, we also examined the number of weeks post-simulation as a predictor to assess for a possible waning effect. We excluded partial weeks from holidays or class retreats. We used a mixed-effects logistic regression model with the resident as random effect in all models.

Results:
From July 1, 2015 to February 20, 2017, 59 residents participated in the neonatal sepsis simulation while 80 residents did not. We collected EHR use patterns for 3262 resident-weeks where the resident had not been exposed to the simulation and 1049 resident-weeks after simulation exposure. Residents who completed the simulation were followed for a median of 19 weeks post-simulation (IQR: 8 - 32). For a given week, if the resident had not been exposed to simulation, there was a 47% chance of having used the data visualization tool at least once and 36% chance of having used the information retrieval tool at least once. If the resident had been previously exposed, those rates increased to 73% and 85% respectively.

In univariate analysis, previous participation in the simulation increased the chance of using the data visualization tool at least once in a given week (OR 5.8, CI: 4.4 – 7.8) and of using the information retrieval tool (OR 10.5, CI: 7.5 – 14.8). After adjustment for the number of inpatient weeks completed, exposure to simulation remained a significant predictor of use of the data visualization tool (OR 2.8, CI: 2.1 - 3.9) and information retrieval tool (OR 3.0, CI: 2.0 – 4.5). The number of inpatient weeks the resident had previously completed was also associated with increased
likelihood of use of the data visualization tool (OR 1.05, CI: 1.04 - 1.06) and use of the information retrieval tool (OR 1.08, CI: 1.06 – 1.09).

After simulation exposure, the number of weeks post-simulation adjusted for total inpatient weeks completed was not a significant predictor of use of the data visualization tool (OR 0.98, CI: 0.94 - 1.02) or use of the information retrieval tool (OR 1.01, CI: 0.96 - 1.07).

**Discussion:**
Our study found that an informatics simulation was associated with changes in pediatric residents’ EHR use patterns. These changes did not wane after simulation exposure during the study period, suggesting that demonstration of new tools through well-designed simulation changes the long-term behavior of simulation participants who find the tools clinically useful. These effects may alternatively be explained by increasing awareness across the institution, although changes to institutional culture may also have been caused in part by the informatics simulations themselves. Residents who were not exposed to the simulation may also have learned about these tools through diffusion of practices from their peers, their supervisors, or annual lectures on EHR efficiency. However, diffusion of EHR practices from simulation participants to non-participants would be expected to bias the impact of simulation towards the null. Nonetheless, the strong association between simulation exposure and weekly use of these tools was robust to adjustment for class year and weeks of inpatient experience.

Simulation requires substantial effort to create and administer cases compared to other modalities such as lectures or online modules. We did not compare the impact of these simpler educational approaches on EHR use patterns. However, previous studies have demonstrated additional benefits of simulation on provider performance. Assessing the impact of simulation on patient outcomes is complex; while procedural simulations have been shown to improve resident performance in randomized trials, EHR simulations have focused on indirect measures showing improvement in recognition of simulated safety issues, novel characterization of EHR-induced errors, better measures of the quality of resident notes, and improved provider satisfaction. Our study also examines an indirect measure, but suggests that the effects of a single simulation may impact users’ long-term use patterns.

EHR simulation presents a new opportunity to improve patient safety through provider education that integrates directly into their workflow. This study suggests that simulation impacts EHR use patterns, and that those providers maintain those patterns long-term. Future efforts to compare the impact of different educational modalities on EHR use patterns and downstream effects on provider efficiency and quality of care will help define how best to incorporate simulation into EHR education.

Improving Electronic Inpatient Progress Notes Using Voice: Results from the VGEENS Project

Thomas H. Payne, MD, J. Andrew Markiel, PhD, W. David Alonso, MD, Ross Lordon, BS, Kevin Lybarger, MS, Meliha Yetisgen, PhD, Jennifer M. Zech, MS, Andrew A. White, MD

University of Washington, Seattle, WA

Abstract

We implemented a system to create inpatient progress notes on hospital rounds (VGEENS), integrating voice recognition, automated note formatting, and EHR links. In a randomized trial we compared VGEENS with usual note writing on note timeliness, quality and physician satisfaction. Results show VGEENS notes were available within 5 minutes after dictation. Notes were on average available sooner, and physicians’ satisfaction greater in control, perhaps due to copy/paste practices. Workflow changes may improve note timeliness.

Introduction

Physician progress notes are an important record for clinical care and communication with care team members and patients. However, electronic notes are criticized for poor readability, overuse of copy and paste, and excessive note length. Physicians have voiced concerns that writing notes in EHRs takes more time than using paper or dictation; a consequence is that inpatient progress notes may not be completed and available to other team members until long after rounds.

This project is an attempt to address these problems. Here we describe the development, implementation, and evaluation of a voice-generated enhanced electronic note system, integrating voice recognition and transcription with natural language processing (NLP) and integration with the EHR, designed to match physician rounding workflow. We also present results of a randomized controlled trial to determine the effect of using this new method of writing inpatient progress notes on note timeliness, quality, and physician satisfaction, in comparison with writing notes in the usual way, through typing into partially populated templates.

Methods

VGEENS (voice-generated enhanced electronic note system), was used by study intervention physicians while on hospital rounds. At the bedside or later, the physician records a voice file on a cell phone application we (DA) developed. The completed dictation voice file is securely sent to a server where it is converted to text using automated speech recognition software (Dragon Medical Practice Edition, Nuance). Voice commands are used to break the note into sections corresponding to the preferred UW progress note format and to insert formatted patient vital signs and select laboratory results. The transcribed note is sent to the EHR Inbox.

We randomly assigned physicians on medical services of two UW teaching hospitals to the intervention group, using VGEENS, and control group, entering notes using a keyboard. We compared: 1. The time between when the patient is seen on hospital rounds and the availability of the note in the EHR; 2. Physician satisfaction with note writing and 3. Note quality as assessed by manual quality review using instrument PDQI-9.

Results
Thirty-one subjects wrote 1,852 inpatient progress notes during the study period, 1,143 by controls and 709 notes by intervention subjects. The median number of minutes between the patient encounter and the availability of a progress note in the EHR for others to view was 190 minutes for the control group and 227 minutes for the intervention group. For the subset of physicians who used VGEENS on rounds (intended workflow—circled at right), notes were available within 5 minutes.

Physician satisfaction survey response rate among the 31 of the 49 subjects who completed at least one note was 100%. Among intervention subjects, an equal number (40%) rated satisfaction with the VGEENS tool as either highly or moderately satisfied (6) and moderately dissatisfied or not at all satisfied (6). Among controls, 50% of subjects rated their satisfaction with note writing as either highly or moderately satisfied (8) and one subject (6%) was moderately dissatisfied. Note quality assessment is underway. (18 subjects were not on a medical service rotation in which their responsibilities included writing daily progress notes during the study period or for other reasons.)

Discussion

We successfully developed and implemented a new note writing method using voice to create inpatient progress notes. Where the physician used VGEENS on rounds, notes were available within 5 minutes, were properly formatted and included patient data in response to voice command. The system was integrated with a commercial EHR. Physicians preferred traditional note writing methods, in part because younger physicians are inexperienced with dictation yet facile with copying the previous day’s note, editing and saving as the current day’s note. VGEENS began each day’s note with the voice dictation and did not carry forward information such as problem list and ‘checklist’ information, though these features could be added.

Preliminary comparison of progress note content shows more preservation of text between successive days’ notes in control than with VGEENS, likely a reflection of copying/pasting workflow common in control notes. Note accuracy was not assessed, but highly similar physical examinations in successive days’ notes raise questions of accuracy. Using voice can potentially permit history and exam findings to be quickly documented reducing need to copy them from previous notes; this was a motivator for our work. We have not yet leveraged advanced NLP techniques to correct semantic errors within the note, nor to extract encoded concepts from the narrative text. Perhaps the greatest promise for this work is that we have developed a system to create notes that capture physician thinking as close to rounds as possible; we have the potential to suggest diagnostic and therapeutic interventions based on that thinking in near-real-time. The VGEENS approach has potential to directly address physician concerns with excessive documentation time requirements and declining note quality, and may also improve progress note accuracy.

Conclusion

VGEENS permits voice dictation on rounds to create progress notes and can reduce note availability and may reduce dependence on copy/paste within notes. Timing of dictation determines when notes are available; in this early trial most notes were dictated after rounds, delaying note availability. Capturing notes in near-real-time has potential to apply NLP and decision support sooner than when notes are typed later in the day, and to improve note accuracy.

Introduction

Chest X-rays are a common radiological examination for screening and diagnosis of lung diseases. Although hospitals have accumulated a large number of raw radiology images and reports in Picture Archiving and Communication Systems (PACS) and their related reports in Radiology Information System (RIS), it is not yet known how to effectively use them to build high precision computer-aided diagnosis systems (CAD). In the last few years, machine-learning techniques are attracting considerable interest due to tremendous progress on medical image recognition and understanding. In particular, recent developments regarding deep-learning models (e.g., deep convolutional neural networks) have led to promising performance in the recognition of objects within medical images 1.

Generally speaking, deep learning models depend upon labeled data. That is, annotators must transfer their knowledge to the dataset in order for a model to learn the correlation between labels and images. However, it is both costly and time consuming to annotate a large-scale corpus to facilitate the data-hungry deep learning models. Thus, crowdsourcing is often used in the general domain. On the other hand, crowdsourcing is frequently infeasible for biomedical images annotation, because it requires comprehension of domain-specific medical knowledge, even if the security and privacy issues with disseminating patient information in a public platform could be adequately addressed.

In this work, we propose a text-mining approach to automatically generate a “weakly” labeled dataset for detecting thoracic diseases in radiology images. These labels can be used as a silver standard by deep learning algorithms. Using this framework, we construct a dataset, CXR-XIV, which contains over 100,000 frontal-view chest X-ray images weakly-labeled with 14 common thoracic diseases. Given such a large-scale dataset, we further propose a unified weakly-supervised multi-label image classification framework, which uses deep learning to effectively detect common thoracic diseases in radiology images.

Methods

CXR-XIV dataset. To build a corpus for deep learning radiology images, we first identified 14 common thoracic diseases/patterns that are frequently observed and diagnosed in radiology reports (e.g., pneumonia and cardiomegaly). Using a list of hand-crafted keywords for each disease, we retrieved all the radiological images and associated reports from our PACS system. We then developed a text-mining approach (described below) to filter negative and equivocal disease asserted in the reports. The resulting database, which we call CXR-XIV, is composed of 108,948 frontal-view chest X-ray images from 32,717 patients and each image/report is associated with one or more weakly labeled (i.e. computer-generated) pathology category or “normal” otherwise. To evaluate our text-mining algorithm, we also manually hand-annotated a random set of 900 radiology reports due to the high cost of human annotation.

Text-mining approach. To detect the positive findings and rule out negative/equivocal findings, our approach processes the radiology reports in two steps (Figure 1). First, we text mine all diseases mentioned in the reports using a state-of-the-art NLP tool, MetaMap 2. Next, we developed a new negation detection tool called NegBio for filtering negative and equivocal diseases in our radiology reports. Specifically, NegBio uses hand-crafted heuristic rules to search the dependency parse of each sentence in the report to determine if a disease mention is covered in its dependency graph by a negated or uncertainty cue (e.g., “no evidence of” or “suspicious”). If so, this disease will be marked as negative or equivocal and subsequently discarded.

Radiology images classification for thoracic diseases. With CXR-XIV, we then built a framework for detecting the presence of multiple thoracic diseases in radiology images (Figure 1). A weakly-supervised deep learning paradigm was adopted by utilizing the text-mined image level labels for the multi-label image classification task. Specifically, we tailored Deep Convolutional Neural Network (DCNN) architectures for multi-label disease classification.
Results

Text Mining Results. We first evaluated our method on the 900 human-annotated radiology reports: we achieved 94.4% in precision, 94.4% in recall and 94.4% in F-measure overall. These highly accurate results meet our need to generate a corpus with weak labels, which serves as a solid foundation for the later process of image classification. To demonstrate the robustness of our method, we applied NegBio to another independent dataset OpenI3. Furthermore, we compared NegBio with NegEx⁴, a rule-based tool for negation detection in clinical NLP. Our results show that NegBio achieves an improvement in precision (over 16%) and overall F1-score (over 8%) on both datasets.

Radiology image classification results. We evaluated and validated the unified DCNN framework with the CXR-XIV dataset¹. Similar to other large-scale dataset released in the computer vision community (e.g., ImageNet and MS COCO), we randomly shuffled the entire dataset into training, validation, and testing subsets. CNN models were optimized via stochastic gradient descent. In general, the quantitative performance varies for different disease patterns, in which the model based on ResNet-50 achieved the best results⁵. For example, the “cardiomegaly” (AUC=0.8141) and “pneumothorax” (AUC=0.7891) classes are consistently well-recognized, compared to other groups where the detection ratios are relatively lower for diseases of small objects, e.g., “nodule” classes (AUC=0.7164).

Discussion

To our best knowledge, this work represents the first attempt to combine text mining with radiology imaging analysis in the era of deep learning. We demonstrate the unique role of text mining for generating weak labels in the use of radiology imaging analysis by deep convolutional neural network. From the text mining perspective, a novel algorithm (NegBio) was developed with state-of-the-art performance for identifying not only negative findings, but also equivocal findings which have largely been ignored in the past.

The subsequent imaging analysis (i.e., recognizing and locating disease patterns) supports the idea that a weakly-labelled dataset can be as effective as one generated by expert annotators in training a deep learning model to detect common thoracic diseases. However, the current results also suggest that building fully-automated high precision CAD systems remains challenging. We hope that these findings will add to a growing body of literature to our understanding of reading radiology images and reports.

Introduction

End of life care and cost continues to trouble patients, providers, and policy makers. 25% of Medicare expenditures are associated with end of life care. It has been shown that shared decision making has been linked to high quality end of life care, which could lower costs. However, Advanced Directives, which capture patient preferences, have low adoption rates, and are often completed 1-2 months prior to death. Accurately predicting mortality risk could allow providers to develop advanced care plans with their patients earlier in the course of disease. Research indicates that the presence of multiple chronic conditions, is a critical factor in health care spending; however, the trajectory of non-cancer illnesses involve exacerbations of disease followed by stabilization may make it difficult for providers to recognize when the final turn for the worse is occurring.

While literature exists on acute mortality, there are few models that address the period six months prior to death. While we identified disease specific models (e.g., CHF and Diabetes), having many disease specific models could result in obfuscation. Multiple, possibly competing mortality risk scores, would force providers to “juggle” multiple predictions. Therefore, we assessed the feasibility of a generalized mortality predictive model to assisting providers and population health organizations to identify patients six months prior to death.

Methods

Data was obtained from Medicare Shared Savings Program (MSSP) Accountable Care Organization (ACO). From eligibility data, we identified a sample of 2,307 members with: (1) a deceased date between 2014 and 2016, and (2) at least 12 months of eligibility history prior to death. We identified 52,298 members with at least 12 months of eligibility between 2014 and 2016. Deceased status was coded as a binary outcome. For the decedents, the surveillance window was the first 6 months of the 12-month period preceding the deceased date, and our prediction window was the 6-month period immediately preceding the deceased date. For the non-decedents maximum eligibility date was a proxy for deceased date. We manually curated 36 concepts mapped to four classes of features: medical claims, pharmacy claims, lab results, and socio-economic data. The selected criteria were selected based on published data on prognosis. We began with common clinical concepts (i.e., Diabetes, CHF and Charlson) and common utilization metrics such as the number of distinct diagnosis codes (Number of DXs). Our clinical expert guided features that reflect frailty, such as Skin Ulcers and difficulty with Activities of Daily Living (ADLs), and recent Body Mass Index (BMI). From that information we built concepts such as Discharge to a Skilled Nursing Facility (SNF) and procedure codes that could indicate impairments to ADLs (Functional Issues). We leveraged Median Income and Poverty rate data (Below Poverty) from the US Census Bureau. For labs we sought signal clinical indicators that can qualify an individual for hospice care: GFR, Albumin, and Creatinine. Given strong performance and ability to handle missing data without imputation, we employed Gradient Boosted Decision Trees. We leveraged Dismo in R with the parameters: folds = 10, complexity = 6, bag rate = 0.5, and learning rate = 0.01.

Results

The mean training c-statistic was 0.88. The mean validation c-statistic was 0.86. Table 1 highlights positive predictive value (PPV), sensitivity, and specificity at various risk thresholds. Figure 1 shows key influential variables.

Table 1: Model Performance

Figure 1: Key Influential Variables
Discussion

It appears feasible to predict morality risk within six months without restricting the population to a particular condition. This is significant because it could allow for a singular risk score to identify patients for end-of-life support services. As a result this model could be of interest to Population Health and providers whom a) may desire a single mortality risk prediction, b) manage an array of comorbidities, or c) manage a population with varied health needs. Our findings are consistent with other research, which found that various factors impact mortality risk. For example, laboratory results has been used previously to predict frailty and subsequent mortality. In addition, the influence of poverty on mortality aligns with literature associating income with life expectancy. While studies on mortality risk factors, specifically for Kidney Disease, have demonstrated that laboratory data are most predictive of short term mortality whereas demographic data is predictive of long term mortality, our research suggests that both socio-demographics and laboratory measurements affect six month mortality. Our data came from a single ACO, so it is questionable whether our results are generalizable to other populations. More validation is needed to determine if the model is generalizes to other populations, and if Gradient Boosted Decision Trees yields the best classifier.

Accurately predicting 6-9 month mortality may allow physicians to engage patients in advance care planning, which may facilitate better coordinated end of life care. However, accurate mortality predictions do not automatically translate into shared decisions between patients and providers, higher quality care, and lower costs. Research has indicated that policies promoting end of life discussions, expanded access to palliative care, and more education on end of life discussions are needed. Therefore, further work is needed to evaluate how end of life discussions impact both quality and cost of care in addition to assessing whether or not accurate mortality predictions facilitate end of life care discussions.

Linking Resident Behavior to Health Conditions in an Eldercare Monitoring System

Mihail Popescu, Andrew Craver, Lorraine Phillips, Richelle Koopman, Gregory Alexander Laurel Despins, Marilyn Rantz

University of Missouri, Columbia, MO

Introduction

Early detection of health changes among older adults is the key to maintaining health, independence, and function. Non-wearable sensors such as depth cameras, motion sensors (passive infrared, PIR) and bed sensors (based on ballistocardiography) are able to detect changes in gait activity and sleep, and have emerged as a possible solution for early detection of health changes. Since 2005, our interdisciplinary research team has investigated, developed and tested a state of the art sensor monitoring system for older adults at TigerPlace, a unique eldercare facility in Columbia, MO1.

Analyzing and acting upon sensor data remains a challenge for clinicians due to data variety (many sensor types) and velocity (continuous monitoring). To view the context of the health alerts sent by the monitoring system, clinicians currently use a secure interface to review multiple data displays that may take 7 minutes per alert. To save clinicians’ time and make alerts easier to interpret, we are investigating a new knowledge-generation methodology based on linguistic summaries as a tool to provide more meaningful and easier to interpret alerts to clinicians.

While certain nonspecific behaviors were shown to be linked to diseases in the elderly2 and non-wearable sensors can capture those behaviors3, more specific information is needed for our monitoring system. As an initial step in creating linguistic summary alerts, our team conducted a survey of clinicians to determine which signs and behaviors captured by the monitoring system they find most relevant in evaluating and treating health conditions among older adults. The results of this survey will guide the development of linguistic summary methods.

Methods

Our survey instrument consisted of a 7-item questionnaire in which clinicians were asked to rate how useful they would find a set of sensor measurements when evaluating or treating health conditions among the elderly. Respondents used a 1-4 scale to assess the usefulness of each behavior and sign: 1 = Not Useful; 2 = Somewhat Useful; 3 = Useful; 4 = Very Useful. Resident behavior measurements were computed by our monitoring system based on the non-wearable sensors shown in Table 1. For example, the number of bathroom visits was computed based on the data provided by the bathroom motion sensor, and the walking speed and stride length were computed based on depth sensor (Kinect) data (see http://eldertech.missouri.edu/papers for more details).

We assessed 12 health conditions in this survey: depression, dementia, mental status change, chronic obstructive pulmonary disease (COPD) exacerbation, chronic health failure (CHF) exacerbation, atrial fibrillation, transient ischemic attack (TIA)/stroke, fall risk, hypo/hyperglycemia, urinary tract infection (UTI), pneumonia and pain.

The sample for this preliminary survey consisted of 11 physicians, 5 registered nurses and 6 licensed practical nurses. These clinicians, all users or familiar with our monitoring system, were recruited from TigerPlace, from our assisted...
living research sites, and via existing contacts in the MU Health System through referral. Clinicians took part in the survey in-person and or via an online Qualtrics (http://www.qualtrics.com) instrument. All materials and protocols were approved by the University of Missouri IRB.

Results

Three resident behaviors (signs) in order of their importance for assessing 12 health conditions are shown in table 2.

Table 2. Three resident behaviors in order of their importance for assessing 12 health conditions among the elderly

<td>Respiration: 27%</td>
</tr>
<tr>
<td>Urinary Tract Infection</td>
<td>Bathroom visits: 96%</td>
<td>Restlessness: 46%</td>
<td>Overall Motion: 46%</td>
</tr>
</tbody>
</table>

From the above table we see that for 9 out of the 12 conditions, more than 80% of the clinicians seem confident (scores 3 and 4) that our system could provide useful information. For three conditions listed above (TIA, hypo/hyperglycemia and dementia) our monitoring system doesn’t seem able to provide useful information.

Conclusions

Based on data in table 2, for residents with a history of one of the above conditions (extracted from our nursing EMR), we will provide linguistic summaries that provide context for the health alerts of the form: “Observed an increase in bathroom visits and an increase in bed restlessness. Possible UTI.” Note that the data in table 2 can be used as a fuzzy rule decision support system for producing alerts, with rules of the form: “IF the number of bathroom visits is high AND night restlessness is high and apartment motion is low THEN the possibility of UTI is high.” Our team is currently exploring the timeframe and directionality of our set of health behaviors through further clinician surveys in order to refine a system of thresholds for deploying alerts.

Identifying Potentially Missing Hierarchical Relations in SNOMED CT based on Lexical Features – Impact of Synonyms and Lexico-syntactic Constraints

Satyajeet Raje, PhD, Olivier Bodenreider, MD, PhD
U.S. National Library of Medicine, National Institutes of Health, Bethesda, MD, USA

Introduction
The quality assurance of large bio-ontologies is extremely critical for their effective and continued use and is an active area of research. For example, recent investigations highlighted issues in the hierarchical structure of SNOMED CT and its detrimental effects on biomedical applications. Previous work by one of the authors established a method to identify potentially missing hierarchical relations leveraging lexical features in SNOMED CT. It used the preferred term for each concept in SNOMED CT to create logical definitions for concepts. These definitions were used to identify missing hierarchical relations. The method was tested on a subset of SNOMED CT concepts and showed limited precision (20% of false positives). In this paper, we propose two improvements on our original method: 1) by adding lexico-syntactic constraints based on shallow parsing, we expect to increase precision; 2) by processing all synonyms, we expect to increase recall. This work is a contribution to quality assurance in SNOMED CT.

Methods
We used the Sept. 2016 release of SNOMED CT (US Edition) in this study. Our methodology can be summarized as follows. We create logical definitions for concepts leveraging all concept labels (preferred terms and synonyms) provided by SNOMED CT and their lexico-syntactic analysis. We infer hierarchical relations from the logical definitions and filter out those already present in the original hierarchy of SNOMED CT. Finally, we review the potentially missing relations. We compare the results of the enhanced method to those of the original (baseline) method.

A. Creating logical definitions. In the original method, each concept in SNOMED CT is represented as a set of words using description logics (see example below in Table 1). In the enhanced method:

1) We distinguish between head nouns and modifiers through lexico-syntactic analysis using the minimal commitment parser provided by SemRep. E.g., “Photogenic epilepsy” has head “epilepsy” and has modifier “photogenic”. We then create logical definitions representing the head and modifier roles of words in the term. Complex terms are ignored. (In the definition below, “some” is the existential qualifier in the OWL syntax.)

2) We create logical definitions for each synonym of the concept in addition to the preferred term. For example, the concept “Photogenic epilepsy” has a synonym, “Television epilepsy” in addition to its preferred term, “Photogenic epilepsy”. Definitions created for terms are later mapped to the corresponding concept.

Table 1. Example logical definitions from the original and enhanced methods.

<table>
<thead>
<tr>
<th>Original</th>
<th>“Photogenic epilepsy” = disorder AND (has_word some photogenic) AND (has_word some epilepsy)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Enhanced</td>
<td>“Photogenic epilepsy” = disorder AND (has_head some epilepsy) AND (has_mod some photogenic)</td>
</tr>
<tr>
<td></td>
<td>“Television epilepsy” = disorder AND (has_head some epilepsy) AND (has_mod some television)</td>
</tr>
</tbody>
</table>

We apply this enhanced method to the same hierarchies as the original study, namely the Disorder of head (disorder) (118934005) and Operative procedure on head (procedure) (89901005).

B. Inferring and filtering hierarchical relations. We use the ELK reasoner to infer a hierarchy of terms from the logical definitions (expressed in OWL 2 EL profile). For instance, ELK infers that disorder AND (has_head some epilepsy) AND (has_mod some photogenic) is a subclass of disorder AND (has_head some epilepsy). We further derive a hierarchy of concepts from the hierarchy of terms. For example, Photogenic epilepsy (disorder) is a subclass of Epilepsy (disorder). We only keep those subclass relations (between concepts) that are not already present in SNOMED CT (transitively closed).

C. Comparing results from original and enhanced methods. We compare the performance of the original and enhanced methods. To validate the results, we manually review all potentially missing subclass relations generated by either method. The results were pooled during review in order to mask the source of the relations.

Results
A. Creating logical definitions. We created logical definitions for the 12,088 concepts of the subhierarchy rooted with the concept Disorder of head (disorder) and for the 3798 concepts from Operative procedure on head (procedure).
by the original method. With the enhanced method, we could create definitions for 15,757 terms (9687 concepts) and 3129 terms (2171 concepts), respectively.

B. Inferring and filtering hierarchical relations. A total of 612 potentially missing relations were found by the original method, and 525 by the enhanced method. Common to both methods were 225 relations, giving a combined total of 912 relations.

C. Comparing results from original and enhanced methods. Of the 912 combined relations, 657 (72%) were judged valid. Table 2 gives a breakdown of the results per method. Contrary to our expectation, the addition of lexico-syntactic constraints and synonyms does not provide the expected gain in performance. However, there is significant gain in precision (~10 points) for the 225 relations retrieved by both methods (intersection).

Table 2. Performance of the original and enhanced methods.

<td>0.456</td>
<td>-</td>
</tr>
</tbody>
</table>

*The combined 912 relations are considered as reference. Recall is based on total 657 “valid” relations in this set.

Discussion

A. Adding lexico-syntactic constraints increases precision. The gain in precision for the 225 relations retrieved by both methods (intersection) indicates that the lexico-syntactic constraints reduce false positives (adding precision). For example, Removal of fixation of mandible (procedure) is no longer recognized as subclass of Fixation of mandible (procedure), because the two terms have different head nouns. This level of precision has potential application to quality assurance. However, it also causes a significant drop in recall, because our method excludes complex syntactic patterns.

B. Enhancements degrade performance. We observed that adding synonyms created additional valid relations that cannot be inferred by the original method. For example, Enlarged parietal foramina (disorder) is recognized as subclass of Craniolacunia (disorder). However, it also adds many false positives. For example, Acquired keratoglobus (disorder) is inferred as subclass of Congenital keratoglobus (disorder), because it has a synonym “Keratoglobus”, reflecting the predominant congenitality of this condition.

Conclusion

We have evaluated the effects of adding synonyms and lexico-syntactic constraints on the identification of potentially missing hierarchical relations in a subset of SNOMED CT. In the future, we would like to apply our method to all of SNOMED CT and study the relative contribution of each enhancement (adding synonyms vs. lexico-syntactic constraints). Importantly, the missing hierarchical relations identified by our methods may only indicate underlying issues in SNOMED CT’s concept definitions, which will require domain expertise to address.

Abstract

Transitioning from hospital to home is a difficult undertaking for many patients, often putting them at risk for adverse events. We are developing a multicomponent care transition intervention (CTI) founded on the concept of a virtual nurse that corresponds with Veterans pre-discharge as an onscreen relational agent, and post-discharge via two-way automated tailored text messaging. We report the process of selecting and refining the characteristics and onscreen personality of our relational agent.

Introduction

Successfully managing complex health conditions requires patients to be engaged in their health intellectually and emotionally. Often, patient-facing eHealth technologies reach patients who are highly engaged, leaving behind those less inclined to participate meaningfully in their own care, or to effectively use technology. Strategies are needed to engage all patients more uniformly. We are examining how to empower, motivate and engage patients within the transition from hospital to home. When transitioning from hospital to home, many patients feel overwhelmed and face limited support for post-discharge self-management tasks. Clinical teams often cannot engage in proactive, tailored, post-discharge communication with patients beyond the scope of usual care. Thus, patients are often readmitted to the hospital due to factors such as limited self-monitoring, suboptimal adherence, or lack of follow-up.

Our CTI is founded on the concept of a virtual nurse to engage and support Veterans with chronic heart failure (CHF) and/or chronic obstructive pulmonary disease (COPD) in their self-management efforts. The virtual nurse first communicates with Veterans in-hospital as an onscreen relational agent, a computer-animated character that simulates conversation. Research shows the effectiveness of relational agents to provide education and counseling to patients, including discharge information. Post discharge, the virtual nurse continues to converse with Veterans via two-way, automated computer-tailored text messaging. The CTI is accompanied by a detailed safety plan including system monitoring to identify instances requiring clinical assistance. We report our process for selecting

Reference
and refining the characteristics and onscreen personality of our virtual nurse, and developing the script that drives the dialogue and interaction with Veterans.

**Methods**

We followed an iterative, multimethod process, with input from Veterans and subject matter experts. We initially developed 12 prototype virtual nurse characters based on previous work conducted in the Veteran population. To choose the physical attributes, we conducted a card-sorting exercise of photos of the characters and semi-structured interviews with six Veterans selected in accordance with the principles of maximum variation sampling (e.g., intentionally gathering data from individuals with varying characteristics). We revised the materials, removing the most disliked characters, and conducted another card-sort and interviews with an additional three Veterans. Analysis of data was descriptive and included frequencies and means. Study team members thematically analyzed the interview data using a brief code list to support deductive coding for key points of feedback.

To design the script, we consulted with experts in CTIs, health behavior, and clinical management of CHF and COPD. CTI experts organized the content of the script to reflect four important conceptual domains or “pillars” (understanding one’s condition, minding “red flags” suggesting a worsening condition, medication self-management, and keeping follow-up appointments) of care transitions. Our clinical experts tailored the script to reflect key symptoms and management for CHF and COPD. Our health behavior experts incorporated verbal and non-verbal cues, along with targeted social talk to build rapport. We role-played the script with two Veterans and solicited feedback regarding the script’s content, flow, and length.

**Results**

The virtual nurse selected had physical attributes that Veterans found realistic, inviting, and compassionate, appropriate for a clinical setting, and reflective of a nurse that they “would feel comfortable speaking with about medical matters.” Veterans also suggested that the virtual nurse should be wearing hospital scrubs and be situated in a “neutral” hospital setting like an exam room. They also emphasized that the virtual nurse’s voice should be soft, professional and without excessive intonation. The Veterans who participated in the script role-playing session reported that the script was understandable, time appropriate, educational, and engaging.

**Conclusion**

Leveraging diverse stakeholder input, we developed a key component of a multi-component CTI intended to meaningfully engage patients. Veterans expressed strong preferences for the virtual nurse attributes, and subject matter experts were instrumental to developing a script that supports clinically-appropriate and engaging interaction. Our virtual nurse CTI is unique as it embodies a personality that strives to relate to patients, making connections that otherwise may not be possible due to the heavy workloads faced by clinical team members. Our next step is to conduct a usability pilot. We will then test the effectiveness of our CTI in a three-site randomized control trial. Our paper will include preliminary results from our pilot as well as a multimedia presentation of the virtual nurse.

Information Retrieval for Biomedical Datasets: The 2016 bioCADDIE Challenge

Kirk Roberts, PhD1, Anupama Gururaj, PhD1, Xiaoling Chen, PhD1, Saeid Pournejati, MS1, Trevor Cohen, MBChB, PhD1, William R. Hersh, MD2, Dina Demner-Fushman, MD, PhD3, Lucila Ohno-Machado, MD, PhD1, Hua Xu, PhD1

Introduction

Biomedical research’s increasing dependence on digital data, as well as recent concerns on reusability and replicability, has led to a significant increase in the number and types of datasets available to biomedical researchers. Finding datasets relevant to one’s own project amid the massive quantity available, however, can be quite challenging due to the diversity of information types associated with a dataset. For this reason, new methods of information retrieval (IR) are necessary. To encourage the rapid development of novel dataset retrieval methods, a publicly available test set was created to provide a benchmark dataset on which IR researchers can compare their methods. The release of this dataset was accompanied by a shared task—the 2016 bioCADDIE Dataset Retrieval Challenge—to spur rapid development and dissemination of ideas for biomedical dataset IR.

The IR challenges in searching biomedical datasets are numerous and complex. Dataset searches are not typically answerable entirely from the structured meta-data (e.g., organism, array type) associated with the datasets. For example, a researcher might be interested in “genome data for IDH1 and IDH2 in humans with glioma”. Answering such a query requires innovative search strategies not only for the structured and unstructured dataset description, but often the linked scientific articles to better place the dataset’s qualities in perspective. Due to this complexity and the many potential IR solutions, evaluating dataset retrieval methods on a common benchmark is vital.

Background

The biomedical and healthCAre Data Discovery Index Ecosystem (bioCADDIE) project1,2 seeks to provide a prototype platform for researchers to find, reanalyze, and revise biomedical data. bioCADDIE is designed to be a common data index, connecting with existing biomedical data repositories (e.g., dbGaP, ClinicalTrials.gov). The meta-data from these sources are collected, normalized, and indexed. The bioCADDIE search engine–DataMed3–utilizes the complex and varied meta-data describing each dataset. Currently, DataMed is a relatively baseline IR system, indexing structured and unstructured data, then performing standard IR search mechanisms. An immediate benefit of the Dataset Retrieval Challenge, then, is to identify innovative search strategies for integration into the DataMed search engine.

Beyond the scope of bioCADDIE and dataset retrieval, IR shared tasks have been enormously successful in fostering innovative methods and encouraging collaboration between IR researchers and biomedical experts. These shared tasks have largely been organized as part of the annual Text Retrieval Conference (TREC), organized by the U.S. National Institute of Standards and Technology (NIST). From 2003-2007, the TREC Genomics track4 focused largely on retrieving scientific articles of interest to genomics researchers. From 2011-2012, the TREC Medical Records track5 switched the focus to retrieving clinical notes. Finally, from 2014-2016, the TREC Clinical Decision Support track6 focused on retrieving scientific articles of interest to clinicians. All these tasks garnered significant interest and participation, well above that of most TREC tracks. The bioCADDIE Dataset Retrieval Challenge most resembles the original TREC Genomics track in its focus on researchers as the primary user. However, bioCADDIE’s focus on datasets and not literature articles is a substantial shift. Not only do datasets have their own meta-data and descriptions, they often are linked to multiple scientific articles. The focus of those articles is generally the scientific findings, as opposed to the potential reusability of the data. This presents a dataset search engine with three very different sources of information: (i) structured data providing basic constraints of the dataset, (ii) textual descriptions providing a high-level overview of the data, and (iii) scientific articles that generally are not focused on the dataset itself, but rather illustrate potential uses of the dataset. This combination of challenges has not been addressed by any previous IR shared task.
Materials and Methods

The bioCADDIE Dataset Retrieval Challenge participants were provided a snapshot of the bioCADDIE index comprising 20 repositories in XML and JSON formats. They were also provided with 6 sample queries with manual judgements and 30 sample queries without judgement. Two weeks before the submission deadline, participants were provided with 15 test queries, for which they were allowed to return 1,000 results each. Up to five submissions were allowed per participant.

Prior to the submission deadline, four baseline IR systems were used to identify 18,416 results for manual judgement. After the deadline, the participant submissions were pooled to identify a further 1,767 results for manual judgements, similar to the TREC approach for creation of judgement pools. Each judgement determines whether a given dataset is relevant, partially relevant, or not relevant to a particular query.

Results

A total of 45 submissions were received from 10 participants. The results are shown in Table 1.

Discussion and Conclusion

To the degree that the bioCADDIE Challenge elicited new and innovative approaches for dataset retrieval beyond those already employed by DataMed, the task was quite successful. Participants utilized a highly diverse set of IR methods for retrieving datasets. These methods ranged from rule-based query processing for identifying specific query elements for special handling (e.g., identifying the organism of interest for use against the corresponding structured metadata field) to machine learning-based ranking frameworks incorporating dozens of features. As a publicly available benchmark dataset, the bioCADDIE Challenge data opens future work by IR researchers in many directions. Further, the bioCADDIE team plans to incorporate many of the approaches used by the participants into the DataMed search engine and further analyze the specific sub-problems related to dataset retrieval.

Association of BMI and Obesity Genetic Risk Score with Surgical Procedures Through a Procedure-wide Association Study

Jamie R. Robinson, M.D., Zongyang Mou, B.S., Lisa Bastarache, B.S., Wei-Qi Wei, M.D., Ph.D., Robert J. Carroll, Ph.D., Joshua C. Denny, M.D., M.S.
Vanderbilt University Medical Center, Nashville, TN

Introduction
Body mass index (BMI), both below and above the optimum, is known to be a strong predictor of comorbidities and overall mortality. We sought to analyze the association of BMI and known obesity genetic risk loci via Mendelian randomization with comorbidities and invasive procedures via phenome-wide association studies (PheWAS) and procedure-wide association studies (ProcedureWAS). We aimed to demonstrate the utility of ProcedureWAS in validating, as well as identifying novel, phenotypic and genetic associations.

Methods
A retrospective, cross-sectional study of all adult individuals with documented BMI at Vanderbilt University Medical Center (VUMC) was performed. Data collection was accomplished using the VUMC Synthetic Derivative (SD), a de-identified version of over 2.4 million patient electronic health records. After removal of outliers and BMIs recorded during pregnancy, median BMIs for each individual were categorized based upon world health organization (WHO) classifications. PheWAS, logistic regression of aggregated International Classification of Diseases (ICD) 9-CM codes against BMI categories, was performed to determine phenotypic associations. Similarly, current procedural terminology (CPT) codes were aggregated into clinically meaningful categories as defined by the Healthcare Cost and Utilization Project of the Agency for Healthcare Research and Quality. ProcedureWAS, logistic regression models of procedure aggregates against BMI categories, was performed. Replication analysis was performed with a separate ProcedureWAS with logistic regression models of procedure categories against a genetic risk score (GRS) for obesity constructed as a sum of risk alleles from 37 single nucleotide polymorphisms (SNPs) with known relation to obesity. The GRS was calculated for adults of European ancestry genotyped on the Illumina HumanExome array platform. All analyses were adjusted for age and gender.

Results
A total of 737,066 individuals had at least one recording of BMI for inclusion in the PheWAS and ProcedureWAS against BMI. Of those, 24,363 individuals had genetic data for inclusion in the ProcedureWAS against the obesity GRS. In PheWAS, WHO categories of underweight (<18.5 kg/m²) and obesity class 3 (≥40 kg/m²) individuals showed significant increases in many comorbidities compared to those with normal BMI (Figures 1-2).

Figure 1. PheWAS of WHO underweight BMI with comorbidities. Red line is Bonferroni significance.
In ProcedureWAS (Table 1), underweight individuals showed significant increases in gastrointestinal (GI), respiratory, and non-cardiac vascular procedures compared to those with normal BMI. In contrast, class 3 obesity was significantly associated with coronary intervention, liver biopsy, bariatric and orthopedic surgery, cesarean section, cholecystectomy, and hernia repair. Coronary arteriography, liver biopsy, gastric bypass, knee arthroplasty, and hernia repair associations were replicated in ProcedureWAS using the obesity GRS (noted by an asterisk in Table 1).

*Replicated (p<0.05) in separate analysis of BMI categories against obesity GRS with Mendelian randomization

Conclusion
This study demonstrates that BMI, both underweight and overweight, are strongly correlated with increased risk for comorbidities and undergoing invasive procedures. This is also the first known study to show that procedure-wide association studies using aggregated procedure codes and pairwise analyses can be used to analyze associations with clinical phenotypes and genetic data, quantifying the magnitude of increased probability due to a specific risk factor.

Deep recurrent neural networks identify transgender patients

Joseph D. Romano¹, Kenrick D. Cato¹,², Rami Vanguri¹, Nicholas P. Tatonetti¹
¹Columbia University, New York, New York; ²NewYork-Presbyterian Hospital, New York, New York

Abstract

We demonstrate a state-of-the-art deep learning approach to classifying patients by transgender status. Our model consists of performing word-embedding on clinical free-text notes, followed by a long short-term memory recurrent neural network classifier. This study represents a machine learning approach for identifying transgender patients, and may prove useful in improving clinical care for transgender patients.

Introduction

Transgender individuals have unique health concerns that should be considered during clinical encounters¹. However, due to stigmas and other social factors, patients may not inform their health care providers of their transgender status. All previous methods for note-based identification of transgender patients are based on simple heuristic searches (e.g., via substring matching or billing/diagnosis codes) that lack sufficient rigor. In response to these and other observations, LGBT researchers and advocacy groups are seeking methods for informing care providers of potential transgender status in a scalable manner.

Recurrent neural networks (RNNs) provide an architecture for performing deep learning on ordered sequences², such as natural language. Currently, RNNs are a state-of-the-art approach to performing text classification, and have seen success in many areas, including biomedicine³. The performance of RNN text classifiers can be further improved using word embedding to convert words to high-dimensional vectors, where the relationships between word vectors represent the natural semantic relationships between their corresponding words.

In this study we demonstrate a novel method for classifying transgender patients using word embedding and an RNN model applied to clinical notes.

Methods

We manually identified an initial cohort of 39 transgender patients—using a string search for terms and pronouns indicative of transgender status —in all clinical free-text notes within the Columbia University Medical Center EHR.
system. We subsequently defined a control cohort as 500 randomly selected patients in the EHR that are not in the case group. For each of these two groups, we extracted all available clinical notes (inpatient and outpatient) and constructed training, testing, and hold-out datasets (via random sampling without replacement of 70%, 20%, and 10% of patients, respectively), where notes were labeled according to the case/control status of the patients to whom they corresponded. An overview of the analysis pipeline is shown in Figure 1.

The classification model we used consists of two components: (1) Learning a high-dimensional embedding for the words using the skip-gram model⁴, and (2) training a dynamic RNN to predict whether a note is from a control or a case patient. The RNN was trained using stochastic gradient descent and a cross-entropy loss function, and monitored for overfitting using the aforementioned holdout validation data set. We implemented the model in the Tensorflow numerical computation library using a long short-term memory architecture⁵ for the RNN, and performed training and evaluation on a CUDA-accelerated Linux server with an Nvidia Tesla k40 supercomputing GPU.

Results

We extracted 4,859 clinical notes for the 39 transgender patients and 13,314 notes for the 500 control patients, each of which we then divided as described above into training, testing, and hold-out sets. The trained model performed surprisingly well, yielding 83.3% classification accuracy, with 87% precision and 93% recall ($F_1$ score of 90.2%). These results are summarized in Table 1.

Learning the word embeddings for the corpus of 18,173 notes completed within 5 minutes, and training the RNN completed within 10 minutes, which is approximately one order of magnitude faster than when tested on a desktop computer without GPU acceleration.

Table 1: Performance of embedding + RNN model trained on transgender notes.

Discussion

This algorithm can form a basis of cohort discovery for future studies regarding the health of transgender patients. One of the primary benefits of our classification model is that it performs well even with a small number of case patients. This classifier holds the potential to be useful in clinical decision support (such as alerting physicians to watch out for certain transgender-related health issues). However, it does not address the ethical issues that accompany the automated identification of transgender patients⁶, and is therefore not yet ready for use in clinical practice. We encourage further investigation in the hopes that care providers can better serve the unique health needs of transgender patients.

Introduction
Awareness of a hospitalized patient’s physiological status and the context of that status are keys to the effective delivery of quality care. For adults, the Rothman Index (RI)\textsuperscript{1}, a validated measure of patient condition, based on empirically derived univariate relationships between 1-year post-discharge mortality and each of 26 clinical measurements, which are available in the electronic medical record, assists clinicians by providing an estimate of physiological status and its trend over time. For pediatrics, there are no data from which a similar measure of patient condition may be derived. We report on the development and validation of a new methodology to leverage adult mortality data to generate estimates of risk and of patient condition for pediatrics, where the relationships between risk and several physiological parameters are continuous functions of the age of the patient.

Methods
Clinical data were extracted from electronic medical records (EMRs) at three pediatric hospitals: Children’s Hospital of Pittsburgh, Yale-New Haven Hospital and a 3\textsuperscript{rd} in the northeast, covering 105,470 inpatient visits over a 3-year period (2009-2013). IRB approvals were granted.

The RI input variable set was used as a starting point for the development of the pediatric Rothman Index (pRI). Age-dependence of continuous variables was determined graphically, by plotting mean values versus age. For variables determined to be age-dependent, polynomial functions of mean value and mean standard deviation versus age were constructed using data from two hospitals. Mean values and standard deviations for previously published corresponding adult risk curves, were separately estimated. Based on the “find the center of the channel” hypothesis (mean value equals lowest risk), univariate pediatric risk was then computed by applying a z-score transform to adult mean and standard deviation values based on polynomial pediatric mean and standard deviation functions. Multivariate pediatric risk is estimated as the sum of univariate risk. Other age adjustments for categorical variables were also employed.

Age-specific pediatric excess risk functions were compared to age-specific expert-derived functions and to in-hospital mortality. Odds ratios for in-hospital mortality were computed for each of eleven nursing assessments, which are part of the pRI and constitute a “head-to-toe” assessment which is a standard part of nursing protocol. AUC for 24-hour mortality and pRI scores prior to unplanned ICU transfers were computed, as were minimum visit pRIs.

Results
Age-adjusted risk functions correlated well with similar functions in two pediatric risk models, Bedside PEWS and PAWS\textsuperscript{2,3}(Fig. 1). Pediatric nursing assessment data correlated well with risk as measured by mortality odds ratios. AUC for pRI for 24-hour mortality was 0.93 (0.92, 0.94), 0.93 (0.93, 0.93) and 0.95 (0.95, 0.95) at the three pediatric hospitals. Average pRI scores
declined prior to unplanned transfers to the ICU (Fig. 1). Moreover, the minimum pRI score for the visit correlated with likelihood of unplanned transfer. A case study is shown (Fig. 1).

Discussion
We have demonstrated that each component of pRI, which is a heuristic model, is credible. Overall model performance as measured by AUC, a standard metric for acuity tools, is excellent, with similar results at each hospital. On a functional basis, the pRI shows potential as an early warning tool, declining prior to unplanned transfers to the ICU. While there are occurrences of sudden decompensation, often physiological deterioration resulting from a surgical or other treatment complication is a process which progresses over hours or days. Intervention to prevent an emergent condition is most effective if done early in that process. The pRI, which is integrated into major EMRs, provides a real-time estimate of patient condition and is presented to the clinician as a graph (see Fig. 1). Viewing an array of pRI graphs allows the clinician to survey many patients, allowing him/her to influence and prioritize the management of those patients. It is currently being used at pediatric hospitals for that purpose4, as well as for hospital-wide surveillance, and will be considered for telehealth applications.

Can Emergency Department Provider Notes Help Achieve More Dynamic Clinical Decision Support?

Justin F. Rousseau, MD, MMSc1,2, Ivan K. Ip, MD, MPH1, Ali S. Raja, MD, MBA, MPH1, Jeremiah D. Schuur, MD, MHS1, Ramin Khorasani, MD, MPH1

1Brigham and Women’s Hospital, Harvard Medical School, Boston, MA; 2Dell Medical School at The University of Texas at Austin, Austin, TX

Abstract
Retrospective observational data were reviewed from notes present prior to image ordering from 438 Emergency Department encounters with chief complaints of trauma, falls, and bicycle accidents and cervical-spine (C-spine) imaging. C-spine clinical decision support (CDS) was delivered in 26.7% of encounters. 59.2% of encounters with a note portion present prior to image ordering contained at least one CDS criterion. Concordance was lacking between polarity of attributes when present in both notes and CDS tool.

Introduction
Imaging clinical decision support (CDS) is an application of health information technology to inform clinical decision-making at the point of care regarding the need for imaging or the optimal diagnostic study based on the best available evidence1. Although clinical decision support (CDS) can be an effective health information technology tool to deliver timely advice at the bedside, many opportunities remain to improve CDS, including timing, sensitivity, and specificity of its delivery. One of the Ten Commandments of imaging CDS is to “respect ordering provider workflow,” and in particular to eliminate redundant data entry1. Currently, when imaging CDS is integrated within a computerized physician order entry (CPOE) system, clinicians enter patient data for CDS at the time of order entry in addition to and independent of data entered in the order entry module, leading to significant interruption of workflow as well as redundancy of documentation likely previously entered in the clinical note within the same electronic health record (EHR). Incomplete or conflicting information resulting from these redundancies may adversely impact quality of patient care, as well as the secondary use of data for purposes such as analyses of guideline adherence or research. Low sensitivity of CDS delivery may lead to missed opportunities to suggest appropriate investigations that might lead to the appropriate diagnosis. Further, CDS often exposes providers to clinical alerts with low specificity, resulting in alert fatigue2.

Cervical spine (C-spine) imaging can be guided by CDS that requires the entry of certain relevant attributes of the patient history and physical examination in typical EHR implementations. Our objective was to assess the frequency of CDS attributes present in emergency department (ED) provider notes at time of C-spine order entry to determine whether these might be a source of data which could be automatically pulled from the notes rather than entered again by the providers in the order entry process.

Methods
This Institutional Review Board-approved, retrospective study was performed in an adult quaternary academic hospital. We included all adult ED patients seen between 4/1/2013 and 9/30/2014 after falls, trauma, or bicycle accidents who underwent C-spine CT or x-ray. We excluded encounters where the trauma team was activated as these encounters involve immediate performance of trauma imaging by protocol, often before orders are placed, making CDS to inform the appropriateness of the study unnecessary. The NEXUS CDS rule identifies a set of five clinical criteria attributes which, when all are absent, indicates that the patient has a very low probability of cervical injury3. At the study institution, CDS based on NEXUS is delivered when a C-spine CT or 3-view plain film study is ordered and the structured indication of “trauma” is selected on the order requisition. CDS based on the Canadian C-Spine rules is delivered when a standard 6-view C-spine plain film study is ordered and the structured indication of “trauma” is selected on the order requisition4.

The primary outcome was the rate of CDS rule attributes identified in the clinical notes at the time of image order entry. Secondary outcome measures included rates of CDS rule delivery and rates of exclusion criteria from the CDS rules identified in note portion versions available at the time of image order entry. We examined concordance in CDS rule attributes identified in the clinical notes available at the time of image order entry compared to the attributes obtained via physician interaction with the CDS rule through the CPOE system using kappa statistic of agreement and
McNemar test of marginal homogeneity of the paired data. As attributes are present in the CDS tool in all encounters where CDS was delivered, concordance was calculated for individual attributes when CDS was delivered and an attribute was described as positive or negated in the note.

Results

We identified 3155 consecutive encounters for 2992 unique patients who presented with a chief complaint of fall, trauma, or bicycle accident where the trauma team was not activated during the 18-month study period. C-spine imaging (CT or plain film) was performed in 438/3155 (13.9%) of these encounters. A portion of the clinical note was submitted before imaging was ordered in 42% (184/438) of encounters. C-spine CDS was delivered in only 26.7% (117/438) of encounters. 59.2% (109/184) encounters with note portions submitted before image ordering had at least one positive CDS criterion identified, 34.8% (64/184) identified CDS exclusion criteria. Overall concordance of C-spine CDS attributes when present in both notes and CDS was 68.4% ($\kappa=0.35$; McNemar $p=0.23$).

Discussion

Information found in unstructured clinical notes present at the time of imaging order entry contained significant amounts of relevant CDS rule attributes and exclusion criteria that should have been entered by the physician into the CDS tool in the CPOE. Harvesting these CDS rule attributes and exclusion criteria from the EHR notes when available may 1) allow pre-population of CDS tools, freeing clinicians from unnecessary redundant data entry, and 2) allow suppression of CDS rules not applicable to the current patient, freeing clinicians from unnecessary visual and workflow interruptions, thus reducing alert fatigue. Our study was conducted in a single academic setting making its generalizability unclear, particularly where there is individual and institutional variation in diagnostic ordering practices and management of trauma cases. However, by bringing the best available evidence to the point of decision-making, a goal of CDS is to reduce such variability.

In this study, rates of delivery of the CDS tool when indicated were surprisingly low, suggesting that using data entered to a CDS tool alone would be insufficient to define a population of patients eligible for the rule. Finally, there was only fair agreement between CDS attributes documented in notes compared to those entered in the CDS tool in the same encounter, raising questions about the quality, sufficiency, veracity, and completeness of data entered into either source.

Conclusion

Clinician documentation in the EHR is an underutilized information resource that contains CDS attributes and exclusion criteria and is available in a significant percentage of encounters at the point of C-spine image ordering. This is a surprising finding in cases of C-spine imaging for trauma in the ED that do not activate the trauma protocol for immediate imaging, where a scarcity of documentation might be expected prior to image ordering. Future work will need to be done to evaluate the quality and quantity of clinical data documented in encounters that are less acute than cases of trauma in the ED. Future work will also need to be done in the area of text mining or natural language processing in order to automate the extraction of these attributes and exclusion criteria to realize a feasible application integrated into the EHR, allowing for pre-population of CDS and less data entry by providers.

Using mHealth to Monitor Asthma Symptoms Between Visits

Robert S. Rudin, PhD,1 Christopher H. Fanta, MD,2 Zachary Predmore, BA,1 Eyal Zimlichman, MD,3 Kevin W. Kron, BA,3 Maria Edelen, PhD,1 David W. Bates, MD2

1 RAND Corporation, Boston, MA; 2 Partners Healthcare, Boston, MA; 3 Sheba Medical Center, Israel

Introduction

Asthma affects more than 25 million individuals in the United States and imposes for many a burden of frequent respiratory symptoms and risk of asthmatic exacerbations. While research suggests that asthma is controllable if treatment is adjusted based on frequent monitoring of patients’ symptoms, such intensive symptom monitoring does not routinely happen. Previous research including 12 RCTs has involved complex interventions with multiple components, limited end user input, and inconsistent results. A recent review calls for better understanding of the contribution of intervention components. To begin to address these limitations, we developed a “minimum viable” asthma symptom monitoring smartphone application and clinical workflows needed to implement it in routine care. Our findings include preliminary critical components for implementing asthma symptom monitoring.

Methods

We combined principles of qualitative research, user-centered design, and “gamification” (i.e. game design elements) to iteratively understand user needs, develop and refine key use cases, develop prototypes, and create a fully-functional app and clinical workflows. We conducted 19 individual interviews or design sessions with patients (n=9, ages 21-74, 6 female, 2 African Americans, 1 Latino, 2 low-income, 2 section-8 housing residents) and clinicians (5 physicians, 2 nurses) practicing at an academic medical center. All patients were daily smartphone users. We conducted multiple design sessions with some patients.

Results

With only a modest sample of users, we achieved saturation of critical intervention components that met the stated needs of users, consistent with the goal of designing a “minimal viable” intervention. The intervention consists of 4 interrelated use cases:

1) Invitation. Patients are invited to use the app by their physicians, which is important for patient motivation.
2) Weekly symptom checks and notifications. Each week, patients receive a 5-item symptom questionnaire via the app. If symptoms are somewhat worse than the previous week or baseline, they are given the option to request a call from a nurse. For much worse symptoms, a request is sent automatically. If they complete several questionnaires consecutively, a smiley face icon appears, which is a surprisingly strong motivator for patients to use the app.
3) Patient review of symptoms. In the app, patients can view their self-reported symptoms in graphical format.
4) In-person visit. Physicians have access to their patients’ reported symptoms in the EHR for discussion during in-person visits.

Benefits to patients may include: helping decide when to call their provider; facilitating discussion and shared decision making; and reducing hospitalizations. Their only burden is the 5-item weekly questionnaire. Benefits to providers may include saving time discussing symptoms, and improved satisfaction. Provider organizations may need to pay nurses extra, but those costs may be offset by reduced visits and hospitalizations (in accountable care).

Discussion

Novel tools and clinical workflows will be necessary for providers to sustainably implement clinical guidelines and succeed under alternate risk-based payment methods. Combining qualitative and user-centered design methods to develop a minimum viable intervention can reveal critical components.

Conclusion

With a modest sample, we achieved saturation of user requirements and design for a minimal mHealth intervention that would facilitate asthma symptom monitoring between visits. Pilot testing is needed to further assess feasibility and impact. Such tools may be necessary for providers to succeed under emerging value-based payment models and may have a secondary benefit of producing large volumes of reliable patient-reported outcome data for research. [This work was supported by the Agency for Healthcare Research and Quality grant #1R21HS023960.]
Rationale and Design for the Duke Connected Care Predictive Modeling Pilot with a Medicare Shared Savings Program Population

Shelley A. Rusincovitch1, Ricardo Henao, PhD2, Michael Gao3, Lawrence Carin, PhD2, Ursula Rogers1,4, N. Benjamin Neely, MS5, Mary Schilder, MA4, Daniel Costello, MPA6, Eugenie Komives, MD6, Erich S. Huang, MD, PhD5,6

1Duke Clinical and Translational Science Institute, Durham, NC; 2Duke University, Durham, NC; 3Duke Institute for Health Innovation, Durham, NC; 4Duke Health Technology Solutions, Durham, NC; 5Duke Office of Research Informatics, Durham, NC; 6Duke Connected Care, Durham, NC; 7Duke Department of Biostatistics and Bioinformatics, Durham, NC

Introduction
Predictive modeling offers the opportunity to assess, manage, and intervene on risk in Accountable Care Organizations (ACOs)1-2. Although the deployment of machine learning and other predictive modeling tools has become well-established in many industries, these methods have only recently become more common in healthcare settings.

In this abstract, we discuss the rationale and design for a machine learning pilot undertaken by Duke Connected Care, an ACO participating in the Medicare Shared Savings Program (MSSP)3, in conjunction with a data science team of informaticists and machine learning experts. The result of the pilot is expected to be twofold: (1) development of a clinically-informed and actionable predictive model that can be assessed for potential implementation within Duke Health, (2) synthesis of experiences arising from an ACO’s engagement and collaboration with machine learning expertise.

Methods
The pilot targets inpatient admissions, complimenting earlier work by Duke Connected Care (DCC) in predicting the risk of readmissions. Predicting this initial hospitalization is broadly applicable to the MSSP population, and yields opportunities for intervention and prevention with the goal of achieving higher quality of care with lower cost.

This operational project is undertaken for patient care and its operational scope is carefully framed within appropriate data use parameters. The computational environment that we developed for the pilot is governed by mechanisms that include an honest broker function to manage secure transport of datasets, individual user agreements, and processes for access control and permissions. Links to external knowledge bases include application program interface (API) calls to the National Library of Medicine RxNorm database4. API calls never involve protected health information nor other patient attributes.

One of the key criteria used to assess the output of the machine learning model is actionability. Both the quantitative team and the larger cross-disciplinary stakeholder group will evaluate the ability of machine learning to identify predictive factors that contribute to higher risk of admissions, particularly those that care coordinators and providers can act upon to mitigate risk.

Results
Our machine learning methodology has foundations in earlier work with Electronic Health Record (EHR) data and is an extension of Deep Poisson Factor Analysis5. We have applied these methods to a new data source: claims data for the MSSP population served by Duke Connected Care. These data are provided by the Centers for Medicare & Medicare Services (CMS) in the ACO Operational System (ACO-OS) Claim and Claim Line Feed (CCLF) file format. These data are transactional and differ notably from the typical structure of research data files available through the CMS Research Data Assistance Center (ResDAC). The ACO-OS CCLF files are received monthly, and the population included in these files varies over time based on complex inclusion criteria and attribution.

A key component for the design of the pilot has been domain modeling to describe the source data and generating high-level concepts applicable across both claims and EHR data sources.

¹ Aggregated using the HCUP Clinical Classifications Software, a common-used schema that is used here to aggregate the individual ICD-9 and ICD-10 encounter-based codes into more meaningful, higher-level categories.

² The National Library of Medicine (NLM) RxNorm medication normalization naming platform is part of the open-source, publicly available Unified Medical Language System® (UMLS®). Here, the original NDC codes for each ingredient are mapped against RxNorm to retrieve the medication’s active ingredient and class listing from RxNorm.

Discussion
We anticipate that the organizing principles of performance and pragmatism will strongly influence our models’ eventual adoption and operationalization. One design consideration is evaluating the tradeoffs in timeliness and accuracy between modeling based on ACO claims versus EHR data, versus the combination of the two. Our current work has been based on Medicare claims data; as a next phase, we plan to combine these claims data with EHR data for the same patient population, and leverage supplemental data sources including geospatial data associated with patient addresses and other auxiliary sources.

Challenges for the pilot have included acquiring and deploying computational resources sufficient to support the high-performance data science within a typical enterprise IT environment, and the effort to assess the claims data structuring and nuances, especially attributes and concepts specific to the MSSP.

ACOs can help health systems achieve better outcomes by efficiently identifying and reducing health risks across populations, and we expect that the pilot model will more quickly and accurately identify high-risk individuals. This improved identification will create efficiency by shifting effort from risk assessment to actual care intervention and patient engagement.

Introduction

In the US, 37% of adults lack the health literacy needed to navigate the healthcare system.¹ Moreover, there exists a negative correlation between health literacy and age.¹ In other words, older adults, who are the largest demographic group interacting with the healthcare system, are often the least qualified. With low levels of health literacy resulting in worse health outcomes,² we find it necessary to reduce the gap between the health literacy of patients and the health literacy demands of the US healthcare system.

High literacy demands of the US healthcare system are due in part to the providers’ complicated usage of language. EHR systems normalize providers’ language through drop-down menus, with the provision to use free text when needed. The nature of the text occurring in the free text tends to be complex from a layperson’s standpoint for multiple reasons. One reason is abbreviations such as the term “RA”, which can stand for “Rheumatoid Arthritis”. Another reason is professional terms originating from Latin such as “prn” (pro re nata), which means “as required”. Also, professional terms such as “prophylaxis”, which means “prevention”, introduce complexity to the providers’ language. Not only do abbreviations increase the complexity of the used language, they also introduce ambiguity. For example, the abbreviation “RA” could mean “Rheumatoid Arthritis” or “Refractory Anemia” among other possibilities depending on the context it appears in. Borrowing from the field of Machine Translation (MT), we propose an automated system, which, to the best of our knowledge, is the first of its kind. By means of a unified framework, our system is designed to tackle both issues (complexity and ambiguity). It translates the multiple types of complicated terms to their simpler counterparts, so that patients with low health literacy can better understand their health information.

Method

Our system is best described as a 4-stage pipeline. The system is further illustrated in Figure 1.

1. Identifying complicated terms: We first identify the complicated terms in the sentence. Assuming complicated terms are infrequently used by laypeople, we consider all words but the 10000 most frequent words as complicated, after collecting frequencies on a corpus (GoogleNews) intended for laypeople. The low threshold ensures that all complicated terms are identified (high recall).

2. Generating candidate translations for complicated terms: Then, for each complicated term, we generate multiple surface forms using the Unified Medical Language System (UMLS).³ All atoms of the first 2 retrieved concepts using the UMLS search feature are considered candidate translations.

3. Generating all candidate sentence translations: Then, we generate all sentences corresponding to all combinations of translations.

4. Scoring candidate sentences: Finally, we score all candidate sentences using a 5-gram language model⁴ trained on a corpus (Gigaword) of texts geared towards the general public. The system outputs the sentence with the highest score. The language model ensures patient friendliness (comprehensibility) and accuracy of the output.

Results

We validate our method by comparing against 3 simpler but strong baseline automatic approaches evaluated for two output criteria: comprehensibility and accuracy. The first baseline takes a dictionary (Dict) approach by utilizing UMLS built-in search feature and the “preferred name” annotation to generate the translation of a word deterministically. This baseline replaces a complicated term by the “preferred name” of the first concept returned by the UMLS database when queried using the complicated term. The second baseline differs from our system in only the fourth stage where it chooses the candidate sentence with the maximum average word frequency (MaxFreq), with frequencies derived from a general domain corpus. The third baseline differs from our system only in the second
stage, whereby instead of the UMLS database, it utilizes state-of-the-art algorithms in NLP to map words into a vector space. Words with the same meaning will be closeby in the vector space. This third baseline generates translations by retrieving the 20 closest words in a vector space created using a word embeddings algorithm (WE).

To evaluate the 4 systems, we collect 150 sample medication instructions intended for patients from an EHR dataset. For each sample instruction, we generate the output of each of the 4 systems and evaluate comparatively. To evaluate accuracy, two physicians independently ranked (87.96% agreement level) all four outputs (anonymized) in terms of accurately depicting the provider’s intent. Our system outperformed the baselines with margins (number of times ranked higher - number of times ranked lower) of 62%, 50%, and 23% against Dict, MaxFreq, and WE respectively. Moreover, in 81% of the instances, our system precisely depicted the provider’s intent. As for evaluating comprehensibility, 4 laypeople (88.46% agreement level) ranked the input against our system (after anonymization). In 20% of the instances, our system increased comprehensibility, reduced it in 12% of the instances, and maintained it in the rest. Hence, results show that this is a promising direction towards simplifying medication instructions while also maintaining provider’s intent. Some ways in which we are addressing the equivocal results of our system in bringing about improved comprehension of medication instruction are mentioned in the Discussion section.

Discussion

We have presented an MT framework for simplifying providers’ medication instructions in EHR. This framework is expected to lower the health literacy requirements for patients in the US, and thus optimize provider-patient communication, enhance health outcomes, and reduce health costs. The performance gains over Dict and MaxFreq emphasize the significance of a language model and the MT framework of our system, whereas those over WE emphasize the benefits of using UMLS to generate our simple translation model. Ongoing experiments include, enhancements to the current MT framework through extending our translation model (unequal distribution of translation probabilities based on ranking in UMLS search results), improving the language model (collecting and training on a medicine-related corpus), and extending the decoding process (phrase-based instead of word-based). Moreover, current projects include speech extensions to Dr. Babel Fish making it an interactive medical Conversational Agent.

DeepPhe - A Natural Language Processing System for Extracting Cancer Phenotypes from Clinical Records

Guergana Savova 1,2, PhD, Eugene Tseytlin 3, MS, Sean Finan 1, MS, Melissa Castine 3, Tim Miller 1,2, PhD, Olga Medvedeva 3, David Harris 1, Harry Hochheiser 3, PhD, Chen Lin 1, MS, Girish Chavan 3, MS, Rebecca Jacobson 3,4, MD, MS
1Boston Children’s Hospital, Boston, MA; 2Harvard Medical School, Boston, MA; 3University of Pittsburgh Department of Biomedical Informatics, Pittsburgh, PA; 4University of Pittsburgh Cancer Institute, Pittsburgh, PA

Introduction: In this manuscript, we describe a novel double-pipeline system for extracting rich cancer phenotypes from sets of EMR documents, combining approaches of information extraction and summarization. We demonstrate the accuracy of the system in extracting key variables as measured against a human-annotated gold standard. Our work differs from previous efforts in that we move beyond entity mention recognition to episode- and patient-levels over the entire set of patient’s records (pathology, oncology, radiology notes etc.), and longitudinally from primary tumor to regional recurrence or metastasis. These tasks require sophisticated extraction techniques such as coreference resolution, relation extraction and temporal relation extraction to achieve reliable summarization. Our work also differs by generating a patient-level summarization across multiple documents and genres, informed by existing cancer phenotype rules and definitions. Project website: http://deepphe.healthnlp.org.

Methods: The DeepPhe system ingests multiple different clinical documents and optionally also discrete data, and outputs a single summary of the patient’s clinical phenotype. The system uses a novel double-pipeline design, combining a mention-annotation pipeline or pipeline 1 (an extension of cTAKES© (1); ctales.apache.org) a phenotype summarization pipeline or pipeline 2 and the DeepPhe domain ontology (2). The methods in each module range from pattern-matching to modern machine learning to knowledge engineering methods and are a result of our research efforts in the field of natural language processing. The system utilizes the engineering framework of Apache Unstructured Information Management Architecture (UIMA; uima.apache.org). A high level visualization of the system is shown in Fig. 1.

Fig 1: DeepPhe system architecture. Abbreviations/acronyms: cTAKES – Apache Clinical Text Analysis and Knowledge Extraction System; NLP – natural language processing; UIMA – Apache Unstructured Information Management Architecture; FHIR – fast health interoperability resources; Neo4J – graph database for visualization; tranSMART – phenotype-genotype analysis platform; http://transmartfoundation.org; DROOLS – rule-based inference engine; PLAY – application framework on which the visualization is built.

Results: Results are in Table 1 and 2. In addition, the performance of the coreference module is MUC 0.53, B3 0.47, CEAF 0.54 and CoNLL 0.53. MUC computes recall by counting the number of inter-cluster links in the gold that are found by the system. Precision is computed by reversing the gold and system outputs. B3 computes precision and recall scores for each mention, as the number of correct elements in the chain containing that mention, divided by the number of elements in the system chain or gold chain, respectively. CEAF computes an optimal alignment between the reference and gold mention sets, and compares that alignment to an alignment of gold outputs to itself (for recall) and system output to itself (for precision). The CoNLL score averages the F1 of those three metrics.
Table 1: Pipeline 1 evaluation results (mention-level). Numbers in brackets are inter-annotator agreement. BrCa - breast cancer; n/a – attribute not applicable

Table 2: Pipeline 2 evaluation results (Phenotype-level) for Cancer summary (A) and Tumor summary (B). Numbers in brackets are inter-annotator agreement. Summarization over 41 documents for two patients. cT – clinical tumor; cN – clinical lymph nodes involvement; cM – clinical metastasis; pT – pathology tumor; pN – pathology lymph node involvement; pM – pathology metastasis; n/a – no metric derived

Discussion: The initial evaluation of the system is quite promising. Results at both mention-level and phenotype-level approximate the IAA which is usually set as a system goal. Extraction of specific attributes in the phenotype pipeline are acceptable but require further refinement. Our study emphasizes even further the importance of research in key (albeit extremely challenging) areas of NLP and information extraction including word sense disambiguation, relation extraction (e.g. coreference, temporal and body location relations) as well as summarization. The DeepPhe software extends the existing state-of-the-art by providing a generalizable information extraction framework for cancer phenotypes. The development of platforms such as DeepPhe provide critical and missing infrastructure to serve the data-intensive needs of precision medicine and cancer surveillance. Future work will include (1) the development of a visualization interface to enable end-users to interact with the data, (2) the application of the system to other types of cancers, including melanoma, lung cancer, and ovarian neoplasms, (3) the expansion of extracted information to include clinical genomic observations, such as somatic variants (e.g. BRAF status), or gene rearrangements (e.g. EML4/ALK) and (4) inclusion of structured EMR data (e.g. synoptic pathology reports).

Novel Approaches to Identifying Rare Diseases Using Electronic Health Record data, Mabry Syndrome as an example

Prabhu R Shankar MD, MS1, Rachel Logan2, Allison Foley3, MS, Hong Li3 MD, PhD

1Dept. of Public Health Sciences, School of Medicine, UC Davis, Sacramento, CA
2 Emory Genetic Counseling Training Program and 3Division of Medical Genetics, Department of Human Genetics, School of Medicine, Emory University, Decatur, GA

Introduction: Rare diseases are uncommon individually, defined as affecting fewer than 200,000 people or 1 in 1,500 in USA (1 in 2000 in Europe). Collectively, however, these diseases affect millions of people worldwide. They can be chronic and debilitating and negatively impact the lifespan of affected individuals. When therapies are available reasonably good quality of life can be achieved, particularly with early diagnosis and intervention. The advent of Next-Generation Sequencing (NGS) has changed the landscape of rare genetic disease diagnosis and research. Advances in NGS, such as Whole Exome Sequencing (WES) and Whole Genome Sequencing (WGS) witnessed a rapid growth in identification of causative genes for rare diseases. By 2012, more than 180 novel genes had been identified by WES1 and new ones are continuously being added. This has spurred interest among genetics researchers to recruit and study patients and families with rare diseases. However, Identification of rare diseases is a challenge as many rare diseases are not recognized during routine patient care and consequently are not documented. Some of the reasons for missing rare diseases include nonspecific presentation during childhood, poorly defined or evolving case definitions, or lack of disease awareness among healthcare professionals. Further, the disease classification and coding systems that are currently used for documenting, reporting and billing purposes, are not granular enough to capture many rare diseases. All of these issues make it difficult to establish search strategies to define patient cohorts using current informatics tools on stored EHR data. Novel methods need to be developed to identify patients with rare diseases utilizing the rich clinical data that has accumulated over the past decade as part of increased implementation of EHRs. We define a new method using Mabry syndrome, a rare disease, as an example.

Mabry syndrome, also called Hyperphosphatasia with Mental Retardation Syndrome (HPMRS), is a group of inherited disorders caused by mutations in genes involved in the Glycosyl Phosphatidylinositol anchor (GPI) pathway. Clinical presentations are variable, but predominantly manifest with developmental delay, intellectual disability or seizure. A unique biomarker of the syndrome is consistently elevated Alkaline Phosphatase (ALP) levels. Diagnosis is often missed and under diagnosed due to 1) variable and non-specific clinical presentation 2) lack of knowledge about the unique chemical biomarker ALP 3) often misinterpret the elevated ALP level to a common effect of growing bone or liver dysfunction without further confirmation 4) genetically heterogeneous nature of Mabry with at least 8 genes being newly identified as disease-associated, and are not part of the currently available commercial seizure/epilepsy/intellectual disability gene testing panels2. A unifying genetic diagnosis of Mabry syndrome can provide family with prognostic information and precise risk assessment for family planning. Some individuals may benefit from a high-dose vitamin B6 treatment for seizures.

Methods: This is a retrospective study conducted using stored EHR data in a tertiary care children’s hospital. After appropriate IRB approval and following standard operating procedures, data Warehouse and data mart was queried from 2012 – 2015 for all patients who had an alkaline phosphatase levels more than 500 international units per liter (IU/L). For each of the patients, demographics, all the associated diagnoses, clinics visited, and relevant other investigations were extracted. Protocol was developed by the genetics study team for phenotypic definition of patients with Mabry Syndrome. Data was analyzed based on consistent elevation of alkaline phosphatase levels and refined iteratively based on associated neurological clinical features, such as intellectual disabilities, seizures and developmental delay, to arrive at a list of most probable patients with Mabry Syndrome. Premature babies, patients with bone/ liver diseases, cancers and medications that may elevate ALP and patients with organ transplants were excluded. Further, chart review of the refined list of patients was done by clinical research team to identify possible Mabry syndrome patients that met the clinical phenotypic definition, for further genetic studies.

Results: There were 2,823 patients with ALP levels at more than 500 IU/L seen at the Children’s Hospital during 2012 – 2015. After excluding patients with known hepatic or bone disease, extreme prematurity, cancer and recipients of organ transplant, and filtering out those who did not have any neurological presentations, 126 (4.4%) patients were left in the list. Further filtering with objective evidence of having had a neurology visit/ consultation with clinical documentation, and persistent elevation of ALP levels, there were 24 (0.85%) patients that were ear marked for manual chart review. Twelve patients (0.42%) met the clinical case definition and were further
considered by genetic study team for thorough clinical evaluation, targeted genetic and functional studies. Currently 6 patients have been recruited and biochemical, genetic and other tests have been conducted. Results will be presented and discussed.

**Discussion:** We describe a new method to identify patients with rare diseases using stored electronic clinical data, collected as part of routine patient care, adding to the growing list of secondary use of EHR data. Here we use sustained elevation of ALP levels, a unique biomarker for Mabry syndrome, along with major Mabry phenotypes (some represented with ICD codes) as part of an algorithm to process EHR data to zero in on patients that match the clinical Mabry syndrome case definition. As mentioned above, the traditional informatics tools to search for certain rare diseases, such as using structured diagnosis codes (ICD and SNOMED) and NLP to search clinical narrative free text data for any mention of the disease, may not yield results as those rare diseases might not have been captured in the clinical notes. This is because the diagnosis was missed due to lack of awareness about the rare disease or inadequacies of diagnosis coding system. A combination of biomarkers and clinical phenotypes could be used to develop algorithms to find patients that match rare disease case definitions. There is significant information content embedded in coded structured data such as diagnosis, laboratory, medications, procedures and specialty care clinic visits (ICD, SNOMED, LOINC, RXNORM, CPT, HCPCS, customized local EHR codes), that could be leveraged using data mining tools to match the case definitions of rare diseases. Additional phenotype features of the rare disease that are embedded as free text in the clinical notes may be amenable to NLP and could be added to the search criteria to streamline the data mining methods. Manual chart review is required to validate the disease descriptions that may match the rare disease case definition. Further, along with identifying potential rare disease patients that met the case definitions of the study protocol, patients with overlapping phenotypes that may be caused by defects in the genes that are part of the same metabolic pathway may also be discovered. For example, our refined list may have patients with Multiple Congenital Anomalies Hypotonia Seizures Syndrome (MCAHS) with defects in the genes encoding for Phosphatidylinositol-Glycan (PIG) proteins which are part of the Glycosyl-Phosphatidylinositol (GPI)-anchor biosynthesis pathway shared by both Mabry syndrome and MCAHS. The ability to identify patients with Mabry syndrome or other GPI-anchor defect diseases will allow us to conduct functional studies and investigate for further diagnostic biomarkers and disease pathway associations in the future.

The shortcoming of this method is that some patients that may have milder versions of the disease with less severe symptoms and signs that are compatible with normal life may not have been seen or investigated and documented by clinicians. Invariably, a certain proportion of the patient population may be missed with difficulty in estimating accurate incidence and prevalence. Additionally, not all rare diseases may have unique biomarkers to help identify them from other rare diseases that share phenotypic features. However, the same set of phenotypic features that are used to clinically define and differentiate a disease/syndrome from others could be used to carefully design algorithms, using a combination of structured and unstructured clinical data that may still yield foot prints of a particular disease. Thus, similar methods could be developed for other rare diseases. Alert systems could be set up in EHRs for prospective patient identification using methods and algorithms defined in this project.

Other approaches such as exome or genome analysis of all patients will likely be the way of the future for accurately identifying and diagnosing patients with rare diseases. Currently, the price for NGS (exome or genome analysis) is expensive and most of the insurance providers do not cover for untargeted next generation sequencing in clinical practice. Further, NGS are valuable for instances when a “pathogenic variant” as recommended by the ACMG guidelines is identified. However, NGS may result in many “Variants of Uncertain Significance” (VOUS) that will need functional analysis and supportive data to substantiate the pathogenicity of a VOUS to establish a definitive diagnosis. In addition, as an unintended consequence, NGS may identify pathogenic variants that cause other secondary conditions including adult onset neurodegenerative disorders as well as cancer. These possibilities with NGS need to be discussed with family members; will require extensive counseling and the genomic findings may have significant impact on the extended family. For these reasons, targeted NGS on phenotypically characterized patients is the current approach, at least till clinical utility of NGS in rare diseases is further established.

Introduction

Adolescence is a time when patients are approaching autonomy, both developmentally and legally. Yet they are still minors and are likely to encounter contradictions between situations in which they are treated as children and ones in which they are treated as adults. Being able to access their medical information may enable adolescents to take on a participatory role in their health care. However, federal policy, state law, and community norms are not consistent regarding adolescent healthcare and privacy. For example, in some regions and under some circumstances, adolescents may have consent and privacy rights similar to those of adults, with the right to make some, or all, of their own sensitive medical decisions privately. In other cases, parental notification is the norm, or guidance is unclear or lacking. In the absence of national guidelines, medical centers encounter serious challenges when developing policies about adolescent access to medical records via patient portals. The American Academy of Pediatrics has made recommendations, but these are not binding.

To explore diversity in adolescent privacy policies and identify common approaches, we are conducting a qualitative study with key informants from different types of medical organizations in different regions of the country. The main objective is to identify diversity in adolescent privacy features within the patient portal. Another objective is to enumerate the factors involved in making portal access decisions. A third objective is to identify the potential need for more formalized guidance and standards on privacy features within the patient portal.

Methods

We are conducting semi-structured interviews with chief medical information officers and other key informants involved in informatics operations. Purposive and snowball sampling is being conducted to identify representatives from medical organizations across the four census regions of the country and multiple organizational types (pediatric hospital, community health center, non-pediatric academic medical center, outpatient practice, public hospital, etc.). The semi-structured interview guide was developed with reference to a 2012 policy statement from the American Academy of Pediatrics (AAP) on ideal principles for the electronic health systems. The minimum sample size is 25, with representation of the four census regions of the country. However, in accordance with qualitative research best practices, we are conducting sampling and thematic analysis in tandem, and will adjust the target sample size upward if thematic saturation is not reached. This study was approved as minimal risk by the Weill Cornell IRB and determined to be exempt by the Georgia Tech IRB.

Results

To date, we have interviewed representatives from 26 medical centers, representing all four census regions of the United States. The most striking finding is the extreme variation in the policies regarding adolescent patient portal privacy. One policy type prohibits portal access completely during adolescence for both adolescents and parents. A second type of policy defaults to access for the adolescent only, with the parent losing access. In some of these, parents could be granted proxy access again, but the proxy rights ranged from complete access to highly limited access (for example, parents might be barred from viewing the record but be able to message with the clinician). Among those with adolescent access, the minimum age ranged from 10 to 14. However, many of the centers did not fit into either of these two policy types. For example, one granted default access for both the parent and the adolescent, and one gave default access for the parent of the young adolescent only until age 16, at which time there was no further access for anyone until 18.

Informants cited many different factors that went into the decision making of adolescent portal access. This study organized these decision-making factors into 8 underlying themes: (1) compliance with state and federal laws, (2) EHR capabilities, (3) accommodation of different types of patient needs, (4) prioritization and availability of resources, (5) insurance of patient safety/care quality and risk aversion, (6) balance of patient

Marianne Sharko, MD, Lauren Wilcox, PhD, Matthew K Hong, MS, Jessica S Ancker, MPH, PhD

1. Department of Healthcare Policy & Research, Division of Health Informatics, Weill Cornell Medical College, New York NY USA
2. School of Interactive Computing, Georgia Institute of Technology, Atlanta, GA USA
autonomy/empowerment and family shared decision making, (7) community expectations, and (8) tension between
teen privacy and parental preferences.

Our interviews helped highlight possible sources of assistance when making portal access decisions. Of
those surveyed, most agreed that guidelines would be helpful. One informant felt that guidelines would be
particularly helpful in complicated situations; such as patients in foster care or with limited mental capacity.
However, there were differing opinions on the form of those guidelines. Multiple informants suggested that policy
could be created with input from medical organizations, physicians, nurses, patient and parent representatives,
informaticians, legal experts, EHR vendor representatives, and administration.

One informant felt that federal guidelines would be essential in the age of health information exchange
when an adolescent’s health information is transferred electronically from one state to the next. However, there
was some concern that federal guidelines would force harmful changes to a current policy, which emphasized adolescent
privacy over parental access. Another informant felt limited by state law and thought that federal guidelines would
enable them to expand their policy to grant adolescents more control over their health information.

Our study identified other potential sources of assistance for medical centers. There is a need for more tech
innovations, such as increased granular control of portal information, flexibility of control over the information in
the portal, clearer identification of sensitive medical information, and a guarantee of privacy control. Another
informant addressed the need for more research-based evidence to evaluate the importance of adolescent portal
access. Importantly, there was also a call for more outreach and education to the general public on the importance of
these issues when understanding parental and adolescent portal access.

Discussion

The increased use of the EHR has great implications for the adolescent patient\textsuperscript{4}, with opportunities for
improved access to the medical provider and to the patient’s own medical information, thereby encouraging patient
autonomy. Multiple studies have found that privacy and confidentiality are vital to adolescent openness with their
physicians as well as adherence to care.\textsuperscript{3} There have been several policy statements regarding adolescent
confidentiality and privacy in the electronic health record. The AAP released a policy statement in 2012\textsuperscript{3} stating that
current health information systems lack the capability to allow for protection of the privacy and security of health
information for minors. The Society for Adolescent Health and Medicine stated in a position paper in 2014 that
“Protecting adolescent confidentiality is a shared responsibility and requires ongoing vigilance.”\textsuperscript{6}

However, there are many different issues that factor into a medical center’s decision on how to balance the
tension between patient autonomy and family shared decision making. Determining the best way to handle
adolescent patient portal access is challenging and involves the consideration of many issues. Therefore, it is not
surprising that there is striking variation in the way adolescent portal access is handled across the country.

Our study identified potential sources of assistance in this process, including improved education and
outreach, more evidence-based research evaluating adolescent portal access, and tech innovations providing more
granular control. Clearer guidelines could be helpful, and could result in more consistent approaches to portal
access. However, it is yet unclear who should determine these guidelines and how they should be implemented.

Acknowledgments: This study is supported in part by AHRQ K01 HS 021531 (PI: Ancker).

Assessing Usability of the D2Refine Platform for Harmonization and Standardization of Clinical Study Data Dictionaries

Deepak K. Sharma, MS, Kevin J. Peterson, MS, Guoqian Jiang, MD, PhD
Department of Health Sciences Research, Mayo Clinic, Rochester, MN

Introduction

D2Refine is a web-based platform developed for harmonization and standardization of clinical research study data elements. D2Refine extends OpenRefine (formerly Google Refine) and leverages its simple interface for representing data dictionaries. D2Refine introduces features of semantically binding study data elements to controlled terminology terms or common data elements. D2Refine enhances semantic interoperability of the clinical research study models, expressed by the data dictionaries, through their harmonization and serialization into standardized representation formats like Archetype Definition Language (ADL), Archetype Modeling Language (AML) or HL7 Fast Healthcare Interoperability Resources (FHIR) Profiles. We plan to assess the usability of the D2Refine features and it will help us understand user perceived usefulness of implemented, planned and desired functions and identify gaps. The objectives of this usability study is to not only quantitatively measure usability of D2Refine platform, but also as a tool to improve development efforts towards existing and planned D2Refine features.

Methods

TURF Usability Framework

The usability study is being designed and conducted using TURF EHR Usability Framework. The usability study includes four components of TURF Framework – Task, User, Representation and Function, to quantifiably assess how useful, usable and satisfying a system is. Task Analysis is to identify the steps (physical and mental) of carrying out operations by using a specific representation. It describes relationships and dependencies among various tasks. User Analysis identifies the users and characteristics of each type of users. Function Analysis is one of the most important components where knowledge of work domain is captured. Representing explicit and implementation-independent description of work domain is usually accomplished as work domain ontology. Representation Analysis is about figuring out the appropriate representation or interface to accomplish a given task efficiently.

Use Cases

D2Refine platform and similar tools should at least enable users to import data dictionaries, bind them and then export them into standardized formats. Based on these functionality requirements, we choose five use-cases of (1) import data dictionary, (2) configure the controlled terminologies for terms search including local terms, (3) search terms from selected code systems, (4) creating term bindings from the search result candidates and, then (5) export the standardized data dictionary to a standard format.

User and Function Analysis

D2Refine is designed for Clinical Study Developers and Clinical Element Modelers. Clinical Study Developers are the ones who would be creating new data dictionaries or editing existing ones to be used in designing new studies. The functionality is derived from the use cases and the steps involved in standardization of data dictionaries and translating them into standardized representations. The use cases require availability of terms from controlled terminologies, which users can configure through an interactive interface. The comparison with other solutions similar to D2Refine would help identify additional functions and hence augment the set of functions.

Task and Representation Analysis

Use cases guide the steps of the tasks to carry out the functions. We intend to articulate the tasks and their effect of the system by creating diagrams of state-transitions. The state-transition model will represent a particular state of the system at each step of a task. This will help us formalize and guide us to enumerate the user (or system) actions needed to accomplish a task in a given workflow. We augmented the domain ontology to represent the tasks.
Metrics

We choose two metrics of TURF Usability Framework to compute usefulness, calculated using Venn Diagrams of the domain model functions (see Figure 1), are:

1. **Within-Model Domain Function Saturation**: Ratio of domain functions in Designer Model to total functions in Designer Model. This is calculated as sum of numerators of the fractions in \( (A, D, E, \text{and } G) \) divided by sum of denominators of the fractions in \( (A, D, E, \text{and } G) \).

2. **Across-Model Domain Function Saturation**: Ratio of domain functions in Designer Model to domain functions in all three models (Designer, User and Activity). This is calculated as sum of numerators of the fractions in \( (A, D, E, \text{and } G) \) divided by the count of all domain functions.

Results and Discussion

The goal of the study is to gauge D2Refine’s effectiveness and usefulness using the TURF framework. We have developed the domain ontology for functions. The workflows and tasks are being added to this as we gear towards conducting the usability study. The first iteration of user analysis and the function analysis of D2Refine is completed - by capturing the functions and tasks in the Domain Ontology. A partial view of domain ontology\(^3\) [developed in RDF/OWL] representing the functional features of D2Refine is shown in Figure 2. The Usability study will compare D2Refine with few other platforms, e.g. OntoMaton\(^4\) and eleMap\(^5\), that provide similar functions and this would augment the domain ontology. The representation analysis of the study (in-progress) would evaluate how well D2Refine represents and aligns with user’s expectations. Using TURF’s Affordance ratings method, we plan to compare isomorphic representations (functionally equivalent) of tasks, which would help us identify gaps and value that D2Refine offers. Identified users would be invited to participate in the study and perform the tasks. The part of observations for each task would also be captured in domain ontology itself. We intend to compute and compare the metrics of usefulness for D2Refine leveraging RDF/OWL reasoning. This usability study would definitely guide us to evaluate our existing strategy and future development efforts.

Rule-Based Criteria for Recommending Algorithms and Visualization Techniques for Biomedical Data Analysis

Leslie Sim, Charlotte Cheng, Ajay Shah PhD, Srisairam Achuthan PhD

Research Informatics and Systems Division, Center for Informatics and Data Science, Beckman Research Institute, City of Hope, CA

Abstract

Data visualization and machine learning are increasing being adopted to analyze biomedical datasets in translational research. With the goal of guiding a researcher to relevant visualization methods and learning models, we have developed SPIRIT-SA, a comprehensive scientific analytics platform. Rule-based criteria derived from data provide visualization techniques and machine learning algorithms recommendations to a user enabling seamless biomedical data analysis.

Background and Introduction

Machine learning and data visualization are increasing being adopted to analyze biomedical datasets in translational research with applications spanning from disease diagnosis to hospital readmission rate prediction. With different types of datasets being utilized in a variety of biomedical applications and a number of visualization techniques and machine learning algorithms in literature, it can often be difficult to decide the best methods to analyze the data in order to yield interesting, actionable, and predictive results. With the goal of guiding a researcher to relevant visualization methods and learning models, we have developed a rule-based criteria derived from data that provide visualization techniques and machine learning algorithms recommendations to a user enabling seamless biomedical data analysis.

Rules derived from data such as data size, number of features, visualization context and machine learning task at hand can be useful to develop a recommendation system to select relevant visualization methods and machine learning models. Each machine learning algorithm has certain strengths and weaknesses which may be suitable for particular datasets, and thus, correctly selected machine learning algorithms can make analysis of datasets more useful. Visualization techniques differ depending on the type of data being analyzed as well as visualization task at hand. Therefore, utilizing the appropriate visualization technique depending on the data context is of utmost importance.

Methods

We have developed SPIRIT–SA, a comprehensive scientific analytics platform, as part of SPIRIT (Software Platform for Integrated Research Information and Transformation) to provide a rule-driven approach to simplify the data visualization method as well as the machine learning model selection problems. Pipeline Pilot⁴, a commercial data pipelining and scientific informatics platform with a large collection of components available for analyzing biomedical datasets is the underlying framework for our scientific analytics platform, SPIRIT–SA. Raw biomedical data sets such as those from a public source like UCI Machine Learning repository [1-2] can contain errors, missing data or outliers. Standard missing data imputation methods and Open Refine [3] are used for data clean up. An initial visualization of the processed data is made available using Orange [5]. This is followed by a summary of the data. One can either select a subset or all of the features to analyze the data. Visualization and machine learning algorithm selection rules are then applied. These rules are derived based on the data size, data visualization purpose, number of features to be analyzed, machine learning task and data properties. Visualization methods falling under categories such as: V1) Distribution, V2) Relationships, V3) Hierarchy, V4) Composition, V5) Geographic, V6) High Dimensional, V7) Time and V8) Comparison are used for selecting appropriate visualization techniques. Rules such as: M1) More than 50 samples present or not, M2) Labeled data present or not, M3) Predicting a categorical variable or not, M4) Accuracy is important or not are used for recommending appropriate machine learning algorithms. The rules we have mentioned here are a snippet of about a number of rules we have implemented in SPIRIT–SA. Finally,
a summary of all the results are captured with metrics numerically and graphically. Both, the visualization techniques as well as the machine learning algorithm rule based recommendations have been built using VisiRule [6]. The techniques and algorithms were implemented using Orange, Pipeline Pilot, Tableau, R and Matlab.

Results
As a proof of concept, we demonstrate our approach using two different biomedical datasets from the UCI Machine Learning Repository [1-2]. Additional illustrations related to bioinformatics datasets will be discussed. Dataset 1 (961 instances with 5 features) is used to predict the severity (outcome - binary response) of a mammographic mass in a patient. After pre-processing the data and selecting features of interest, histograms and box-plots available to us under visualization rule V1 can be selected to visualize the selected features across the two cohorts. Applying rules M1-M4 for this dataset we recommend that neural network, random forest and decision tree algorithms be used for the supervised learning task. Initial analysis of the prediction accuracy indicates that both neural network and decision tree models have the highest accuracy. The parameters of the random forest model had to be optimized to obtain better performance. Dataset 2 (345 instances and 6 features) is used to cluster male patients likely to develop liver disorder. After pre-processing the data and selecting all features, scatter plot matrix available under visualization rule V6 can be used to visualize the multi-dimensional dataset. Rules M1: More than 50 samples present. M2: Labeled data present, M3: Number of clusters known for this dataset leads us to recommend PAM (Partitioning Around Medoids), K-Means and Fanny clustering algorithms.

Conclusions
SPIRIT-SA can be a powerful end-to-end scientific analytics platform that has been developed to provide a seamless user experience for analyzing biomedical datasets. Key features that highlight the utility of this platform are the rules based approach for selecting visualization techniques and machine learning algorithms appropriate for a given dataset. A guided approach to choosing visualization methods and machine learning models make the tasks of prediction and trend analysis when analyzing data as seamless as possible for a user. The machine learning algorithm rules help a user determine which algorithms to implement on their dataset, whether to use machine learning, and when certain types of algorithms are most suitable. SPIRIT-SA will immensely help multiple translational research projects.

Learning Objective
After participating in this session, the learner should be better able to:

- Gain better insight to processing raw data.
- Selecting appropriate technique to visualize a given dataset.
- Choosing machine learning models to recommend for analyzing a given dataset.

Keywords
- Machine Learning, Data Processing, Data Visualization, Data Analysis Pipelines.
Personal Health Information Management in the Virtual Home: 
A New Taxonomy for a New Perspective

Catherine Arnott Smith, AMLS, MA, MSIS, PhD\textsuperscript{1}; Yuqi He, MLIS\textsuperscript{1}; Gail Casper, RN, PhD\textsuperscript{1}

\textsuperscript{1}University of Wisconsin-Madison, Wisconsin, USA

Introduction: Patient work “is situated in the larger context of life”\textsuperscript{1} and the home is where the majority of patient work occurs. Most studies of patient self-management focus solely on behavior, not on the tools used or the context in which the behaviors occur. There is evidence that individuals are more comfortable in familiar environments (e.g., one’s home) and as a result will perform tasks in a different way\textsuperscript{2}. To understand patient behavior holistically, outside of the clinic, independent of treatment, we must understand the spaces in which people live and perform their health-work.

Methods: This study utilized data from the vizHOME Project (AHRQ R01HS022548), the goal of which is to understand the impact of the home environment on Personal Health Information Management (PHIM). The vizHOME project defines PHIM as a broad range of behaviors including seeking health information on the web, applying information in decision-making, developing a system to remember appointments, being reminded by an object (a cue or reminder) to do something, and self-monitoring or self-tracking. The vizHOME team used advanced visualization tools (see 3) to create perfect 3D models of the interiors of 20 real houses representing four types of homes as characterized in the U.S. Census: detached, semi-detached, multi-unit and mobile (or manufactured) homes (https://www.eia.gov/emeu/efficiency/recs_2_table.htm). These homes had not been modified to accommodate any chronic illness or disability; participants were asked not to change or “prepare” their homes for scanning visits. These scans generated a reference set of 20 virtual households. By study design, in-depth interviews of household occupants were explicitly focused on information-intensive tasks representing medication management, self-monitoring, and general information management tasks - all real-life tasks deemed important by the participant. These interviews resulted in a catalog of personal health information management (PHIM) tasks performed in each of the 20 houses\textsuperscript{3}.

In the second phase of the study, six researchers with expertise in informatics, industrial engineering and nursing performed home assessments in 16 of the virtual homes—four of each U.S. census type-- in a six-sided immersive CAVE automatic virtual environment. Each house was viewed three times resulting in a total of 47 individual assessments (one assessment was discarded due to a CAVE malfunction). Each individual researcher identified items in each home that would be useful for PHIM; these items were captured electronically and by a note-taker. They resulted in a cumulative list of features, that is, both objects and spaces, further refined and normalized by consensus. Thus, a key product of this work is a taxonomy enumerating 71 PHIM-supporting “features” – including both objects and spaces - in the interior household environment.

The third phase of the vizHOME project enabled us to test the taxonomy we developed. Twenty lay people who had been told they have diabetes each performed two virtual home assessments. This resulted in a total of 40 individual assessments. The lay participants selected a total of 54 PHIM features, of which 51 matched the features selected by the experts, and three that were not chosen by the researchers: the bed, bathtub and glucometer. The original list of 71 features important to PHIM in the home forms the corpus upon which our taxonomy was built. These features range from things that are obviously healthcare-related – a pill organizer, reminder cards – as well the less obvious – a backpack (described by one professional as a tool used to carry diabetes supplies in the house) and whiteboard (used to record and share health information).

Our taxonomy is based on the Art and Architecture Thesaurus (AAT), a reference source for thesaurus builders used in different fields to facilitate classification and information retrieval. The AAT’s descriptors are drawn from hundreds of sources in the fine and applied arts.

Results: Sixty-one (86%) of the vizHOME household features were present as concepts in the AAT, either as exact matches or modified matches. Ten (14%) features are exclusively associated with healthcare activities. We found
that the ECRI Universal Medical Device Nomenclature System (UMDNS), a well-accepted source of vocabulary for describing home health equipment, was able to match all but 2 of those 10 features (see Table 1 below).

Table 1. Match results between vizHOME household features, AAT and UMDNS

| Step 1: Match results between vizHOME household features and AAT (Number = 71) |
|-----------------|-----------------|-----------------|
| Number | Percentage | Examples |
| Exact Match | 34 | 48% | Floor – Floors |
| Modifications | 27 | 38% | Backpack – Knapsacks; water dispenser - dispensers |
| No Match | 10 | 14% | Whiteboard; Inhaler; CPAP; TV and remote; |
| Total | 71 | 100% | |

| Step 2: Match results between AAT “no match” features and UMDNS (Number = 10) |
|-----------------|-----------------|
| Number | Percentage | Examples |
| Exact Match | 8 | 80% | Inhaler - inhaler; CPAP - CPAP; |
| No Match | 2 | 20% | Free weights; TV/ Remote |
| Total | 10 | 100% | |

Even in virtual worlds, space is an important dimension. Naming, and the sorting of names into meaningful categories, is how humans make semantic sense of those physical instantiations. We adopted AAT terminology to label our categories and sub-categories. Eight categories of the AAT hold the features in our vizHOME taxonomy: containers, furniture, storage spaces, architectural elements, information form, timepieces, equipment, and telecommunication. For the ninth category, we developed the category label “Durable Medical Equipment” to represent features such as CPAP and walker, terms not unsurprisingly missing from the AAT, but common terms used by third-party payers in the US healthcare system.

Discussion: To model health behaviors at home, a general taxonomy of household objects and spaces – as opposed to a purpose-built health taxonomy – is required. Existing knowledge representations of health-related objects and spaces, for example, the Unified Medical Language System (UMLS), focus on individual behavior, absent of context. For example, pillboxes are recognized by the UMLS, but only as an aspect of desirable behavior on the part of the patient: “Promoting medication adherence using pillbox” [C2364343]. Sofa is recognized only as part of the patient’s medical history, “exposure to sofa fire” [C2905436]; steps are something patients fall from [C0417023] and toilet is something a patient either does [C0562819] or does not [C0562820] use.

What makes a particular household feature “important” or “useful”, to domain experts no less than patients and members of their households, may be shaped by the interaction of the feature with its physical context. The feature’s location in space, the feature’s proximity to other features of the room, may be as important in personal health information management as the feature’s affordances. Our new taxonomy offers formal ways to characterize and understand both the virtual and actual home. This organized knowledge can give us insights on where home environment may influence health information management and behaviors. Ultimately, it may help inform the design and deployment of consumer-facing health information technologies due to its capacity for knowledge representation of home context.

Discordances between Patient-Reported Family History and Family Histories in EHR

Jung Hoon Son, MD\(^1\), Chunhua Weng, PhD\(^1\)

\(^1\)Columbia University Department of Biomedical Informatics, New York, NY, USA

Abstract

Reporting of data quality problems in family history data is difficult due to the complexity of family history data. Although statistical methods can be utilized to report data quality issues in family histories, visualization of the discordance between family histories documented in EHRs and patient-reported oncology family histories promises to be a more effective method and makes results more comprehensible.

Introduction

Family history information plays an important role in genomic medicine (1) and allows the calculation of risk for heritable conditions. Subsequently, efforts to supplant this traditionally clinician-curated data with patient-provided data has been gaining momentum (2). However, traditional measures of data quality are rather difficult to apply to family history data because of the heterogeneity and complexity of family history data (3). Statistical tools such as positive and negative agreement measurements (2) and kappa values may not convey the discrepancies intuitively; therefore, we aim to explore more informative ways to visualize the data quality of family history.

Methodology:

We obtained patient-reported surveys completed by patients with personal cancer histories from Columbia University Medical Center’s Data Base Shared Resources (DBSR) center, which maintains a repository of cancer-related clinical databases for our institution. The family history section elicited detailed extended positive and negative family history for diagnoses of various types of cancer. A manual chart review was conducted on 702 patients with the purpose of assessing data quality of the EHR data (Allscripts Touchworks) generated by primary care physicians and oncology specialists at large academic medical center, compared to the survey data. We assessed the documentation-completeness measure (4), counting the presence of data in the EHR that were semantically equivalent to the survey item response.

Results:

The survey data contained itemized family cancer history, consisting of each family member’s relationship to the patient, cancer type, living status, and age of cancer onset. A total of 5,970 family members were identified, with 1,038 family members reported to have current or past histories of cancer. EHR data were concordant on 536 of these family members. The top cancer types are shown in Figure 1. Positive (0.464) and negative agreements (0.989) of family history data were calculated as a reference. To further illustrate the discordance between the two data sets, the percentage of family members with a diagnosis of cancer was compared (Figure 2). In addition, we examined the discordance of first, second, and third degree relatives using the same plot, which is shown in Figure 3.

Conclusion:

Our findings show the patient-provided family history data from the survey consistently contains more complete family cancer history than the EHR data, demonstrated by the large discordances between the compared data sets. The major limitation of this study is that the evaluation was performed at a single hospital system, which does not include a dedicated cancer center. Clinicians only spend a small fraction of time obtaining and documenting family history in such settings. Nevertheless, our findings suggest that family cancer history data is lost or obtained at a cursory level during the clinical interaction and/or during the subsequent documentation into the EHR. Therefore, we conclude that family cancer history data from the EHR warrants additional data quality evaluation, particularly in cases where it is intended for secondary use. Furthermore, we hope to encourage development of more direct methods of integrating patient-generated family history data into patient medical records to improve documentation of family history.

Implementing NLP-Based Point-Of-Care CDS Drives Adherence to Evidence-Based Clinical Pathways

Srinivasan Suresh, MD, MBA1; Andrew Buchert, MD1; Gabriella Butler, MSN, RN1; Amy Urban, DO1; Curtis Stratman, MBA2; Nancy Zimmerman, RN, BSN3; James Colbert, MD3,4

1Children’s Hospital of Pittsburgh of UPMC, Pittsburgh, PA; 2UPMC Enterprises, Pittsburgh, PA; 3medCPU, New York, NY; 4Harvard Medical School, Boston, MA

Introduction

Health care in the United States is largely delivered in systems of care that are complex, inefficient, error prone, and costly. There currently exists a high degree of variability in the delivery of care between providers and facilities. Other industries have been successful at reducing inefficiencies and eliminating waste through the standardization of processes. Clinical pathways allow for an opportunity to reduce variability in the delivery of health care.1 As part of their 10-yr strategic plan, Children’s Hospital of Pittsburgh (CHP) of UPMC is developing and implementing clinical pathways that provide consistent, safe, efficient, effective and timely care that yield positive patient outcomes while reducing the inappropriate use of unnecessary resources. The appendicitis pathway demonstrated measurable reduction in length of stay (LOS) and costs.

PowerPlans (order sets) were created in the Cerner electronic medical record application (EMR) to promote adherence to the pathways. The clinical goal is for clinicians to utilize these PowerPlans for all cases of appendicitis. Utilization of the appendicitis PowerPlans was initially high, however CHP observed a steady decrease, and by August 2016, fewer than half of appendicitis cases were managed using the appendicitis PowerPlans. The hospital decided to implement intelligent clinical decision support (CDS) technology with the goal of improving PowerPlan utilization.

Methods

CHP implemented an advanced CDS solution that can analyze both free text as well as structured data to identify patients eligible to receive care under the defined clinical pathway. To achieve these goals, the hospital partnered with medCPU, a company offering a CDS platform with natural language processing (NLP) capabilities. Using this technology, the appendicitis CDS module identifies patients with a diagnosis of appendicitis based on real-time analysis of free-text clinician documentation and radiology reports. Once a diagnosis of appendicitis is established by the CDS platform, a prompt is fired alerting the clinician to utilize the appropriate appendicitis PowerPlan if not already ordered.

Data elements are extracted in real-time as clinicians record them into the EMR using User Interface Automation (UIA), Document Object Model (DOM) parsing and Optical Character Recognition (OCR) technologies (collectively known as the “Reader”). This capability overcomes the deficiencies of HL7 and web service interfaces that typically allow only limited amounts of data to be outbounded, thus preventing latency and enabling real-time response. The Reader runs continuously in the background on the organization’s servers. Data is compiled and processed from an unstructured format utilizing a NLP engine that achieves high accuracy scores (both precision and recall) through an innovative clinical-context extraction technology.

Data were collected to measure the effect of this CDS implementation for patients with appendicitis. We measured and compared compliance with usage of the appendicitis admission and post-operative PowerPlans for the time periods before and after the implementation of CDS, as well as the resulting impact from increased adherence to the pathway on LOS for complicated and uncomplicated appendicitis.
Results

Table 1 shows the increase in utilization of the appendicitis PowerPlan after advanced CDS with NLP was implemented. Usage of the admission PowerPlan increased from 63% to 92%, while use of the post-operative PowerPlan increased from 62% to 92% for uncomplicated appendicitis and from 52% to 94% for complicated appendicitis. As a result of the improvement in use of the PowerPlans driving adherence to the pathway, we found a significant decrease in median LOS, with a 21% decrease for uncomplicated appendicitis and a 16% decrease for complicated appendicitis. The expected cost reductions were also observed.

</tr>
</tbody>
</table>

We also assessed the impact of the NLP-enabled CDS platform on performance of the Cerner EMR and did not find any deleterious effects. A chart review performed on March 2, 2017 found the NLP engine performed with an accuracy of 95% in identifying patients who were not on the appropriate clinical pathway.

Discussion

CHP achieved improved adherence to an evidence-based clinical pathway for appendicitis, with resultant reduction in LOS through implementation of an advanced CDS platform that leverages NLP technology to extract a clinical diagnosis in real-time from both structured and unstructured data elements. CHP is planning to expanding the use of this novel technology to impact other hospital-wide improvement initiatives.

A Probabilistic Scoring Model to Evaluate Providers Regarding Continuity of Care from a Relational Perspective

Kazim Topuz, PhD¹, Scott Shepherd, DO¹, William Paiva, PhD¹, Dursun Delen, PhD¹, Krista Schumacher, PhD¹, Mehmet Yildirim, PhD², Shrieraam Sathyanarayanan, MS¹
¹Oklahoma State University, Center for Health Systems Innovation, Tulsa, OK
²Wichita State University, Industrial Engineering, Wichita, KS

Introduction

Studies have shown the importance of continuity of care (COC) in improving health care and clinical outcomes. Although COC lacks a universally accepted definition, it is generally agreed upon that COC consists of three interrelated components: informational, relational, and management continuity. Relational COC is defined as an established and ongoing relationship between a single physician and patient and is considered a key factor in the provision of quality primary care through the accumulation of medical knowledge and the development of a high level of trust between patients and providers. Reid et al. contend that chronological measures, e.g., sequence of care, can be valid indicators of continuity only if chronology is closely linked to a particularly continuity type. Therefore, we maintain that chronological measures can be valid indicators of at least one aspect of relational continuity, but only when taken as a whole.

Several approaches to measuring chronological continuity exist but focus on distinct aspects of chronology of care, such as concentration of care (e.g., density), provider dispersion, sequence of visits to same provider, and number of providers seen. Most COC measures rely on visit patterns, which use the patient as the unit of analysis and fail to probabilistically represent visit patterns in terms of providers. Using Markov decision processes, we developed an index comprised of four dimensions: usual provider care, dispersion among providers, number of providers seen, and sequential continuity using visit patterns. The index is based on a framework that unifies existing indices as well as shifts the focus of analysis to providers. Our model defines the chronology of care aspect of relational continuity as a product of density, dispersion, and sequence of visits and shows transitions among providers.

Methods

Two objectives guide this research: 1) develop a framework encompassing different COC indices to create a more robust COC model; and 2) apply the proposed model in a primary care setting to study the effects of different visit characteristics on model outcomes. The Markov model contains states corresponding to each provider, and each transition represents the set of all patients for a provider. Starting with a given provider for the first visit within a pre-determined timeframe, a patient may stay with the same provider or transition to a different provider the following visit. Some of these may return to their original provider on subsequent visits. All visit patterns are represented in the model. Any given patient-visit pattern can be expressed as a transition trajectory among various states over time. Every pair of states is connected with a pair of directed arcs representing whether patient transitions have historically occurred between corresponding providers in consecutive visits. Associated with each arc is a weight, the so-called transition probability, representing the relative frequency of such transitions. This yields a Markov chain describing patient visit progression over time (Figure1).

We calibrated the Markov model using HIPAA-compliant electronic medical records (EMR) extracted from the Cerner Health Facts data warehouse. Data came from the pediatric setting of a single teaching hospital in the Midwestern U.S. and consisted of primary care providers and resident physicians. After censoring patients with < 5 primary care visits and providers with < 40 service hours per week between 2005-2015, the final dataset consisted of 248,516 patients from infancy to 21 years of age (Table 1) and 253 providers.

The transition probability for each pair of states represents the relative frequency of transitions between associated providers in consecutive visits and is estimated using historical data on visit patterns during a given timeframe. An unbiased estimator for the transition probability from state  \( i \) to state  \( j \), denoted by  \( P_{ij} \), is calculated by the ratio of (1) all patient visits specific to provider \( i \) during the given period to (2) the subset of patients who visited provider \( j \) during their next visit. The proposed Markov-chain model can be used to assess visit characteristics for a patient, provider, or clinic. The provider score is calculated using the geometrically distributed sojourn time associated with each state of the Markov chain. The expected provider score, or sojourn time \( st \) for each provider, is calculated by \( st_k = (1 - p_{kk})^{-1} \), where \( k \) is the provider index, and \( P_{ii} \) is the transition probability from \( i \) to \( i \). Scores represent the number of patient visits with the same provider before seeing another.

Results

Figure 2 shows the distribution of provider scores. Most scores were between 2 and 3, with a mean of 2.8. Only 18 (out of 253) scores were greater than 5, while 30 were below 1.5.

![Box-plot](image)

Figure 2. Box-plot for provider score values (color points indicate scores greater than five)

Conclusion

An ongoing relationship with a provider is a critical factor in the overall quality of primary care delivery. This study addresses a gap in the literature by unifying various aspects of COC chronological continuity to create a more robust model of relational continuity that can be used at the provider level. The model can be extended by employing transitions between hospitals and/or clinics. Future studies are needed to test the framework in other settings and validate provider scores by comparing to other measures of relational COC and patient outcomes. A limitation is that while the model is presented as addressing relational continuity for ease of discussion, it is just one aspect of relationship quality and does not consider quality of the actual interactions.

Retrospective and Prospective Evaluations of the System for Hospital Adaptive Readmission Prediction and Management (SHARP) for All-Cause 30-Day Pediatric Readmission Prediction

Fuchiang (Rich) Tsui, PhD¹, Victor Ruiz, MS¹, Amie Barada, MS¹, Ye Ye, MS¹, Gabriella Butler, MSN, RN², Srinivasan Suresh, MD, MBA², Andrew Urbach, MD²

¹Tsui Lab, Department of Biomedical Informatics, University of Pittsburgh, Pittsburgh, PA
²Children’s Hospital of Pittsburgh of UPMC, Pittsburgh, PA

Abstract
Most existing approaches to predict 30-day hospital readmissions use ad-hoc risk factors for modeling. We have developed and evaluated the innovative real-time System for Hospital Adaptive Readmission Prediction and Management (SHARP), which estimates each inpatient’s risk of readmission from structured and unstructured electronic health record data. Both retrospective evaluation (AUC 0.81) and prospective evaluation of SHARP indicate that the system has the potential to allow care providers better identify patients with elevated risk of readmission and to facilitate better discharge planning and intervention for reducing readmission burden. SHARP is now integrated into Cerner® Millennium system at the Children’s Hospital of Pittsburgh of UPMC.

Introduction
Excess unplanned 30-day hospital readmissions are an indicator of quality of care and pose a financial burden to hospitals. Moreover, public reporting of high readmission rates may affect hospitals’ reputations. In October 2012, the Centers for Medicare and Medicaid Services (CMS) started enforcing reimbursement penalties for excess hospital readmissions. Existing approaches for identifying patients with readmission risk rely on manual screening or simple predictive algorithms using few risk factors; however, these approaches either require additional resources or have limited prediction performance.

Recent studies have identified interventions that have helped reduce readmission rates in adults and children. While successful interventions have been disease-specific, readmission risk is dependent on multiple, varying factors. Thus, researchers have highlighted the need for evaluation of interventions aimed at broader (all-cause) populations, and the use of risk assessments for guiding the use of specific interventions for patients with elevated readmission risk.

To address the unmet clinical need, we have developed a real-time 30-day all-cause readmission prediction system, the System for Hospital Adaptive Readmission Prediction and Management (SHARP), which estimates each pediatric inpatient’s risk of readmission from a variety of structured and unstructured electronic health record (EHR) data. In this study, we conducted both retrospective and prospective evaluations of SHARP.

Methods
We describe dataset and study design for retrospective evaluation and prospective evaluation in this section.

Dataset
We collected clinical and administrative data for all inpatient visits to the Children’s Hospital of Pittsburgh of UPMC (CHP) from January 1, 2007 to December 31, 2013. The data types we collected were comprised of two categories: structured and unstructured. The structured data types include demographics, hospital utilization (e.g., number of hospital visits, length of stay, etc), laboratory reports, medications, vital signs, ICD-9 diagnosis codes, Current Procedural Terminology (CPT) codes, Diagnosis-related group (DRG) codes, nurse assessments, intensive care unit (ICU) length of stay, and total length of stay. The unstructured data types are narrative clinical notes including history and physical examination (H&P) notes, progress notes, and discharge summaries. We used MedLEE² to extract medical concepts from free text clinical notes.

Study Design
Retrospective Study: We hypothesized that the use of a variety of linked patient data types could improve prediction performance. We used visits from 2007-2011 as training data to learn readmission-prediction models and visits from 2012-2013 as test data to evaluate the models’ predictive performance. We included data from patients aged 0 to 21 years that were admitted to inpatient units for any cause, and excluded visits from patients who died during admission or whose age was not recorded. We trained a series of naïve Bayes (NB) and K2 Bayesian models by first learning models with feature selection process from a subset of the available data types (Table 1, Group A) and then learning additional models by incrementally adding additional data source types (Table 1, Groups B and C). We did 10-fold
cross validation. Previously we tested several machine learning algorithms and found Bayesian networks in general reached best results. We used the area under the ROC curve (AUC) to evaluate predictive model performance.

**Prospective Study:** We deployed the SHARP system at the end of December 2016 at the Children’s Hospital of Pittsburgh of UPMC (CHP). Author G. Butler reviewed all discharged patients from non-intensive care units during Jan. 2017 and identified unplanned readmissions within the discharged patient cohort. An unplanned readmission was defined as a non-scheduled visit (e.g., any scheduled chemotherapy visits or EEG visits are considered planned readmissions). We measured the sensitivity, specificity, negative predictive value and positive predictive value for the high-risk flagged patients.

**Results**

Table 1 shows the performance of the models learned in the retrospective study. Increased performance was observed as additional data sources were included, i.e., as additional data sources were added, the AUC improved from 0.77 to 0.81 and from 0.76 to 0.80 in the NB and K2 models, respectively. Before deploying the naïve Bayes model to CHP, we identified a probability threshold $P_{\text{high\_risk}}$ based on test dataset and assigned a high-risk flag when $P(\text{readmission}|\text{Data}) \geq P_{\text{high\_risk}}$ based on acceptable sensitivity and specificity.

Table 1: Retrospective evaluation of 30-day all-cause pediatric readmission prediction using AUC.

<table>
<thead>
<tr>
<th>Data Sources</th>
<th>Number of Features [Naïve Bayes]</th>
<th>Number of Features [K2]</th>
<th>AUC (95% CI) [Naïve Bayes]</th>
<th>AUC (95% CI) [K2 Bayesian Network]</th>
</tr>
</thead>
<tbody>
<tr>
<td>Group A: Medications + Laboratory + Vitals + Clinical notes, ICU stay status + Nurse assessments</td>
<td>24 (=24+4)</td>
<td>27 (=27+1)</td>
<td>0.77 (0.76-0.78)</td>
<td>0.76 (0.76-0.77)</td>
</tr>
<tr>
<td>Group B: Group A + Demographic + hospital utilization (length of stay)</td>
<td>28 (=28+5)</td>
<td>28 (=28+5)</td>
<td>0.80 (0.79-0.81)</td>
<td>0.79 (0.78-0.80)</td>
</tr>
<tr>
<td>Group C: Group B + Diagnosis (ICD-9/10 codes, CPT, and DRG codes)</td>
<td>33 (=33+5)</td>
<td>30 (=30+2)</td>
<td>0.81 (0.80-0.81)</td>
<td>0.80 (0.79-0.80)</td>
</tr>
</tbody>
</table>

In the prospective evaluation, we reviewed 957 discharges. Of the discharges, 160 were readmitted within 30 days and 102 of the readmissions had been assigned a high-risk flag. The sensitivity, specificity, positive predictive value (PPV) and negative predictive value (NPV) for the high-risk flagged patients were 0.64, 0.76, 0.35 and 0.91 respectively.

**Limitation**

The findings identified in this study were based on one hospital setting. Additional experiments in different populations may be required to generalize the performance.

**Discussion and Conclusion**

We found that using multiple data types improved readmission prediction performance in the retrospective study. Moreover, the high-risk flag used in deployment at CHP demonstrated an appropriate combination of sensitivity and specificity, and a majority of readmissions were captured by the system. We conclude that SHARP has the potential to allow care providers better identify patients with elevated risk of readmission and to facilitate better discharge planning and intervention for reducing readmission burden.

Developing Computable Phenotypes of Pediatric Chronic Conditions in PEDSnet

Levon H. Utidjian, MD, MBI1,2, Ritu Khare, PhD1, Hanieh Razzaghi, MPH1, Amanda Dempsey, MD, PhD, MPH3, Michelle Denburg, MD, MSCE1,2, Christopher B. Forrest, MD, PhD1,2, L. Charles Bailey, MD, PhD1,2

1Children’s Hospital of Philadelphia, Philadelphia, PA; 2Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 3Children’s Hospital Colorado, Aurora, CO

Introduction

The ability to accurately identify patients with specific medical conditions is essential for constructing study cohorts. Traditional cohort construction often relies upon detailed chart abstraction or administrative datasets that are limited to billing data like diagnosis and procedure codes. Electronic health record (EHR) data provide a large number of clinical variables to allow for complex cohort construction. Computable phenotypes (CP) utilize multiple EHR data elements such as laboratory results, medications, and vital signs data to define cohorts of patients with specific conditions.1

In pediatrics, achieving adequate cohort sizes is a challenge given that most chronic diseases of childhood are rare. PEDSnet is a multi-institutional network that aggregates EHR data from eight of the nation’s largest children’s hospitals. The purpose of this study was to develop and validate CPs for Crohn’s Disease (CD), Glomerular Disease (GD), and Type 2 Diabetes Mellitus (T2DM) using a reproducible process applied to structured EHR data elements that balances sensitivity and specificity in order to support case-finding for observational research.

Methods

To develop the CPs, the study team worked with clinical content experts to generate clinical specifications for chronic conditions of interest, comprising combinations of diagnostic and procedure codes, laboratory results, and medications (Table 1). These clinical specifications were then converted to technical specifications that mapped clinical definitions to a common data model (OMOP CDM version 5). Once the technical specifications were complete, code was developed and executed against the aggregated network data.

</tbody>
</table>

Internal validity of the CP algorithms was evaluated through a series of models that sought to test several hypotheses regarding associations between the conditions of interest and healthcare events and used to refine the algorithms. Univariable analysis using \( \chi^2 \) testing was done on each variable used in the algorithm to test the independent associations between each variable with outcomes of interest. Logistic regression modeling was used to estimate the
odds ratios adjusted for potential interactions. External validation of the algorithms was done by using the algorithms on cohorts with confirmed diagnoses for the condition of interest and examining precision and recall.

Results

The CD CP is presented in this abstract as an example of the development and validation of the CP. For all three CPs, univariable analyses uniformly produced significant associations between CP elements and disease-related outcomes (data not shown).

As a non-case comparator for the CD CP algorithm, we used a cohort of PEDSnet patients with visits to gastroenterology (GI) clinic and GI diagnoses (n = 1,060,127 patients). For logistic regression modeling, the exposures of interest were a continuous variable for the count of CD diagnoses (1, 2, 3, 4, 5+ occurrences) and binary value for any use of CD medications. The outcomes of interest were procedures for endoscopy or a GI fluoroscopic exam. The presence of CD diagnosis codes and medications were significantly associated with each outcome of interest (Table 2).

**Table 2. Odds ratios and 95% confidence intervals for the Crohn’s disease (CD) Computable Phenotype**

<table>
<thead>
<tr>
<th>Outcome</th>
<th>CD Diagnosis Code</th>
<th>CD Medications</th>
</tr>
</thead>
<tbody>
<tr>
<td>Endoscopy</td>
<td>1.24 (1.21-1.27)</td>
<td>1.56 (1.54-1.58)</td>
</tr>
<tr>
<td>GI Radiographic Exam</td>
<td>3.80 (3.65-3.97)</td>
<td>3.39 (3.27-3.51)</td>
</tr>
</tbody>
</table>

External validation was done by comparing different models to a cohort of 1,713 patients with confirmed CD. Models consisting of different combinations of CD diagnoses and medications were compared against this cohort. As illustrated in Figure 1, a model requiring at least three CD diagnoses with any CD medications improved precision from 0.66 to 0.81, and achieved similar recall (0.99 vs 0.98) to a model requiring only a single diagnosis.

**Figure 1.** Comparison of models for Crohn’s disease phenotypes against a curated list of Crohn’s disease patients.

Conclusion

We have developed rule-based CPs for structured data with strong internal and external validity, using a reproducible design and validation process that maximizes return from available data before confirmation using resource-intensive chart review. Our CP algorithms demonstrate how incorporating clinical data elements like procedures, medications, and laboratory results can lead to models that are better predictors of case identification than diagnosis codes alone. By using a large aggregated EHR data set, our CP algorithms can also be used to develop multi-institutional study cohorts.

Clinical Workflow Visualization: Representation of clinician activity from location tracking data

Akshay Vankipuram, MS1, Stephen Traub, MD2, Vimla L. Patel, PhD1,3

1 Department of Biomedical Informatics, Arizona State University, Scottsdale, AZ; 2 Emergency Medicine, Mayo Clinic, Phoenix, AZ; 3 New York Academy of Medicine, New York City, NY

Introduction
The Health Information Technology for Economic and Clinical Health Act (HITECH) enacted as part of the American Recovery and Reinvestment Act (ARRA) of 2009 introduced incentives for healthcare organizations to adopt Electronic Health Records (EHR). This has led to a significant increase in EHR adoption and as of 2015, 96% of hospitals reportedly possessed certified EHR technology and 84% had adopted a basic EHR which was up from 9.4% in 2008. In less than a decade, EHR systems have transitioned from impacting a subset of hospitals to becoming nearly ubiquitous, and, subsequently, adding a new dimension and focal point to clinical workflow discussions. Shortly after the ARRA, the Center for Medicare and Medicaid services (CMS) released their guidelines for meaningful use of certified EHRs. This has required organizations to adopt techniques to quantify clinical workflow such as patient or clinician location tracking. However, the methods to present this information meaningfully to the end-users (clinical personnel), as feedback to impact behavior or as an overview of clinical workflow, are lacking. In this paper, we present a set of visualizations of workflow metrics developed using location tracking via sensor-based technology (Radio Frequency Identifier or RFID).

Methods
The data used for this study was collected at the Mayo clinic emergency department (ED) in Phoenix, AZ. The Mayo clinic ED uses a system developed by Versus® for RFID and Infrared (IR) based location tracking. The Versus system consists of RFID+IR receivers tracking 60 locations within the ED and tags given to each tracked physician. Being a proprietary technology, we had no control over data collection or tracking algorithms but we could pull the data from the system as needed. We then ordered the data temporally. The final dataset consisted of the following attributes: location, start time at location, and end time at location. Overall, this RFID dataset consisted of one month of data (November 2016) for five clinicians (6269 rows).

Results
Figure 1 shows the time spent by clinicians in each of the locations tracked. ‘Physician Workspace’ corresponds to the location in the ED where the EHR systems are housed. All the ancillary locations were combined into an attribute called ‘Other’ making it easier to visualize. Another technique to visualize relationships between entities is known as a force-directed graph. Figure 2 shows our use of the force-directed graphs to summarize workflow. The nodes (circles) represent locations and the relationships between them (links) are meant to represent movement of a tracked subject from location A to location B. The size of the circle represents the time spent in each location while the thickness of the links is used to code the strength of that relationship i.e. the number of times a tracked subject moved from location A to location B. The third type of summary visualizations we created were using hierarchical edge bundling. A Hierarchical edge bundling plot (Figure 3) was created as an alternate plot of ED locations. Hierarchical edge bundling places all the nodes/locations on the circumference of a circle to avoid any overlap, improving clarity. Figure 3 also shows the highlighted (in red) links to all the other nodes/locations from the workspace. Figure 4 is a radar plot showing the probabilities of the next location starting at the workspace (this can be created for all the locations as start
points). These graphs are useful both for immediate feedback and as part of a workflow visualization dashboard, or to create metrics that could be used in larger data sets combining RFID data with other data sources.

Discussion and Conclusion
We created visualizations that provide a way to convey summary and individual level information rapidly to the users. Clinicians can assess their total time spent at various locations as well as their movement behaviors. In addition, we can use the results of their analyses and visualizations to create metrics that can be used in more sophisticated workflow analysis techniques for example, probabilities of location can serve as metrics that can combine with location specific behaviors to create a better picture of clinical workflow. Additionally, we can use temporal information in sequence analysis techniques to contrast physician behavior or to assess bottlenecks during a specific time within a shift. We are also looking to combine RFID analysis with EHR log files (essentially a deeper analysis of the time spent in the workspace location which takes a majority of a clinician’s time as seen in Figure 1). This is both a first step towards that larger goal of creating quantifiable metrics and a means to allow clinicians to have feedback on their workflow.

Acknowledgements
This research is supported by grant #R01HS022670 from the Agency for Healthcare Research and Quality (AHRQ). The content is sole responsibility of the authors and does not necessarily represent the official views of the AHRQ. We also thank our Mayo clinic staff who supported our data collection efforts.

Using EHR and HIE data to identify patients’ need for services that address the social determinants of health

Joshua R. Vest, PhD, MPH\(^1,2\), Shaun J. Grannis, MD, MS, FAAFP\(^2\), Jennifer L. Williams, MPH\(^2\), Dawn P. Haut, MD, MPH\(^3\), Nir Menachemi, PhD, MPH\(^1,2\)

\(^1\)Indiana University Richard M. Fairbanks School of Public Health, Indianapolis, IN; \(^2\)Regenstrief Institute, Indianapolis, IN; \(^3\)Eskenazi Health, Indianapolis, IN

Introduction

Increasingly, health care organizations need to deliver services that address patients’ broader social, contextual, and environmental needs. Identifying patients in need of services to address the social determinants is a critical first step to key operational activities like effective resource planning and risk stratification. However, identifying the patients in need of such services is challenging due to incomplete and nonstandard documentation, variable billing practices, technology limitations, a lack of physician time, and potential patient response biases and sensitivities. A multi-modal and multi-information systems approach was used to identify primary care patients with documented needs for social determinants of health services.

Methods

We identified needs for services addressing the social determinant of health in a sample of 84,317 adult (>18 years) patients. All patients had at least one outpatient encounter at an Eskenazi Health’s federally qualified health center (FQHC) site between 2011 and 2016. Eskenazi Health serves the Indianapolis, IN metropolitan area with 10 FQHC sites. The services of interest were: social work, behavioral health, nutrition counseling, dental, respiratory therapy, financial planning, medical legal partnership assistance, patient navigation, and pharmacist consultation. Notably, the social determinant(s) of health services were offered on a co-located basis at the primary care sites during the study period, i.e. Eskenazi Health was not relying on referrals to external providers and agencies for these services.

Because many individuals who need services do not always receive services, we could not solely rely on receipt of services as a representative indicator of need. Therefore, we operationalized the concept of “need” as an indication that a health care professional judged that any of the aforementioned services were appropriate, recommended, or potentially beneficial to the patient. This definition extended indications of need beyond only instances of delivered or received services. In consultation with Eskenazi Health’s information technology staff, need for social determinants of health services was identified using the following information sources:

1) Billing codes – From G3, Eskenazi Health’s Regenstrief Institute developed EHR, and the Indiana Network for Patient Care, the area’s health information exchange (HIE), we identified ICD-9, ICD-10, and CPT procedure codes associated with behavioral health, dental, nutritionist, respiratory therapy, and financial assistance.

2) Appointments – From four different outpatient registration systems, we identified all kept, cancelled, and “no show” visits for dietitian, behavioral health, and respiratory therapy.

3) Orders & notes – From G3’s order entry system we searched provider orders for all nine of the social determinants of health services using keywords informed by a review of the literature and professional society’s documentation recommendations.\(^1-6\) Additionally, because the G3 progress notes contained a specific section for social worker documentation, we used Regenstrief’s NLP tools to identify instances of social worker contact with patients in the outpatient setting. Because it was routine practice for all inpatients to have a social work consult before discharge, we excluded any notes associated with inpatient admission periods.

In sum, documentation of “need” reflected any ordered, scheduled, or received services. For each service, we recorded where the documentation was found (i.e. billing, appointment, or orders) and created a summary binary indicator of any need.

We described the prevalence of the need for social determinants of health services, and where information was identified, using frequencies and percentages. To assess the level of agreement between information sources, we also calculated kappa coefficients for documented need of any service and for individual services (when possible).
Results

Overall, 54% of patients were in need of services to address a social determinant of health during the study period (Table 1). A total of 22% were in need of two or more services. Based on all available information sources, nutrition counseling services were the most common needed (33%) followed by behavioral health (19%), social work (13%), and dental (11%). All other social services were less common.

For the majority (61%) of patients, the need for social determinant of health services was only documented by one source. Procedure codes were a poor source of information regarding social determinants of health services. In addition, evidence for the need of social determinants of health services was inconsistently documented among the various information sources. The overall agreement between need for any social service as defined by appointments and as defined by orders & notes was only 0.30. Similar, low correlations existed per service as well. For example, the agreement on need of behavioral health services between appointment data and order & note data was 0.16.

Discussion

While previous research has documented the prevalence of social determinants of health risk factors, to the best of our knowledge, this analysis was the first attempt to quantify the need for social determinants of health services in primary care. An urban safety-net population demonstrated a frequent need for services to address social determinants of health. Health care organizations preparing for population health activities and payment reform need to identify approaches for both ensuring patient access to social determinants of health services as well as documenting services delivery. Identification of patients in need of such services required multiple information sources. Most often the need for services was recorded in unstructured formats. Organizations relying solely on procedures codes, and even appointment data, will likely underestimate needed services that directly address the social determinants of health. Moreover, clinical information systems will require better data capture and standardization before organizations can better identify patients in need of social services, be prepared as more non-clinical services become reimbursable, and to support effective referrals to a wide range of services in support of population health.

A Conceptual Model of Personal Health Informatics for Chronic Illness

Lisa M. Vizer, PhD¹, Jordan Eschler, MS², Bonmi Koo, PhD¹, James D. Ralston³, Wanda Pratt, PhD²

¹University of North Carolina, Chapel Hill, NC; ²University of Washington, Seattle, WA; ³Kaiser Permanente Washington Health Research Institute, Seattle, WA

Introduction

Over half of Americans have a chronic illness—described by the World Health Organization as having long duration and resulting from “genetic, physiological, environmental and behaviors factors”—with 25% having more than one. It is also the leading cause of poor health, disability, and death, accounting for up to 86% of health care spending. Self-management is central to regulating chronic illness, but we give people limited guidance about how to self-manage, transferring much of the design of day-to-day management practices to people with chronic illness. Many personal informatics tools—such as continuous glucose monitors, activity trackers, heart rate monitors, and smartphone apps—promise to ease the burden of self-management. But people experience barriers to use around choosing and using tools and making sense of data. Despite barriers, people self-track to better manage chronic illness. To decrease the self-management burden in light of evolving informatics opportunities, we need to understand and design for self-management support. Here, we see an opportunity to improve models used to understand self-management tool use to (1) incorporate the iterative nature of self-management work and (2) append a social dimension to more accurately depict the context of self-management. This abstract presents analysis of chronic illness self-management practices of 63 expert and novice self-trackers resulting in the Conceptual Model of Personal Health Informatics (CoMPHI) depicting the process of chronic illness self-management in the person’s social context. Through insight into users’ practices, we as technology designers and implementers can improve the quality of chronic illness self-management support, better informing and engaging people with chronic illness.

Methods and Analysis

We collected and analyzed the processes described by people managing chronic illness from three cohorts:

- Video transcripts of 29 Quantified Self (QS) show and tell videos (www.quantifiedself.com) depicting experiences with managing chronic illness from a cohort of 23 people
- Interview transcripts from a cohort of 20 adults with Type 2 diabetes
- Interview transcripts from a cohort of 20 mothers of children with asthma

Videos were freely available and did not require IRB approval, and use of interview transcripts was approved by the Group Health IRB. Three authors coded transcripts in Atlas.ti using open coding as well as concepts from the Li et al.4 and Swan5 models and MacLeod et al.6; our analysis required the creation of additional concepts. We then reviewed the coded transcripts for themes, using an affinity diagramming method to iterate a final coding schema. We used the final schema to organize data and inform the CoMPHI.

Results

We constructed a Conceptual Model of Personal Health Informatics that is distinct from prior models of personal informatics and healthcare. The CoMPHI consists of two parts: Actors and Work. Actors are people involved in management: the Person with Chronic Illness, possible Carers, Community Members, and Clinicians. The Work in which those Actors engage includes: Information, Collection, Integration, Reflection, and Action. We found no specific order for work or transitions between types of work.

Discussion

Our analysis shows that self-management of a chronic illness is a social experience, the interpersonal nature of which is not adequately represented in current models. As a result, our primary contribution is an explicit description of the social sharing of health information while managing chronic illness. All people with chronic illness described instances of sharing the data collected, whether with health care professionals, to inform clinical actions, or with friends or colleagues, to synthesize feedback and maximize benefit from self-tracking activities. Although the Pew Internet Research Project’s survey on health tracking found that 12% of trackers track for someone else, no other model includes carers. We included carer as a main actor because he or she takes on a critical management role depending on the type of illness and needs of the person with chronic illness.
We have modified Li’s notion of stages to types of work because people with chronic illness continuously perform work in support of their health. We also changed Li’s Preparation stage to Information work.

Finally, we propose that the process is more fluid than implied by Li’s stage paradigm. The notion of work in the CoMPHI is also different from that in Swan’s model of personal health informatics. In that model, all the work rested with the individual, but we found that sharing work was key to successful self-management.

For people with chronic illness, effective self-management improves health outcomes, and new personal health informatics tools can further support self-management activities. We have an opportunity to understand how individuals achieve successful self-management, and use that knowledge to design more useful tools. Understanding how people with chronic illness and carers use tracking to successfully manage chronic illness informs the design of systems to support people outside of the clinic, where most self-management activities occur. As one person stated: “in chronic diseases, health is not created in healthcare.” She creates health when implementing therapies in life outside the clinic, and her tracking practice is critical. We recommend that designers consider interoperability, data richness, and shared work when designing health informatics tools. Most importantly, this work drives home the impossibility of extricating people with chronic illness from their social environment, even when describing their work. We must consider the social aspects of self-management when designing any health informatics tool. People employ technology to assist in managing their chronic illness, but that is only part of the puzzle. As another person said, “It’s not just technology, it’s people.”

Introduction

Despite advances in biomedical imaging technology and growing adoption of electronic health records (EHRs)\textsuperscript{1}, imaging information often lacks interoperability across systems.\textsuperscript{2} Currently, each radiology facility typically still creates its own nomenclature to identify its imaging procedures,\textsuperscript{3} which hinders data exchange and aggregation.

To address these problems, both the Regenstrief Institute, Inc. and the Radiological Society of North America (RSNA) initially undertook separate efforts to create standardized radiology procedure names. Regenstrief expanded and enriched LOINC\textsuperscript{4} to include radiology terms.\textsuperscript{5} RSNA developed the RadLex\textsuperscript{5} Playbook\textsuperscript{5}, an outgrowth of its RadiLex terminology that focuses specifically on procedures names. The organizations were on parallel paths, but shared common perspectives. With funding from the National Institute of Biomedical Imaging and Bioengineering (NIBIB), in 2013 the organizations began to unify their standards. The goal of this joint effort is to provide a common information model and unified terminology with a single governance process for radiology orders and results. Here we describe our unification approach for the jointly developed LOINC/RSNA Radiology Playbook.

Methods

In 2011, a subcommittee of the RSNA RadLex project began the RadLex Playbook. RadLex is a comprehensive lexicon of radiology terms for standardized indexing and retrieval of radiology information resources.\textsuperscript{6} The RadLex Playbook\textsuperscript{5} aims to provide a standard system for naming radiology procedures, based on the elements which define an imaging exam, and has two components: 1) the model used to generate names (the grammar), and 2) the names generated from that grammar. The RadLex Playbook grammar describes how to create pre-coordinated terms, with each Playbook term being comprised of several RadLex terms. Each unique combination of RadLex terms makes a unique Playbook term and is given a unique identifier (the RadLex Playbook ID, or RPID). Thus, for each RPID there is a corresponding set of associated RadLex clinical terms.

LOINC is a freely available international standard for health measurements, observations, and documents. Today, LOINC is used in more than 166 countries by many kinds of organizations. It is a national standard in more than 30 countries, including the U.S.\textsuperscript{6} LOINC began representing radiology procedures in 2000 (Version 1.0O). The current release (version 2.61) contains more than 5,600 active radiology terms. LOINC names radiology procedures within the six major, and up to four minor, attributes of the LOINC concept model. Within these LOINC attributes, some specialized conventions were developed for radiology. Prior analyses\textsuperscript{5} have demonstrated that LOINC has good coverage (91-92\%) of the procedure codes found in local radiology systems.

In 2013, the two organizations agreed to cooperate on a single standard for radiology procedure names, bringing together the globally-recognized terminology experience of Regenstrief and the preeminent domain expertise of the RSNA. The unified, jointly developed terminology is called the LOINC/RSNA Radiology Playbook.

The organizations agreed that LOINC codes would be the primary identifiers for procedures in the unified terminology. We would map RadLex Playbook identifiers to corresponding LOINC codes, but new RadLex Playbook identifiers would not be created in the future. The organizations developed a unification plan with these objectives: 1) develop a unified model for radiology procedure names that represents the attributes with an extensible set of values, 2) transform existing LOINC procedure codes into the unified model representation, 3)
create a mapping between all the attribute values used in the unified model as coded in LOINC (i.e., LOINC Parts) and their equivalent concepts in RadLex, 4) create a mapping between the existing procedure codes in the Core Playbook (a subset of the RadLex Playbook) and the corresponding codes in LOINC, 5) develop a single integrated governance process for managing the unified terminology, and 6) publicly distribute the terminology artifacts.

Results

The first phase of the unification spanned two years ending September 2015. We created a unified model and governance process for the collaboration, and implemented the unified model and mappings for computed tomography (CT). We defined a release format, including mappings between LOINC and the RSNA Playbook at the procedure code level, and connections between procedure terms and their attribute values expressed as LOINC Parts and RadLex IDs. In December 2015, we published the first version along with a Users’ Guide.

The second phase spans from October 2015 through September 2017. We expanded the modeling and mapping, and have iteratively improved the unified model and its application. The current version (June 2017) contains unified modeling of 5,500+ terms covering all imaging modalities. Table 1 shows the attribute values from the unified model for an example term. Other example names include [42274-1] CT Abdomen and Pelvis WO and W contrast IV, [39077-3] XR Shoulder AP and transthoracic, and [82800-4] PET+CT Heart W contrast IV.

</tr>
</tbody>
</table>

For these 5,500+ terms, there are over 37,000 attribute value relationships linking more than 830 LOINC Parts to RadLex clinical terms. Before Phase II ends, we will complete modeling of the last remaining content: modality-agnostic interventional procedures. As Phase II ends, the collaboration will transition into an ongoing, sustained activity that is jointly maintained and governed by the two organizations. Users can requests additions to the terminology through the existing LOINC submission process.8

Discussion

The Regenstrief Institute and the RSNA have created a unified terminology standard for radiology procedures that builds on the strengths of LOINC and the RadLex Playbook. The approach to developing this freely available standard is novel because it represents a true unification, rather than independent efforts tenuously joined by an ongoing mapping effort. The Office of the National Coordinator for Health IT lists the unified LOINC content as the standard for imaging procedures in its 2017 Interoperability Standards Advisory. As the remaining content is modeled, the LOINC/RSNA Radiology Playbook will become a complete resource of imaging procedures.

Conclusion

The LOINC/RSNA Radiology Playbook provides a universal terminology standard for radiology orders and results.

Impact of Clinician Experience on Machine Learned Clinical Order Patterns

Jason K. Wang,1 Alejandro Schuler,2 Nigam H. Shah, MBBS, PhD,2 Jonathan H. Chen, MD, PhD3

1Mathematical & Computational Science Program, Stanford University, Stanford, CA, USA; 2Center for Biomedical Informatics Research, Stanford University, Stanford, CA, USA; 3Department of Medicine, Stanford University, Stanford, CA, USA

Introduction

Clinical decision-support (CDS) aims to reinforce best-practices by distributing knowledge-based content through order sets, templates, alerts, and prognosis scoring systems. The current standard for developing and distributing content is from the top-down (e.g. human-authored order sets curated by hospital committees). As such, one of the “grand challenges” in CDS is to automatically generate content by data-mining clinical data sources from the bottom-up. We previously developed a data-driven recommender system for clinical orders (e.g. lab tests, medications, imaging) drawing inspiration from Netflix and Amazon.com’s “customers who bought A also bought B” system. Our engine dynamically generates order recommendations based on real-world clinical practice patterns represented in electronic health record (EHR) data. However, effective medical decision making and patient outcomes may be compromised if patterns are learned from less experienced fellows, residents, and medical students administering care. This phenomenon gives rise to the concern over learning indiscriminately from the “wisdom of the crowd” when the crowd consists of both experienced attending physicians and trainees. In this study, we investigate how clinical orders learned from board-certified physicians alone versus physician-trainee teams can influence the quality of learned clinical order patterns.

Methods

We extracted deidentified patient data from the (Epic) electronic medical record for inpatient hospitalizations in 2013 at Stanford University Medical Center via the STRIDE clinical data warehouse. Using patient provider information, we prepared two cohorts of general medicine services: 1) patients seen by a private attending-only service (n=1774) and 2) patients cared for by physician-trainee teams through the university teaching service (n=3404). To minimize biases due to confounding features, we conducted propensity score matching to balance the two patient cohorts. Using demographic data, initial vital signs recorded before the onset of care, and existing diagnoses as covariates, we applied a logistic regression model to compute the probability (p) of each patient’s assignment to the attending-only cohort. The propensity score is then defined as the logit function \( \log \frac{p}{1-p} \). Caliper matching on the propensity score at a threshold of 0.25 resulted in balanced cohorts of 1530 patients each, corresponding to >1.7 million and > 2.3 million recorded clinical data elements for the attending-only and teaching service cohorts, respectively.

Given a dataset of patient encounters, our previously described clinical order recommender algorithm counts co-occurrences for all clinical item pairs occurring within 24 hours by association rule episode mining. These counts are then used to populate 2x2 contingency tables to compute association statistics such as baseline prevalence, positive predictive value (PPV), relative risk (RR), and P-value for each pair of clinical items. For a given query item (e.g. admission diagnosis), we generate a list of clinical item suggestions ranked by a specified association statistic. We trained two distinct models either using patient encounters from the attending-only or the teaching service cohorts. We generated a predicted order list ranked by PPV from each model for admission diagnoses including pneumonia (ICD9: 486) and gastrointestinal (GI) hemorrhage (ICD9: 578.9). To develop an external reference standard, we curated “gold standard order sets” based on clinical practice guidelines available from the National Guideline Clearinghouse (www.guideline.gov) and PubMed. Orders were included in the reference if they were mentioned or heavily implied as appropriate to consider in the guideline text for general hospital admissions for the respective diagnosis. PPV-ranked predicted order lists were compared against guideline reference orders by receiver operating characteristic (ROC) analysis.

Results

The post-matching standardized difference in means and p-values computed using two-sample t-tests were < 0.1 and > 0.15, respectively, across all covariates, demonstrating a statistically insignificant difference between balanced
attending-only and teaching service patient cohorts. Table 1 shows an example of the clinical orders generated by our recommender engine for an admission diagnosis of pneumonia trained separately on each patient cohort. Figure 1 shows plots generated for two admission diagnoses: pneumonia and GI hemorrhage. Each plot reports 3 order lists compared against the external reference standard: attending-only predicted orders, teaching service predicted orders, and a pre-authored order set curated by Stanford Hospital. Pre-authored order sets have no inherent ranking to convey relative importance and are thus depicted as a single discrete point on the ROC curve. Area-under-curve (AUC) is reported as c-statistics with 95% confidence intervals empirically estimated by bootstrap sampling items with replacement 1000 times.

**Table 1.** Top clinical order associations for pneumonia generated from attending-only and teaching service trained models sorted by P-value calculated by Yates’ chi-squared statistic, alongside association statistics and 95% confidence intervals.

**Figure 1.** ROC plots for pneumonia (left) and GI hemorrhage (right). Each plot compares a hospital-authored order set and automated predictions from attending-only and teaching service models against the external reference standard.

**Discussion**

While the specific association statistics vary, the overall top clinical order recommendations generated from association models trained on attending-only vs. teaching service cohorts yield comparable c-statistics (AUC) against the external reference standard. This supports the argument that aggregating clinical order patterns of less experienced clinicians (e.g. resident trainees) and more experienced providers (e.g. private attendings) will converge towards comparable top results as both cohorts share the common end goal of patient care. Although propensity score matching was conducted to minimize the influence of confounding covariates recorded in EHR data, study limitations include results influenced by undocumented biases and the necessity of interpreting practice guidelines to define reference standards. When trainees administer care, they may simply follow university attending directions or hospital-approved order sets. Thus, a potential risk of interpretation is recapitulation of existing order sets, though usage rates are relatively low (15% of all orders) and clinical items derived from order sets do not significantly change our results when excluded from analysis. This study provides insights into the consistency of clinical order patterns learned from historical data and how their quality is influenced by underlying practitioner experience.

Interactive Medical Word Sense Disambiguation with Instance and Feature Labeling

Yue Wang, MS¹, Kai Zheng, PhD², Hua Xu, PhD³, Qiaozhu Mei, PhD¹,¹
¹Department of Electrical Engineering and Computer Science, University of Michigan, Ann Arbor, MI; ²Department of Informatics, University of California, Irvine, CA; ³School of Biomedical Informatics, University of Texas Health Science Center, Houston, TX; ⁴School of Information, University of Michigan, Ann Arbor, MI

Introduction

Medical documents contain many ambiguous words. Word sense disambiguation (WSD), i.e. assigning the appropriate meaning to an ambiguous word in context, is a critical step for many medical natural language processing applications, such as named entity extraction and computer-assisted review. Previous works have proposed many approaches for medical WSD, including unsupervised learning, supervised learning, semi-supervised learning, active learning, and interactive search and classification. However, these approaches still lack the ability to learn from domain knowledge, and take relatively long time to reach a reasonable performance, which is known as the “cold-start” problem. In this study, we design a novel interactive learning algorithm that directly incorporates expert knowledge into the WSD model training process. We consider two types of expert knowledge in the WSD task: prior knowledge and reasoning process. The expanded form of many ambiguous abbreviations are documented in medical ontologies, and the expert may know contextual words of a particular sense before looking at any instance, both of which are prior knowledge. Upon seeing an instance containing an ambiguous word, the expert can pinpoint the words and phrases that support his decision on the word sense, which is the reasoning process hidden behind the label. In the new interactive learning process, an expert can express knowledge as the association between senses and textual patterns, and the machine learning algorithm can directly learn from such association. Experiments on one biomedical literature corpus and two clinical notes corpora show that the proposed algorithm makes better use of human efforts in training WSD models than all previous approaches, achieving the state-of-the-art performance with the least effort from domain experts.

Methods

The proposed algorithm has an interactive learning component and two computational components (Figure 1A).

1) Labeling instances and features. In the labeling process, a domain expert can come up with informative contextual words, label instances, and highlight informative text snippets as “rationales” behind the label decision. As a result, the expert provides two types of supervision: instance labels and feature labels. An instance label is assigned to an individual instance containing an ambiguous word, as in traditional machine learning. A feature label is assigned to a word, a phrase, or a textual pattern, all of which can be viewed as features. When the expert provides informative words for a label (sense), these words are explicitly associated with the label. When the expert highlights words in an instance, the highlighted words are implicitly associated with the label of that instance.

2) Learning from labeled instances and features. The machine learning module takes in both instance labels and feature labels from (1) to train a WSD classifier. At each iteration, labeled features may contain arbitrary textual patterns (e.g. n-grams) that are hard to know beforehand. We start with a set of base features (unigrams) and dynamically expand the feature set as new features are provided/highlighted. We use logistic regression with a linear kernel as the WSD classifier. We train the classifier by adding a new term to the original logistic regression loss function, such that any instance containing a labeled feature is more likely to bear that label. A labeled feature may carry substantially more information than a labeled instance if the feature appears in many instances.

3) Selecting instances. An instance selector picks up new instances from the unlabeled pool, presents them to the expert, and asks for labels. We use the margin active learning algorithm to select uncertain instances. To evaluate the new algorithm, we compare it with several baseline methods, including random sampling, margin active learning¹, and ReQ-ReC expert². We use two settings of the proposed algorithm: providing labeled features and highlighting informative features in labeled instances. To make head-to-head comparison with a previous work², we use the same evaluation settings. We simulate an expert by leveraging benchmark medical WSD corpora, including MSH (biomedical literature), UMN, and VUH (clinical notes). Labeled instances are sense-tagged examples in these corpora, and labeled features are n-grams (n = 1, 2, 3) with high information gain for an ambiguous word. In all experiments, the expert provides only one labeled feature at the beginning; all subsequent labels are instance labels. To make realistic assumption on feature labeling, we simulate experts that provide or highlight the k-th best feature.
Results

Figure 1B, 1C, and 1D show the learning curves of different algorithms on three WSD corpora. The new interactive learning algorithm outperforms strong baseline methods. On biomedical literature WSD corpus (MSH), the new algorithm achieves 90% accuracy with 15 labels, saving 40% of labeling effort compared to active learning. WSD in clinical notes is more difficult. On UMN corpus, the new algorithm achieves 90% accuracy with 15 labels, saving 35% of labeling effort compared to active learning. On VUH corpus, the new algorithm saves labels at the beginning.

Discussion

The proposed approach effectively handles the “cold-start” problem in active learning. Active learning works best when the model has a reasonably good “understanding” of the problem space so that the selected instances are the most informative. At the beginning, the model trained on very few labeled instances can perform poorly. In the new learning process, human experts can kick off training by providing domain knowledge, giving the model a warm start.

Real-Time Queries of Millions of Patients Using Probabilistic Sketches

Griffin M Weber, MD, PhD\textsuperscript{1,2}
\textsuperscript{1}Harvard Medical School, Boston, MA;
\textsuperscript{2}Beth Israel Deaconess Medical Center, Boston, MA

Abstract

Large clinical research databases provide investigators access to millions of patients. However, queries often take minutes or even hours to complete. Although this is sufficient for many use cases, it creates a barrier to true exploratory analysis that would be possible with a real-time system. In this study, we show how “streaming algorithms”, which transform Big Data into small probabilistic data structures called “sketches”, can produce sub-second query times with less than 1% error.

Introduction

Sketching algorithms, which are also called “streaming” or “sub-linear space” algorithms, represent big data as small probabilistic data structures. They are extremely efficient, requiring only a small amount of data storage, and producing fast accurate estimates of cardinality (number of distinct items), quantiles, frequency distributions, and other properties of a dataset. They were first invented in the 1980s and are widely used today by search engines like Google, internet routers, and many other applications [Flajolet 1985, Heule 2013]. However, they have had little attention so far from the biomedical community, other than in a few genomics use cases.

An important aspect of sketching algorithms is that the data only have to be read once. In other words, the data are treated as a stream of elements that are processed one at a time and then discarded. A simple example of how a sketch can be used to determine the number of distinct items in a stream is as follows: For each element in the stream, use a hash function to convert it into a random value, \(H\), between 0 and 1. As each element is processed, keep track of the smallest hash value you see: \(S = \min(H)\). The only thing that needs to be stored is the one value \(S\) (the sketch), regardless of the size of the stream. The more distinct items in the stream, the more likely it is to have some element that gets hashed to a very small value. In other words, on average, the smaller \(S\) is, the larger the cardinality. Precisely, the number of distinct items can be estimated as \(N = (1/S) - 1\). This is illustrated in Figure 1. With two items, on average, one will get hashed to value of about \(S = 1/3\); with three items, \(S = 1/4\); and, with ten items, \(S = 1/10\).

![Figure 1. Cardinality Estimates Using a Random Hash Function.](image)

The problem with this particular algorithm is that although \(S\), on average, accurately estimates the cardinality, the variance is so large that the estimate is not very useful. For example, an element in a small dataset can always get hashed to an extremely low value by random chance, causing the cardinality to be grossly overestimated. The solution is to use multiple hash functions and keep track of the smallest value from each hash function in the sketch. The average of those values provides a much better estimate. A popular algorithm, called HyperLogLog (HLL), introduced an efficient way of doing this, where only a small number of values are needed to generate a highly accurate cardinality estimate [Flajolet 2007]. For example, only 64 integers results in just a 10% expected error. Larger sketches can be used for smaller error if needed.

A nice feature of this approach to estimating cardinality is that the result is the same if all the data exist in one dataset/stream or if the data are distributed across many datasets/streams. In the distributed version of the algorithm, a sketch is created for each dataset. The sketches are combined by determining the smallest \(S\) across all sketches. That smallest \(S\) can be used to estimate the cardinality of the entire distributed dataset.

Several enhancements and extensions to HLL have been proposed. For example, Google modified the algorithm to support high cardinalities (HyperLogLog++) [Heule 2013]. AdRoll showed how HLL combined with another streaming algorithm MinHash can generate accurate estimates the cardinality of the union and intersection of multiple datasets (in a manner similar to how distributed HLL sketches are combined) [Pascoe 2013].

This presentation will provide a brief overview of these algorithms, show how they can be adapted for queries of clinical research databases, and give specific examples using a large nationwide administrative claims database.
Methods
Informatics for Integrating Biology & the Bedside (i2b2) is an example of a widely used software platform for query and analysis of clinical repositories [Murphy 2010]. i2b2 users can define an arbitrary Boolean query (e.g., inclusion and exclusion criteria) through a web-based interface, and the software will return the number of distinct patients who match the query. In i2b2, data (diagnoses, medications, laboratory tests, etc.) are primarily stored in a single indexed fact table, which can have billions of records at large institutions. The records include a concept code (e.g., ICD-9 diagnosis), a patient number, an observation date, and optional metadata, such as a laboratory test result.

To create a probabilistic representation of the i2b2 fact table, all the facts associated with a given concept, like hypertension, can be thought of as a stream of patients. HLL is used to hash the patient numbers into a small sketch. That sketch can then be used to estimate the number of distinct patients with that concept. Similarly, a sketch is made for every medical concept. A typical i2b2 instance might have a few hundred thousand concepts; though the amount of storage needed for the sketch is so small that hundreds of thousands of them are still small compared to the size of the fact table. Boolean queries are implemented as unions and intersections of the sketches. Dates and laboratory test results are stored as additional data structures linked to the concept sketches.

The approach was applied to a large claims database. First, 3 billion diagnoses (64 thousand separate ICD-9 and ICD-10 diagnosis codes) for 51 million members were loaded into an i2b2-like fact table in a Microsoft SQL Server 2012 database. Unlike a regular i2b2 fact table, non-essential columns and indexes were removed, the table was compressed, and a columnstore index (a special index for large tables was added). This basically created an optimized version of the traditional way clinical data are stored. Next, the table was transformed into probabilistic sketches, with each sketch containing $2^{15}=32,768$ values. In practice, smaller sketches are often used, but this creates a worst-case scenario in terms of performance and reduces the expected error to under 1% relative to the actual number of patients who match a query.

Results
The optimized diagnosis fact table contained 3 billion rows and used 160 GB of disk space. The sketch version contained 3.8 million rows and used 1.2 GB of disk space. The equivalent query can run orders of magnitude faster as sketches. Two examples: (1) The query “Hypertension (ICD9 401.9) OR Diabetes (ICD9 250.00)” returns 8,293,530 distinct members in 6.6 seconds in the fact table compared to 8,309,356 (0.19% error) in 33 milliseconds as sketches. (2) The query “Hypertension AND Diabetes” returns 2,131,928 members in 7.5 seconds compared to 2,150,878 (0.89% error) in 100 milliseconds as sketches. More complex queries in a standard i2b2 fact table can require far more time to run, while queries using sketches remain fast because they scale linearly with respect to the number of concepts in the query (not the number of patients).

Conclusion
Research queries run on probabilistic representations of large clinical data repositories can scale to tens of millions of patients, while retaining real-time sub-second performance. The method was demonstrated using a single nationwide claims database. However, the distributed version of the algorithm could perform equally well as a privacy-preserving approach to queries in a federated network of multiple hospitals or payors since only the sketches, not the actual lists of patients, would need to be shared.

Clinical code set engineering for reusing EHR data for research: A review
Richard Williams, MA Cantab1,2, Evangelos Kontopantelis, MSc, PhD1, Iain Buchan, MD, FACMI1,2, Niels Peek, MSc, PhD1,2
1MRC Health eResearch Centre; 2NIHR Greater Manchester Primary Care Patient Safety Translational Research Centre, University of Manchester, Manchester, UK

Introduction
The rapid adoption of electronic health records (EHRs) is creating unprecedented opportunities for studying clinical medicine, health services, and population health1–2. Adoption of EHRs has more than doubled in the US over the last decade and is expected approach 100% in 20203. UK primary care providers switched to using EHRs in the 1990s, and this has made large EHR databases available for research4–5. The re-use of EHR data for research provides large datasets with long follow-up times against low costs6–8. However, there are considerable methodological challenges because raw EHR data are not "research ready": they need to be transformed before they can be meaningfully used for research9. Most studies that re-use EHR data for research focus on the structured part of the EHR, using clinical codes to extract meaningful information from the raw EHR data. Clinical code set construction is the process of assembling a set of clinical codes that represent a single clinical concept such as a diagnosis, a procedure, an observation or a medication. Once constructed the set is then used to query and extract data from an EHR database, for use in further analysis. These sets of codes, variously referred to as "code lists", "clinical code lists", "code sets" and "value sets", are one of the main building blocks for creating the database queries. It is frequently an early step in research, and arguably a hazardous one, as errors introduced here of missing or wrongly specified codes could result in selection biases that propagate throughout subsequent analyses having a major impact10. However, several reviews have shown that code sets are rarely included in applied papers11–12, let alone the process by which the code sets have been constructed. The construction process is perhaps of greater significance than the set itself as the process could, and should, be scrutinised by reviewers, and can form the basis for other researchers to reuse their methods rather than taking a crude set on trust. We aimed to review and compare methods and tools for managing (constructing, validating, sharing, and reusing) sets of clinical codes and to develop recommendations.

Methods
A PubMed search was performed in August 2016 by the lead author for papers with a substantial methodological component using the terms: "code list(s)", "code set(s)", "value set(s)", "list of codes", "set of codes". The list was supplemented with papers identified by searching citations of relevant material, via snowball sampling using PubMed and Google Scholar. Papers were excluded if they were not related to clinical code sets or not written in English. In total, 507 papers were discovered from the initial searches with 502 screened after 5 duplicates were removed. 464 papers were rejected for lack of relevance (435 from the title and 29 from the abstract). The snowball sampling commenced from the 38 full papers read and in turn this identified 31 additional papers (initial list of 183 papers was reduced by removing 26 duplicates, 109 rejected from the title and 17 rejected from the abstract). Out of the 69 full papers reviewed, 39 were rejected as not relevant. This review is based on the remaining 30 papers.

Results
Although differences existed between the methods described, common themes emerged. A popular approach was to reuse an existing code set (n=21) from: a previous study (n=5); a national clinical quality management scheme such as the Value Set Authority Centre (VSAC) (n=11); or both (n=4). The reused set was almost always updated or extended (n=20). Authors reported some specific strategies for searching for relevant codes: exploiting the hierarchical nature of coding terminologies (n=23); preparing an initial list of synonyms to search for (n=20); and employing an iterative approach after preliminary searches (n=13). The putative sets were usually reviewed (n=26), mostly with clinician input (n=20), before definitive use. There were calls for openness and sharing of code sets and code set management methods (n=14), with some giving suggestions or platforms for sharing (n=8). The need for sensitivity analysis (n=19) and caution due to the dynamic nature of code sets (n=13) were also mentioned. Seven papers described software to support the selection of code sets and a further two suggested features for such tools.

Discussion
The process of constructing clinical code sets is time-consuming and error-prone. This review has identified and analysed the code selection methods that are commonly reported. However, despite the existence of relevant software
tools, their use is seldom reported, suggesting they are underused. Potential barriers to their uptake might be: lack of awareness of their existence; ignorance of their necessity; or deficiencies in the tool themselves, either in functionality or that they are time consuming to use. Researchers frequently modify existing code sets which is likely time consuming and error-prone. Future work is needed to reduce this effort. We propose the following recommendations: the objects reviewed in this paper should be called “clinical code sets” or simply “code sets”; journals should insist that code sets for retrospective studies on routinely collected data are published alongside the article; sensitivity analyses with multiple codes sets should be performed; and a clinician should help to create the initial list of synonyms and review the final code set. Code set construction tools should: be open source, publicly available and easily accessible; have minimal setup to facilitate widespread adoption; make use of the hierarchy of clinical dictionaries to assist in the searching and selection of codes; facilitate the initial construction of a list of synonyms; facilitate an iterative process by suggesting additional synonyms based on codes discovered by searching the code hierarchy that are not found themselves directly; facilitate the various stages of the review process from the selection of the initial list of synonyms, to the review of the included and excluded codes; make this process as simple and quick as possible; facilitate and encourage the creation of multiple sets of codes for sensitivity analyses; record metadata such as: the initial list of synonyms, the excluded codes, the purpose for the set and the author; and facilitate the reuse, validation and sharing of codes sets, not simply their construction. Code set sharing platforms should: be discoverable, maintained indefinitely and support versioning; and support the storage of metadata alongside the code set. Online code repositories such as github.com and bitbucket.org could be used to store code sets and their associated metadata.

Conclusion

Research using healthcare databases could be improved through the further development, more widespread use and routine reporting of the methods by which clinical codes were selected.

\textbf{Introduction:} Microbiology laboratory data is essential to the diagnosis and treatment of infectious diseases. Accurate, timely, and complete microbiology results guide selection of antimicrobial therapy, enable detection of disease outbreaks, and can help prevent the development and spread of antibiotic-resistant microbes.\textsuperscript{[1]} However, compared with other types of laboratory data, microbiology data are unusually complex and can be cumbersome to review and interpret.\textsuperscript{[2]} Integrating structured microbiology results into EHRs has been hindered by the variability of test results, their inherent temporal nature and mix of qualitative and quantitative findings and the numerous data elements that can be returned for each test. As such, microbiology results are often loaded into EHRs as unstructured documents, with limited or no automated capabilities for sorting and filtering results. We sought to develop a new review tool to improve the ease and accuracy of microbiology results review.

\textbf{Methods:}Clinicians were observed using existing microbiology results tools and informally interviewed to determine areas in which existing tools were lacking. Based on this user input, a new tool was developed that reorganizes infectious disease and microbiology laboratory data by time and organism. A scenario-based evaluation of the new tool was conducted, with comparison to existing legacy tools and using a balanced block design to control for scenario difficulty and learning effects. For each scenario, accuracy, completion time and ease-of-use (using the Single Ease Question) were assessed. Additionally, participants were surveyed using the System Usability Scale to evaluate the usability of the new tool.

\textbf{Results:} The average time-on-task to complete all 8 scenarios decreased from 45.3 minutes for the legacy tools to 27.1 minutes for the new tool (P < 0.0001). Users made a total of 41 errors with the legacy tools and 19 errors using the new tool (P = 0.0068). The average Single Ease Question (SEQ) score was 5.65 (out of 7) for the new tool, compared to 3.78 for the old tool (P < 0.0001). As shown in Table 1, the average time-on-task, accuracy, and SEQ score stayed the same or improved for each metric in all 8 scenarios. The overall System Usability Scale score was 88 for the new tool, which is “Excellent.”

\textbf{Table 1.} Comparison between the legacy tools and the MV are shown for three metrics: time-on-task, accuracy, and SEQ score. For each metric, a pooled analysis across all scenarios is also shown in the last row. The SEQ score was measured in two parts for scenario 3, and these scores are shown separately.

*Difference between tools is significantly non-zero at: *p < 0.05, **p < 0.01, ***p < 0.001*

**Discussion:** Our results strongly suggest that the new tool represents a substantial improvement compared to existing tools. Compared to legacy tools, users were more satisfied with the new tool, completed clinical scenarios much faster, and made fewer errors. The design and results of our study also have an important implication for system architectures. We built the new tool entirely outside of our legacy EHR systems and used web services to fetch coded microbiology and infectious disease laboratory data from our clinical data repository. We also used web services to support user authentication and access control, and to enable patient search and patient list functionality. Our ability to do this work was enabled by Partners’ significant investment in service-oriented architecture[3] and provides a model for how clinical and informatics teams can innovative alongside a commercial EHR. After the completion of the study, the tool was rebuilt to enterprise standards and deployed throughout Partners healthcare.

**Conclusion:** The new tool reduces time required to review microbiology results, increases accuracy, and is considered useful and usable by infectious disease clinicians.

Detecting Body Location Modifiers of Disorders in Clinical Texts via Sequence Labeling

Jun Xu, Ph.D., Yonghui Wu, Ph.D., Yaoyun Zhang, Ph.D., Hua Xu, Ph.D.
School of Biomedical Informatics, The University of Texas Health Science Center at Houston, Houston, TX

INTRODUCTION
Body location is an important type of modifier for disorders and it is critical for clinical natural language processing (NLP) systems to capture this information. It is a typical relation extraction task in NLP research. However, body location and disorder pairs could be complicated in clinical text. As shown in Figure 1, the sentence contains two disorders: ‘intra cranial hemorrhage’ and ‘fractures’ and two body location modifiers: ‘intra cranial’ and ‘head’. An NLP system needs to determine that ‘intra cranial’ is an inside body location modifier (BLM) for ‘intra cranial hemorrhage’ and ‘head’ is the BLM for ‘fractures’. If we assume that disorder entities are given, traditional methods for identifying BLM relations typically consist of two steps: 1) recognition of all body location entities (BLE) and 2) classification of possible BLM relations. In this study, we propose a new relation extraction method for identifying BLMs for disorders, which recognizes body location entities and classifies their relations with the target disorder in one step, via a sequence-labeling model. We conducted several experiments to compare our sequence labeling-based approaches with traditional two-step relation extraction methods and our results show that sequence labeling-based method achieved much better performance for identifying the BLMs of disorders than traditional methods.

MATERIAL AND METHOD
Dataset We used the ShARe corpus developed by the organizers of the SemEval 2015 challenge task 14. It consists of 531 de-identified notes. We used the training set for model development and the development set for evaluation. The training set contains 6,402 BLMs and the development set contains 3628 BLMs.

Traditional relation extraction approach (baseline): The traditional method consists of two steps to identify BLMs. 1) BLEs recognition: it is a typical NER task to recognize body location entities and we collected four anatomy-related lexicon resources: directional terms, anatomy abbreviations from the training set, body location terms from WordNet, and anatomy lexicon from UMLS. 2) Classification of BLM-disorder pairs: it can be further divided into two tasks: candidate BLM-disorder pair generation and classification. Candidate BLM-disorder pairs were generated according to heuristic rules (e.g., either within one sentence or look at the previous sentence if no BLE exists in the current sentence) and then labeled as positive or negative based on the gold standard. To classify candidate BLM-disorder pairs, we developed two methods: one was a rule-based system and the other was a machine learning-based system using the Support Vector Machines (SVMs) algorithm.

Relation extraction by sequence-labeling (RESL) approach: In our new approach, we treat BLM-disorder detection as one sequence labeling task. This is done by a new transformation schema. For each disorder entity in a sentence, we will generate a sequence labeled sample. As shown in Figure 1, the sentence has two disorders so that it will generate two labeled sentences as samples: one for the target disorder ‘intra cranial hemorrhage’ and the other for the target disorder ‘fractures’. For a given target disorder, only body locations that are modifiers of the target disorder will be labeled as ‘B/I’. For example, in the sample generated for ‘intra cranial hemorrhage’, ‘head’ is not labeled as ‘B’. After we transform each disorder (with its sentence) to samples with BIO labels, we train a single sequence-labeling model for all disorders. We use the following features: 1) Disorders (target and non-target); 2) All position, direction, discourse, context and relation information between all body location and disorder entities, which have been used for traditional approach model building; 3) The output semantic labels recognized by the dictionary lookup program and 4) Other features including word representation features learned from the unlabeled corpus. We evaluated two sequence labeling algorithms: Conditional Random Fields (CRFs) and the Structured Support Vector Machines (SSVMs), to recognize the BLMs for the target disorder.

Evaluation Following the evaluation guideline by the SemEval 2015 challenge, we used the standard precision (P), recall (R) and F1-measure (F1) under both strict and relaxed criteria. We also adopted per-disorder accuracy (Acc) to evaluate the ability of identifying the BLM for a given disorder, defined as: \( Acc = \frac{N_{\text{correct.predict}}}{N} \), where, \( N \) = total number of gold standard disorders; \( N_{\text{correct.predict}} \) = number of disorders which BLM is predicted correctly.
RESULTS
Table 1 shows the performances for our new approaches and the traditional approaches for identifying BLMs of disorders in the ShARE corpus. The RESL approach achieved much higher performance than baseline methods. RESL-SSVMs achieved the highest performance, which was over 9% higher than the SVM-based traditional method (F1 0.8213 vs. 0.7285) under the strict evaluation.

DISCUSSION and CONCLUSION
In this study, we propose a novel method for a relation extraction task – detecting BLMs of disorder. Through a new transformation schema, we combined the entity recognition and relation classification into a single sequence labeling model. Our evaluation shows that the new approach achieved much better performance than the traditional methods on the ShARE corpus. We think the performance gain may come from the combined features for both entity recognition and relation classification in one model.

Using Logistic Regression to Verify Completeness of Electronic Health Records for Infant Mortality Analysis

Luge Yang, PhD¹, Jose D. Posada, MS¹, Lingyun Shi, MS¹, Fan Mi, MS¹, Fuchiang (Rich) Tsui, PhD¹

¹Tsui Lab, Department of Biomedical Informatics, University of Pittsburgh, Pittsburgh, PA

Introduction
Completeness is a frequently used concept in the field of data quality assessment. Traditional completeness concept addresses counts of missing values. When one seeks to predict a response of interest such as mortality, a newly defined concept on completeness refers to whether the dataset contains sufficient information or risk factors for the predictive task. However, the predictive completeness is not readily observable in the sense that we can't tell the risk factors without running model on dataset. Traditional measures are not able to assess implicit predictive ability of dataset because data required are those that can contribute to prediction. Further, predictiv completeness assessment fully based on physical presence of risk factors in dataset is limited, especially when research interest is associated with more than handful non-ad-hoc risk factors.

It is known that the risk factors of infant mortality include but not limited to a wide range of categories such as antepartum complications, maternal diseases, maternal demographic characteristics, maternal reproductive history, infant birth injuries, infant delivery characteristics, labor and delivery complications, infant diseases, maternal behavior, health care quality and access, and environmental exposures. Therefore, for researches aimed to predict infant mortality, it is imperative to assess data completeness before initiate further data analyses. We propose an assessment method on predictive completeness, and we verify our method on infant mortality by using Magee Obstetric Medical and Infant Database (MOMI) in Allegheny County, which is generated and maintained by the University of Pittsburgh Medical Center (UPMC) Magee-Womens Hospital (Magee). The database includes demographic and medical information for all deliveries at Magee. The datasets retrieved from the MOMI database contains 128,023 records corresponding to 117,929 deliveries of total 88,780 patients between January 1, 2002 and December 31, 2014.

Methods
MOMI dataset has no flags for infant deaths. To identify dead cases in MOMI, we linked 1,021 infant death cases in Allegheny County between 2003 and 2013 from the Allegheny County Department of Health Service (DHS) with MOMI dataset. MOMI records in 2002 and 2014 were removed from this study so that its time range was in accordance with that of DHS data. We applied direct matching using mother’s SSN, mother’s full name, mother’s date of birth and delivery date, which labeled total 496 death cases in MOMI. Further, both stillbirths and fetal deaths were excluded from MOMI dataset. In addition, we removed some features from analyses due to their data quality issues. Final dataset contained 117 predictors including 6 numeric variables and 111 categorical variables. Moreover, DHS provided causes of deaths data for 496 dead cases where death causes comprised 115 diseases. We found the dataset contained 35 causes of deaths that resulted in 281 death cases.

We modeled probability of event of infant death by logistic regression with all 117 variables as predictors. Then we ranked the p-values of regression coefficients of 117 predictors in an increasing order. We listed significant factors (p-value < 0.1) and compare them with 35 causes of deaths.

Results
15 variables in MOMI dataset are identified to be significantly related with infant death (p-value < 0.1, Table 1). The data shows the majority of deaths of infants born at Magee were due to respiratory diseases of infant, short gestation and low birth weight, genetic defects, maternal complications of pregnancy and complications of placenta cord. For assessment on predictive completeness, we found 10 risk factors among 15 are perfectly matched or closely related with 14 causes of deaths, which accounted for 84% of 281 death cases. Associations of other 5 significant risk factors with causes of deaths were not clear. Besides, the value of odds-ratio indicates an association between infant death, and each risk factor is in agreement with common knowledge.

Discussion and Conclusions

Whether a dataset contains sufficient information to predict research interests is the most complex definition of completeness. In this sense, current assessment methods such as simple incidence rate, standardized incidence ratios (SIRs), incidence rate ratios (IRRs), and kappa statistic are not able to measure completeness especially when research interest is associated with many risk factors. We proposed a logistic regression method to examine significance and magnitude of effects of all available features in dataset on research interest. We picked significant risk factors and compared them with known causes of deaths. Our method provides a quantitative, comprehensive yet straightforward data completeness assessment in terms of predictive ability.

Introduction: EHR-based phenotyping is the classification process that infers whether a patient has a specific phenotype, based on the information recorded in his/her electronic health records (EHR). Such extracted phenotypic information can be used to reproduce results of previous genomic studies based on conventional cohorts[1,2], and it is driving new studies as well, such as the phenome-wide association study (PheWAS)[3–5]. The phenotyping process requires an algorithm that aggregates “features”, such as codes or identified terms from the EHR, including diagnosis, symptoms, medications, labs etc. that are related to the phenotype, and the coefficients associated with the features are conventionally determined by model fitting using expert annotated training samples. Designing the features and annotating the samples require tremendous expert involvement and are the major bottlenecks of the development of phenotyping algorithms, which typically takes many months. Previous studies have successfully automated feature designing by leveraging online knowledge sources and unannotated EHR data[6,7]. In this talk, we present PheNorm, a technique to generate phenotyping algorithms without using expert-annotated samples.

Methods: We use a patient’s count of the target phenotype’s ICD-9 codes $x_{ICD}$, the count of the phenotype’s positive mentions in the narrative notes $x_{NLP}$, the count of notes $x_{note}$, and other natural language processing (NLP) features automatically selected by the SAFE method[7] to form a working data set. A derived feature $x_{ICD,NLP} = x_{ICD} + x_{NLP}$ is added. All features are logarithm-transformed. A multiple of the note count is subtracted from the features to make them resemble normal mixture distributions, where the multiplier is determined by minimizing the difference between the empirical distribution and the normal mixture fitted by the EM algorithm. For $x_{ICD}$, $x_{NLP}$, and $x_{ICD,NLP}$, the two modes in the normal mixture represent patients with and without the phenotype. The modified features, excluding the note count, further go through a denoising process using dropout training, where a corrupted version of the features are used to predict the uncorrupted normalized $x_{ICD}$, $x_{NLP}$, or $x_{ICD,NLP}$. The denoising process yields a formula that scores the probability of the phenotype.
Results: We evaluated the accuracy of PheNorm by AUC, using the annotated samples for the phenotypes coronary artery disease, rheumatoid arthritis, Crohn’s disease, and ulcerative colitis that were presented in Yu et al.[7] The AUC of $x_{ICD}$ was 0.84, 0.87, 0.82, and 0.81, respectively for the four phenotypes, and the AUC of $x_{NLP}$ was 0.84, 0.90, 0.91, and 0.90, respectively. Based on $x_{ICD\&NLP}$, PheNorm achieved AUC 0.90, 0.94, 0.95, and 0.94 for the 4 phenotypes, respectively. For comparison, the AUC of algorithms trained with gold-standard labels was 0.90, 0.92, 0.94, 0.94, respectively, when the training sample size $N = 100$ and 0.91, 0.93, 0.94, and 0.95, respectively, when $N = 200$. These sample sizes were chosen as references because current large-scale phenotyping efforts (e.g. 10 phenotypes at a time) rarely have the bandwidth to offer more than 200 gold-standard labels for training for each phenotype, and it shows the potential of our method to streamline phenotyping without compromising the accuracy of a supervised approach.

Conclusion: The key characteristic of high-throughput phenotyping is accurate algorithm generation without the intensive involvement of clinical experts. PheNorm has achieved this by exploiting the underlying joint distribution of the automatically curated features, thus avoiding expert annotation. By fully automating the generation of accurate phenotyping algorithms, PheNorm demonstrates the capacity for EHR-driven annotations to scale to the next level – phenotypic big data.

Predicting Non-Small Cell Lung Cancer Diagnosis and Prognosis by Fully Automated Microscopic Pathology Image Features

Kun-Hsing Yu, MD, PhD1,2,3, Ce Zhang, PhD4, Gerald J. Berry, MD5, Russ B. Altman, MD, PhD2, Christopher Ré4, PhD, Daniel L. Rubin, MD, MS2, Michael Snyder, PhD3

1 Department of Biomedical Informatics, Harvard Medical School, Boston, MA; 2 Biomedical Informatics Program; 3 Department of Genetics; 4 Department of Computer Science; 5 Department of Pathology, Stanford University, Stanford, CA

Abstract

Lung cancer is the most prevalent cancer worldwide, and histopathological assessment is indispensable for its diagnosis. However, human evaluation of pathology slides cannot accurately predict patients’ prognoses. In this study, we obtained 2,186 hematoxylin and eosin stained histopathology whole-slide images of lung adenocarcinoma (AC) and squamous cell carcinoma (SCC) patients from The Cancer Genome Atlas (TCGA) and 294 additional images from the Stanford Tissue Microarray (TMA) Database. We extracted 9,879 quantitative image features and used regularized machine-learning methods to classify cancer types (AUC>0.73) and to distinguish shorter-term survivors from longer-term survivors with stage I AC (P<0.003) or SCC (P=0.023) in the TCGA test set. We validated the survival prediction framework with the TMA cohort (P<0.036 for both tumor types). Our results suggest that automatically-derived image features can predict the prognosis of lung cancer patients and thereby contribute to precision oncology. Our methods are extensible to histopathology images of other organs.

Introduction

Lung cancer causes more than 1.4 million deaths annually. Visual evaluation of the microscopic histopathology slides is indispensable to establishing the diagnosis and defines the types and subtypes of lung cancers1. However, qualitative evaluation of histopathology patterns alone is insufficient for predicting the survival outcomes of patients with lung adenocarcinoma (AC) or lung squamous cell carcinoma (SCC)2,3, and even the best-characterized histopathology features only achieve modest agreements among experienced pathologists4. In this study, we aimed to improve the diagnostic and prognostic prediction of lung AC and SCC patients through machine learning methods5.

Materials and Methods

2,186 whole-slide hematoxylin and eosin (H&E)-stained histopathology images were obtained from The Cancer Genome Atlas (TCGA), which included samples from 515 lung AC patients and 502 lung SCC patients. A segmentation and feature extraction pipeline for 9,879 features (including the size, shape, and texture of cells and their nuclei) was designed using CellProfiler6. Seven supervised machine learning approaches (naïve Bayes, support vector machines with Gaussian, linear, and polynomial kernels, bagging, random forest with conditional inference trees, and Breiman’s random forest) were used for diagnostic classification. Elastic net-Cox proportional hazards models were employed for survival prediction. A held-out test set from TCGA was utilized to evaluate the classification performance. For survival prediction, patients in the test set were classified into good or poor prognostic groups, and the log-rank test was employed to examine the difference between groups. To ensure the extensibility of the developed methods, tissue microarray (TMA) images of 227 lung AC and 67 lung SCC patients from Stanford Department of Pathology were used to validate the diagnostic and prognostic prediction methods. Detailed methods and source codes are available at http://www.nature.com/ncomms/2016/160816/ncomms12474/full/ncomms12474.html.

Results

We extracted 9,879 image features and used them to build machine-learning models for diagnosis and prognosis prediction. Our classifiers identified images of lung AC from those of adjacent dense benign tissue (e.g. inflammation, atelectasis, or lymphocytic infiltration in the absence of tumor cells) with area under the receiver operator characteristics curves (AUC) 0.85 in the test set, classified lung SCC from adjacent dense benign tissue (test set AUC = 0.88), and distinguished AC from SCC (test set AUC > 0.73 for most classifiers; Figure 1A). Our diagnostic classification method was validated in the TMA dataset (test AUC > 0.73; Figure 1B), and the performance of the top classifiers did not differ much (ANOVA test P-value ≥ 0.08). In addition, we built survival models based on the extracted image features and successfully distinguished shorter-term survivors from longer-term survivors with AC (log-rank test P-value < 0.003) and SCC (log-rank test P-value = 0.023). Our machine-learning workflow was validated in the TMA cohort (log-rank test P-value < 0.036; Figure 2).
Figure 1. Quantitative image features successfully distinguished histopathology images of lung AC from those of lung SCC. (A) ROC curves for classifying the two malignancies in the TCGA test set. (B) The results were validated in the TMA cohort.

Figure 2. Quantitative image features predicted the survival outcomes of lung cancer patients. The survival prediction methods were validated in the TMA datasets for both (A) stage I AC and (B) SCC.

Discussion
To our knowledge, this is the first study to predict lung cancer patients’ diagnoses and prognoses by fully-automated quantitative histopathology analyses. Previously, the vast amount of information contained in whole-slide pathology images has posed a great computational challenge to researchers. In this study, we designed an automated workflow that identified thousands of objective features from the images, built and evaluated machine-learning classifiers to predict the tumor types and prognosis of lung cancer patients, and validated our results in an independent cohort. The top features associated with survival outcomes included Zernike shape features of the nuclei and nuclei texture features, demonstrating that the nuanced tumor nuclei patterns are important determinants of patient prognosis.

Conclusion
In summary, we demonstrated that histopathology image classifiers based on quantitative features successfully predicted tumor types and survival outcomes of patients with non-small cell lung cancer. This capability was superior to the current practice utilized by pathologists. Our methods could facilitate prognostic prediction based on the routinely collected H&E stained slides, thereby contributing to precision oncology and enhance the quality of care.

China

Introduction

Patient recruitment has been a persistent barrier to clinical and translational research1. Over 50% of studies fail due to difficulties in recruitment. The universal adoption of electronic health records makes it possible to query distributed, large clinical databases for prescreening potentially eligible patients for performing feasibility assessment or cohort identification for clinical studies. However, interpretations of clinical research eligibility criteria may vary from site to site or from person to person, which can lead to incompatible or mismatched patient queries and compromise the integrity of multi-site studies. In addition, encoding of eligibility criteria into database queries often involves laborious human effort, which is costly, not scalable, and often prohibitive for clinicians and researchers, who do not necessarily understand informatics and know how to map criteria concepts to their data representations. This study aims to build a natural language processing system to transform eligibility criteria text into standards-based cohort identification queries that are sharable and configurable by end users, who can then focus their energy on feasibility assessment and iterative refinement of the criteria based on dynamic feedback with patient counts during eligibility criteria design.

Methods

The system Criteria2Query consists of five modules (Figure 1): i.e., text parsing, criteria filtering, terminology standards-based concept mapping, automatic query formulation, and query execution with dynamic feedback generation for users. Criteria parsing is supported by an open-source machine learning parser, EliIE2, which outputs XML representations for recognized entities and their temporal relationships using the Observational Medical Outcomes Partnership (OMOP) common data model (CDM) V5. Criteria (e.g., “willing to sign the consent” and “able to walk 5 miles on treadmill”) that cannot be queried within EHR for prescreening purposes are filtered out based on heuristics or empirical knowledge. On this basis, an initial event, which is needed to establish the target population, is selected automatically while allowing for user configuration. Concepts and their relationships in retained criteria are then mapped to the Observational Health Data Sciences and Informatics (OHDSI) controlled clinical vocabularies to obtain concept IDs for each concept and to create structured cohort definitions, which are further translated into cohort queries in JSON or SQL formats using a public OHDSI Web API (https://github.com/OHDSI/WebAPI). These queries can be executed against any OMOP CDM-based patient database to prescreen potentially eligible patients. We evaluated the usefulness and cost-effectiveness of Criteria2Query by documenting the time saved by using Criteria2Query when translating clinical trial eligibility criteria into queries for a professional clinical database query technician.

Results

Example queries and their results are shown in Figure 2. Criteria2Query enables the generation of executable cohort queries that can be shared across different CDM-based databases to return counts of distinct patients satisfying the criteria. The system enables a closed feedback loop from criteria text to patient counts and allows iterative criteria refinement based on data feedback. This feedback can inform clinical study designers to author more realistic criteria for their research. Criteria2Query can be used as a standalone system to generate SQL queries from text or used as a middleware for different clinical decision support systems based on OMOP CDM. According to our preliminary evaluation with one technician, who performs criteria-to-query translation in our institution, in general an experienced user needs > 40 minutes to create CDM cohort queries for clinical studies. This time includes defining concept sets and identifying the condition event, the observational event and several other events. The use of Criteria2Query noticeably reduced cohort generation time to be an average of 15 minutes per study, with nearly 60% reduction of time.

To successfully perform clinical research of sufficient power, clinician researchers need to recruit an adequate number of patients meeting the eligibility criteria of their research. Clinicians may not have the information about how many
patients meet their requirements in clinical data warehouse, and may not know the number of the candidates when they are designing the criteria. Criteria2Query empowers clinicians and researchers to interrogate the patient databases directly and provides real-time feedback about the number of potentially eligible patients so that they can further fine tune the criteria in a user-friendly interface iteratively. Criteria2Query removes the need for clinicians and researchers to understand SQL and allow them to better focus on iterative feasibility assessment and criteria optimization.

Conclusions
Criteria2Query demonstrates early promise for improving the efficiency for cohort identification for EHR-based comparative effectiveness studies and empower researchers or clinicians to identify patient cohorts without mastering knowledge of patient database or clinical terminology. Future studies are warranted to test the correctness, usability and cost-effectiveness of this system at a larger scale and in a more systematic manner.

Revision of Order Sets Using Experts’ Knowledge and Data-Driven Evidence

Yiye Zhang PhD¹, Richard Trepp MD²,³, Jorge Luna MS, MPH, MPhil², David K. Vawdrey PhD²,³, Victoria L. Tiase MSN, RN-BC²
¹Weill Cornell Medical College, New York, NY; ²NewYork-Presbyterian Hospital, New York, NY; ³Columbia University Medical Center, New York, NY

Introduction
Order sets are a core component of Computerized Provider Order Entry (CPOE) systems and serve to facilitate more efficient and effective order entry¹. Order sets allow providers to select multiple relevant orders with a few clicks by presenting appropriately grouped medical orders, thus increasing the efficiency of ordering. They also serve to reduce variation in the ordering process and encourage compliance with best practices². Order sets are designed based on the intended functions and ordering times of their content items¹. For example, an ‘AM Lab Order Set’ is used at our institution to order laboratory tests to be collected the next morning. Items in the order set can be further customized with default settings according to clinical relevance, recommended practices, and frequency of usage.

One significant concern raised with CPOE is the burden of excessive mouse clicks in placing orders, which potentially lead to undue workload for providers and even medical errors². As an alternative to using order sets, providers can place orders a la carte; however, a la carte items often require even more clicks than order sets, and thus contribute to increased workload. An emerging approach to this challenge is to develop and optimize order sets based on data-driven evidence²,³. With data-driven order sets, though, it may be difficult to incorporate experts’ knowledge and policy-driven standards that are not identifiable from data. Taking our institution’s ‘AM Lab Order Set’ as a case-study, we investigated the workload associated with the usage of this order set. We simulated 5 scenarios to examine approaches for order set revision that incorporates data-driven evidence, experts’ knowledge, and policy-driven standards, and compared the number of mouse clicks required to use the order set after each simulated revision.

Methods
We obtained patient characteristics and order-related information from September 2014 to September 2015 from an electronic health record (EHR) system (Allscripts Healthcare Solutions, Inc.) at our institution. The ‘AM Lab Order Set’ contained the 12 order items shown in Table 1. It was used nearly 200,000 times during the one-year study period. Data included 1,065,401 order placements for 27,419 patients who had at least one order placed via the ‘AM Lab Order Set’. This order set was used 6.7 times (SD=10.55), on average, over an average length of stay of 4.8 (SD =10.31) days during the study period. Variables include de-identified ID, order name, order set name (or a la carte), time stamp of order placement, Diagnosis-Related Group (DRG), and patient demographic information. All items in the ‘AM Lab Order Set’ were unselected by default (i.e., default-OFF) in the CPOE user interface.

232
Click cost (CC) is defined as the number of mouse clicks associated with performing a task\(^2\). For this analysis, to compute CC from data, we estimated that it required three clicks to open an order set, and one click to select a default-OFF item or to de-select a default-ON item. We also estimated that it required three clicks to place an *a la carte* order. Estimates were based on the specific EHR interface at the study site. Table 2 describes seven simulated scenarios for revision of the ‘AM Lab Order Set’. In M1, orders that were defaulted to ON are ‘basic metabolic panel’, ‘CBC with differential’, and ‘magnesium.’ The six most common orders in M3 include ‘b/p, hr, rr and temp’, ‘general nursing’, ‘glucose whole blood poc’, ‘magnesium sulfate inj’, ‘calcium, serum’, and ‘heparin inj’. Furthermore, we applied simulations (M4 to M7) that combine scenarios M1 to M3.

**Results**

Figure 1 shows the average CC per patient across M0 to M6. The lowest CC was obtained in M4 when we revised using experts’ knowledge with the data-driven evidence of most commonly co-occurred orders with ‘AM Lab Order Set.’ The reduction was 65,806 clicks for all patients in a year for this one order set. M6 incorporates M4 with policy-driven standards, which noted that while ‘general nursing’ is a common order, it should be replaced by a specific nursing order. M6 had the second lowest CC, which shows promise in its future implementation, and we also expect to see a larger effect of M6 in reducing CC in future data. Adding defaults in M1 resulted in the third lowest CC, performing better than revising orders based on experts’ knowledge or data-driven evidence alone. The difference in the average CC between M0 and M4 is significant with a p-value <0.00 and a confidence interval of [0.78, 4.22] using T-test.

![Figure 1](image.png)

**Discussion**

This study demonstrated that when revising order sets, incorporating both experts’ knowledge and data-driven evidence may result in the most efficient ordering process for providers. Future work should examine order sets of varying complexities and designed for disparate purposes to generalize findings, as well as relations between over-utilization of services and order set settings such as defaults. While data-driven evidence in this study was based simply on frequency of orders, future work will also employ more advanced data analytics methods such as clustering algorithms to identify optimal order set assignments in reducing the click costs.

Abstract

Objectives: To discover the cohesive progressive subtypes of Parkinson’s Disease (PD) patients using comprehensive data provided by the Parkinson's Progression Markers Initiative (PPMI). Methods: To explore the sequentiality of the patient records, we propose to leverage the Long-Short Term Memory (LSTM) model, which is a variant of Recurrent Neural Network that received extensive attentions in natural language processing in recent years. In particular, we first concatenate the records for each patient into a sequence according to their associated timestamps. Then we train an LSTM model on top of those sequences and embed them into a latent homogeneous sequence space. Patient similarity will be evaluated on those latent sequence embeddings and finally the progressive subtypes were identified through clustering with the learned patient similarities. Results: We performed evaluation using 6-years PPMI data including 15,798 patient records with our proposed methodology. Eventually three PD subtypes were identified. Statistical testings were conducted to identify the discriminative factors for each subtype for characterization purpose. The first subtype was characterized by moderate function decay on motor ability and stable cognitive ability. Patients in the second subtype had mild function decay on both motor and non-motor ability. The third subtype was characterized by rapid progression on both motor and non-motor ability.

Methods

As Parkinson's Disease has been demonstrated large clinical heterogeneity, identifying subtypes may facilitate the further research on underlying etiologies and designing appropriate therapies. Because of the various challenges on working with heterogeneous patient data (e.g., sparsity, heterogeneity, noisiness, etc.), learning proper representation for each patient is important. This paper presents a novel framework based on Long-Short Term Memory (LSTM) recurrent neural network to represent patients by incorporating patient records from multiple sources. We divided the feature in patient records into two parts: inputs or targets. Targets are a set of determinant variables that are closely related to the progression of PD shown in previous clinical studies. Other variables were regarded as input features. The dimension of input features and targets were 319 and 82, respectively.

Before training the LSTM with inputs and targets, we first performed some pre-processing on the raw patient records. Most of the patient features are temporal with different value types. Some of them are continuous while the others are categorical. We transformed the categorical features into one-hot representation. For instance, if one variable contains three values: red, blue, and green, we encoded the red as 001, blue as 010, and green as 100 respectively. There could also be lots of missings in patient records, we just use the simple Last Occurrence Carry Forward (LOCF) to impute them. If the missing value is at the beginning, we will carry next value backwards. Otherwise if the all values for the entire feature are missing, we just impute them with average feature values over all patients. Once the sequential input and target vectors are prepared, the neural network can be trained on top of them. In LSTM, the representation vector $h_t$ (t is the index for timestamp) can be computed by following equations:

$$i_t = \sigma(W_i[x_t, h_{t-1}] + b_i); \quad f_t = \sigma(W_f[x_t, h_{t-1}] + b_f); \quad o_t = \sigma(W_o[x_t, h_{t-1}] + b_o)$$

$$c_t = \tanh(W_c[x_t, h_{t-1}] + b_c); \quad h_t = o_t \cdot \tanh(c_t)$$

where $\sigma(x)$ is the logistic sigmoid function, $i$, $f$, $o$ and $c$ are respectively the input gate, forget gate, output gate, cell state. When training LSTM, we use square loss for continuous valued targets and logistic loss for binary valued targets. After the sequential embeddings $\{h_t\}$ are learned, we use Dynamic Time Warping (DTW) to measure the similarities between pairwise patient embeddings and t-SNE to visualize the patients as data objects in two-dimensional space, where the pairwise patient similarities are preserved. Finally, Kmeans was deployed on the t-SNE results to get the patient clusters as subtypes.

The data set we used in our study is from the Parkinson’s Progression Markers Initiative (PPMI) study organized by Michael J. Fox Foundation. PPMI is an ongoing observational, international, multi-source study that has various Parkinson’s disease progression markers including demographics, clinical, imaging and biospecimen. The data contained archives of enrolled subjects from June 1, 2010 to June 1, 2016, and consisted of 15,798 heterogeneous records of 683
subjects including 466 PD patients and 217 healthy controls. On average, each patient had approximately 23 records. To build an LSTM model, the data were randomly split to 60% training, 20% validation, and 20% testing.

Results

One difficulty for evaluation of disease subtyping results is that there is no ground truth. Therefore, visualization provides an effective way of perceiving the results. Figure 1 shows the t-SNE visualization of the patients in two-dimensional space based on the DTW similarities, from which we can clearly observe three relatively well-separated and compact patient groups. To characterize each subtype, we also conducted rigorous statistical testing for each of the features in patient records. The testing is done with respect to both the value mean at the baseline and follow-up for each feature. Discriminative variables with \( p \)-value \(<0.05\) were identified and shown in Table 1. At baseline, the first subtype of 201 patients with average age 58.79 years old was characterized by the mild motor stage of H&Y and MDS-UPDRS Part I-II, the slightest non-motor symptoms of cognitive impairment, depression, anxiety among three subtypes. The motor severity of the second subtype of 107 patients with average age 61.93 was similar with the first subtype. However, several non-motor manifestations such as cognitive, depression, and anxiety of subtype II were worse than subtype I. As for subtype III of 158 patients with average age 65.32, almost all of the motor and non-motor symptoms were severer than the two former subtypes. After a 6-year follow-up, we conducted the statistical tests on the difference of mean values between the start timestamp and end timestamp, and discovered discriminant variables of disease progression. By comparing the baseline and follow-up feature values, we can observe the following: the first subtype was with moderate function decay on motor ability and stable cognitive ability; the second subtype had mild function decay on both motor and non-motor ability; and the third subtype suffered rapid disease progression on both motor and non-motor ability.

Assessing Electronic Health Record Readability

Jiaping Zheng¹, Hong Yu, PhD²

¹College of Information and Computer Sciences, University of Massachusetts Amherst, MA; ²Department of Quantitative Health Sciences, University of Massachusetts Medical School, Worcester, MA

Introduction

Patient engagement¹ has emerged as an important component of strategies to improve health care. A growing body of evidence has accumulated on better health outcomes and care experiences associated with higher engagement². Electronic Health Record (EHR) systems with patient engagement capabilities have also enjoyed tremendous growth in usage recently³. However, access to EHR by itself is not sufficient to motivate patients to be involved because of the complex and technical nature of the EHR. Furthermore, many patients have limited health literacy and are not proficient in comprehending and acting on health information⁴. Integrating tools that can match clinical narratives within patients’ literacy capabilities into EHR may make them more accessible.

In this study, we explore methods to automatically assess readability levels of clinical narratives in EHR. Numerous readability metrics have been developed to assess the a document’s grade level. For example, Flesch-Kincaid Grade Level (FKGL)⁵ predicts grade level using average sentence and word length. This metric and many others rely on the assumption that longer words and sentences are more difficult. However it may not hold for EHR narratives as sentences are usually short and abbreviations are common. Our previous work⁶ has demonstrated that these formulas did not show adequate correlation with readers’ perceived difficulty, and were not appropriate to assess the readability of EHR notes. In this work, we considered measuring readability as a ranking task, where the relative difficulty of two documents are compared. Our method can be applied to both EHR narratives and a Personal Health Record system.

Method

Amazon Mechanical Turk (AMT) users were recruited to rate 20 random document pairs based on their perceived difficulty. They are requested to rate the readability of the documents on a scale from 1 (easy) to 10 (difficult). The document pair was of similar length (±50 tokens) and comparable difficulty according to FKGL (±0.5). The sources of the documents included Wikipedia (denoted as “wiki”) and de-identified EHR notes (denoted as “med”). Three common diseases were selected: cancer, diabetes, and hypertension. Wikipedia documents were randomly selected from the respective disease category, EHR notes using ICD-9 codes. Document statistics are shown in Table 1.

<table>
<thead>

</tr>
</tbody>
</table>

We learned a support vector machine model from the pairwise comparisons from AMT user’s ratings. In this setting, one example is generated when two documents were assigned different scores by a user. Score differences by different users were not used to generate examples since the difference may be due to the users’ background knowledge. A model was then learned using SVM²³⁶. We employed several types of features, including readability formula based, word frequency, and neural language models. We included word and sentence length, and proportion of polysyllabic words from readability formulas. We also included word frequency obtained from Wikipedia and EHR notes as features, since common words are likely to be easier to understand. Additional features included document length in words and sentences. Long documents requires more cognitive processing to comprehend, which might translate to higher perceived difficulty. Lastly, we captured language patterns using word embeddings learned from a combination of Wikipedia documents and de-identified EHR notes.
Results

We split the annotated data three ways (70%/10%/20%) into training, development, and test sets. The three disease topics were stratified. Hyperparameters were optimized on the development set. We evaluated our system using Kendall’s coefficient of concordance $W$, a statistic that measures the agreement between rankings. This metric ranges from 0 to 1. The best agreement between our system and the AMT annotators on the test set was 0.65. As a comparison, we show the distributions of $W$ between two AMT users in Figure 1. Our system’s concordance to a human annotator is comparable to the average between two AMT users’. Existing machine learning based systems were usually designed around classification. They are often limited to a few pre-defined labels or require corpus labeled at distinct levels.

![Figure 1: Histogram of Kendall's W between AMT users.](image1.png)

To highlight the range of difficulty perceptions by AMT users, Figure 2 shows the maximum difference in ratings assigned by AMT users on documents that were rated by at least two users. The mean difference is 3.6, suggesting that perceptions of difficulty vary considerably among users.

![Figure 2: Max difference in AMT ratings on a document.](image2.png)

Conclusion

Patient’s access to EHR notes has increased dramatically according to national statistics. However, actively engaging patients remains challenging. Assessing EHR notes’ readability may make them more accessible. We developed a new machine learning based method toward this end. We collected document difficulty ratings from AMT users on EHR notes and Wikipedia articles. Our method learned a ranking model from comparisons of the difficulty judgments. Our experiments showed that its concordance with a human user was similar to the concordance between different human annotators. This method can potentially be personalized to better accommodate for users’ background knowledge.

Acute Kidney Injury in the Intensive Care Unit: Timing and Detection

Leming Zhou, PhD1, Valerie Watzlaf, PhD1, Christopher Keener, BS2, Dilhari DeAlmeida, PhD1, Rebecca DeSensi, BS2, Emily Foldes, MS2, Gilles Clermont, MD1, John A. Kellum, MD2

1Department of Health Information Management, University of Pittsburgh, Pittsburgh, PA; 2Department of Critical Care Medicine, University of Pittsburgh, Pittsburgh, PA

Introduction

Acute kidney injury (AKI) is common during critical illness occurring in approximately 30-60% of patients and is associated with a case fatality rate of approximately 60%-70%1-3. With no known unifying mechanism and unsatisfactory treatment, AKI is a devastating illness4. Serum creatinine (sCr) is used as one of the biomarkers (along with urine output) in the standardized AKI definition recommended by the Kidney Disease Improving Global Outcomes (KDIGO) guideline5.

However, sCr is a delayed signal of AKI and is not monitored continuously. AKI may occur in between measurements of sCr. In other words, AKI staging based on sCr lags behind actual renal damage. This delay may directly impact patient outcomes. Therefore, in this work, we sought to determine the time delay between the theoretical start of stage 2 AKI according to the sCr trajectory and the actual detection of stage 2 AKI from measured sCr values, and the impact of this delay to the patient outcomes, such as cost, length of stay, and mortality. The results may lead to a more proper way of managing AKI cases at the early stage. Here the stage of AKI is determined by the widely validated KDIGO criteria5.

Methods

This retrospective, observational cohort study used information from the HiDenIC database. Clinical and administrative data, including demographic, procedural, diagnostic, laboratory, pharmacologic and billing information on all patients admitted to one of eight intensive care units (ICUs) at the University of Pittsburgh Medical Center (UPMC) from 2000 to 2008 are contained in HiDenIC. The source population includes more than 54,000 patients. We excluded patients with severe existing kidney disease (sCr > 3.5 mg/dl), including those on chronic hemodialysis or kidney transplant recipients. From 41,821 patients 18 years of age or older, we identified 1,014 patients who developed stage 2 or 3 AKI based on the KDIGO criteria after ICU admission. These patients also had a baseline sCr value and a sufficient number of in-hospital creatinine measurements available to reliably fit a regression line to determine the AKI event time and slope of the creatinine kinetics. Once the creatinine kinetics were determined and the AKI event time was identified for each patient, we further excluded patients whose projected AKI event occurred prior to hospital admission, whose creatinine values fluctuated heavily during hospitalization, or with gaps > 96 hrs between sCr measurements. The final study population included 362 patients and almost all of them (98.9%) were admitted to UPMC Presbyterian.

All sCr trajectories were visually examined. It was noticed that only the last three sCrs (before or at the detection of stage 2 AKI) reflected the trajectory of AKI and all other sCr measures before the start of AKI typically fluctuated around the baseline. Linear regression precisely shows the trajectory of these three sCr values (as demonstrated in Figure 1). The slope from the linear regression is a measure of the rate of renal functional loss and probably is proportional to the degree of injury. The time windows from the theoretical onset of AKI to the detection of stage 2 AKI were determined according to this linear regression. The times of onset of AKI and theoretical stage 2 AKI were calculated. The time difference between this theoretical stage 2 AKI and the actual detection of stage 2 AKI is the diagnosis delay (Dx Delay in Figure 1). By definition, before the start of AKI, time gaps between sCr measurements do not have direct impact on the timeliness of AKI detection. Only the last two gaps (sCr measure gap 1 and sCr measure gap 2, especially sCr measure gap 2 shown in Figure 1) are closely related to the diagnosis delay. The average of these two sCr measure gaps is the mean gap. The correlation coefficients between diagnosis delay and slope, and between slope and mean gap were calculated.
Total hospital cost associated with the hospital visit was determined by first converting all charges recorded during
the visit to cost using the appropriate cost-to-charge ratio as defined for the specific cost center and year of the charge.
All resulting costs related to the visit were summed and a total cost calculated. The costs were inflated to 2013 US
Dollars using the Consumer Price Index for Medical Care Services from the US Bureau of Labor Statistics. Hospital
and ICU Length of Stay (LOS) were determined by calculating the number of days between admission and discharge.

We used logistic regression to examine the association between mortality and the slope of the sCr kinetics and
diagnosis delay. Mortality outcomes included hospital mortality, as well as mortality at 30-days and 1-year following
ICU admission. Models were adjusted for patient age, severity of illness factors, comorbidities and surgical
admissions. In addition, we assessed resource use and factors that contribute to hospital costs, including the hospital
and ICU LOS and renal replacement therapy (RRT) use. Models for LOS were created for patients who were
discharged from the hospital alive in order to eliminate the competing risk of death prior to discharge. Zero-Truncated
Negative Binomial Regression models adjusted for baseline illness and admission type (surgical or medical) were
created to predict the relationship between hospital and ICU LOS and the slope of the creatinine kinetics and diagnosis
delay. Adjusted logistic regression models were also created to determine the association between slope and detection
delay and in-hospital RRT use. We created multiple regression models of the log-transformed costs to determine the
association between the slope and the diagnosis delay and total hospital costs.

**Results**

The minimum value of the mean gap was 3.35 hours and the maximum value of this variable was 71.5 hours (mean =
20.5 and SD = 8.85). The median time window between the start of AKI to stage 2 AKI was 41 hours (min = 6.43,
max = 184.73, mean = 54.05, SD = 29.91). The median diagnostic delay was 2.25 hours (min = 0, max = 34, mean =
6.74, SD = 6.45). The correlation coefficient between slope and diagnosis delay was -0.070 (P = 0.18). In other words,
the rate of AKI development was not correlated with the diagnosis delay. The correlation coefficient between slope
and mean gap is -0.587 (P < 0.001), which means the faster the AKI developed (greater slope), the more frequent the
sCr was measured. The logistic regression models did not show a significant association between hospital mortality
(30-days and 1-year mortality after ICU admission) and slope or diagnosis delay (P = 0.49, OR = 0.98 for 30-day
mortality and P = 0.27, OR = 0.98 for 1-year mortality, respectively). Similar results were seen for the relationship
between hospital LOS, ICU LOS, RRT use, and slope or diagnosis delay. There was no significant association between
hospital costs and the slope or diagnosis delay. However, we did notice that steeper slopes (more rapidly worsening
renal function) were generally associated with increased mortality, hospital cost, and RRT use.

**Discussion**

Using existing knowledge concerning creatinine kinetics, changes in serum creatinine over time, and the time-stamped
reporting of creatinine, we determined the relationship between diagnosis delay (slope or rate of sCr change during
AKI development) and patient outcomes. The results indicate that clinicians already adjust the frequency of sCr
measurement according to the speed of AKI development, thus limiting diagnosis delay. This delay therefore was not
associated with a significant difference in patient outcomes. If simple computational modeling could be introduced to
forecast the development of stage 2 AKI, physicians might introduce interventions (such as fluid administration,
discontinuation of ongoing nephrotoxic drugs, or administration of drugs that reduce the nephrotoxicity) before the
occurrence of stage 2 AKI, which may in turn produce lower mortality rate and costs. However, our results indicate
that more frequent monitoring with sCr would not produce a meaningful improvement in the timeliness of AKI
diagnosis. Other methods to predict AKI before it occurs will be needed to improve outcomes.

Introduction

Traditionally, clinical trials are conducted within the confines of academic medical centers, hospital systems, or institutions where clinical care is delivered. This is a longstanding process due to the effectiveness of research within a clinical setting related to regular contact with patients, access to clinical data, and research teams to execute data collection and analysis. Inadvertently, the current approach neglects patients who fall outside of the clinical system and may otherwise be the most eligible for clinical trials. We present a novel approach to recruit eligible patients directly from the community, while also leveraging affiliated health systems to extract clinical data for community participants. This approach will be tested in a PCORI funded, nationwide trial, ADAPTABLE.

ADAPTABLE (Aspirin Dosing: A Patient-centric Trial Assessing Benefits and Long-Term Effectiveness) trial is the first demonstration project conducted through PCORNet1. PCORNet: The National Patient-Centered Network is purposed to build a “network of networks” of various healthcare institutions and stakeholder groups and build partnerships to collect and use data for improved comparative-effectiveness research2,3. ADAPTABLE not only seeks to answer a clinical question, but to assess whether efficient and low-cost clinical trials can be conducted during “real-world” medical care1. ADAPTABLE presents a new model for clinical trials, aiming to minimize the burden of research activities on patients, clinicians, and institutions, by using existing EHR data and patient-reported outcomes to answer clinical questions1. This three-year pragmatic clinical trial is designed to compare the effectiveness of two aspirin doses, low (81 mg/day) vs. high (325 mg/day), in preventing myocardial infarction and stroke among 20,000 individuals with coronary heart disease1.

Methods

Northwestern University is the lead CAPriCORN (Chicago Area Patient Centered Outcomes Research Network) site for the ADAPTABLE trial, among four additional sites, University of Chicago, Rush University Medical Center, NorthShore University HealthSystem, and Cook County Health & Hospitals System. Each site maintains their own pool of eligible patients for ADAPTABLE. The community-based recruitment strategy is unique to the ADAPTABLE national network, proposed and tested by the CAPriCORN system. No other participating Clinical Data Research Networks (CDRNs) are engaging the community in ADAPTABLE recruitment at this time. The community-based recruitment strategy incorporates two community institutions into this existing workflow, the Sinai Urban Health Institute (SUHI, https://www.sinai.org/content/sinai-urban-health-institute-0) and PASTORS4PCOR (P4P, http://www.southlandmhn.com/pastors4pcor/). The community-based recruitment workflow is depicted in Figure 1.

Figure 1. Overall community-based recruitment workflow and participating organizations.
To be eligible for the ADAPTABLE trial, potential participants identified at the community site must be linked to a CAPriCORN institution for future follow-up queries of the participant’s clinical data by the ADAPTABLE Team. The linkage not only allows for assessment of whether the participant receives care at a CAPriCORN site, but also validates eligibility for patient-reported answers to the initial screening questionnaire by comparing these data to clinical data at CAPriCORN sites. Potential study participants are directly enrolled at community events, and the eligibility is assessed and demographics are collected using REDCap (Research Electronic Data Capture, https://projectredcap.org/about/). Medical Research Analytics and Informatics Alliance (MRAIA), serves as CAPriCORN’s data hub and honest broker, and assists in the de-identified patient linkage. For matching patients, the “Golden Ticket” is assigned and credited to community partners. Various stages in the community-based recruitment are described in Figure 2.

**Results/Discussion**

The CAPriCORN approach to the ADAPTABLE trial is leading the way in demonstrating the potential for new, low-touch, clinical trial methods. Recruiting participants directly from the community is a primary step in building more efficient and thorough patient recruitment methods for clinical effectiveness research. Through our initiative, we developed a community-based recruitment strategy to connect two community institutions, SUHI and P4P, to clinical sites within the CAPriCORN ADAPTABLE trial system. We created a workflow incorporating tools for data collection, linkage, and tracking. The CAPriCORN recruitment goal for ADAPTABLE is to consent and randomize 2,800 participants over the 1.5-year enrollment period, ending January 2018. Of the total enrollment goal, 30% are anticipated to come from the community. The methods described above will be used to reach this recruitment target. By the end of year one, we anticipate to have a demonstrable patient population recruited from the community. We will present learnings from implementation and actual recruitment results at AMIA 2017 Annual Symposium in November 2017.

Abstract

The human microbiome consists of the organisms that accompany us at all body sites our entire life and contribute to the health and disease processes. Actionable associations of the host microbiota with health conditions span many health areas, such as oral and dental health, inflammatory bowel disease, metabolic syndrome, and other systemic conditions, and cancers. In addition, the value of microbiome for diagnostic and prognostic tasks is becoming more prominent. As such, microbiome is becoming a vehicle for precision medicine research. The underlying data enabling microbiome research are high-throughput, complex, and heterogeneous. Extensive informatics expertise is required at all translational steps (basic, clinical, consumer and public health) to understand and utilize these data for precision medicine. The purpose of this panel is to discuss the representative precision medicine efforts in the microbiome domain at academic, public, and federal institutions. Our goal is to understand the breadth of deployed expertise in these efforts and achieve roadmap for alignment of informatics efforts to maximize the broad positive impact on precision medicine.

Panel description

Microbiome is a term used to describe the collection of all microorganisms that colonize our bodies. In their numbers the bacteria are at parity with the mammalian cells in our bodies. Functionally, our microbial ‘second genome’ contributes upwards to 100 times the functional genomic diversity. Whereas understanding the human genome has received enormous amount of attention in the last 15 years, the impact of host associated microbiome genomes (the metagenome) and their function in human health and disease is still in very early stages of being conceptualized. The recent surge in microbiome science has been afforded by increasing availability of technologies, such as high-throughput DNA sequencing, mass spectrometry, automated cell sorting, etc. Most notably, of course, the ability to sequence hundreds of individual microbiomes in a single run of a sequencing instrument has resulted in a perfect storm of microbial community profiling datasets addressing a vast array of biomedical questions. In addition to being a vehicle for hypothesis generation in basic research, increasingly, microbiome is being utilized for translational tasks. Specific examples include hospital associated infection management and more recently building personalized precision medicine approaches for clinical decision support.

The complexity of the microbiome itself and the sophistication of the microbiome assay technologies necessitates involvement of quantitative scientists in many branches of knowledge including informatics. Many data challenges are still outstanding in the microbiome arena. For example, there is currently a gap in standards and standard reference resources for microbial identification. Standardization of microbiome measurement is still to be achieved. This results in lack of comparability of outcomes of different experimental groups. Poor reproducibility of results is a major barrier to translating the findings into useful application. Another translational roadblock is the fact that the experimental microbiome data is typically far removed from the health record data. A standard for integration of microbiome assay results into clinical reports does not currently exist. Finally, microbiome research is maturing to include true epidemiological scale studies involving thousands of subjects. This brings the field to novel challenges all too familiar to medical informatics community, including data standardization, management, integration, security, etc.

This is the third panel on microbiome research presented to the biomedical informatics community. The first panel on “S09: The Human Microbiome: Informatics Challenges and Opportunities” has taken place at the AMIA Annual Symposium 2016 in Chicago and provided a high-level overview of the challenges in the microbiome research where informatics can make a difference. The main goal has been to introduce the concepts in microbiome to the medical informatics community and invite collaboration among AMIA members. The panel has been attended by over 70 individuals including the 2017 AMIA Annual Symposium keynote speaker, Jessica Richman. The panel has been...
followed by an informal social, ‘Probiotic breakfast’ attended by about half dozen of AMIA members. The second panel on “IIT02: Tools for Accessible and Reproducible Computing in Microbiome Research” at AMIA Summits 2017 will specifically address implementation science in microbiome research and focus on tools that enable reproducible computing and lower the bar for biomedical investigators to perform their own analyses.

This goal of the proposed panel is to highlight translational microbiome research at academic institutions, public, and federal agencies. Specific focus will be on how this research links to precision medicine, as well as the ways that this research will have a lasting formative impact on human health. The secondary goal of the panel is to strengthen links between government agencies, public organizations, and medical informatics community. A likely outcome of this will be standing communication and collaboration between these communities.

**Brief description of each panelist’s presentation**

- **Dr. Alekseyenko**, “Microbiome as a platform for precision medicine at population level”
  This presentation will focus on our efforts at MUSC to measure microbiomes of our entire in-patient population and to utilize these data for development precision medicine approaches to triage and intervention in common clinical conditions, growing new branches of our learning health system.

- **Dr. Proctor**, “NIH Human Microbiome Project and Trans-NIH Microbiome Working Group”
  This presentation will highlight the funding history of the microbiome at NIH including conception, execution, and results of HMP and current state of the HMP 2.0: the Integrative Human Microbiome Project. The presentation will highlight future ways that NIH is supporting translational microbiome research as it relates to precision medicine.

- **Dr. Carlson**, “Microbiome research at Food and Drug Administration”
  This presentation will discuss research related to the microbiome that is ongoing across FDA centers. Projects focused the microbiome in infectious disease resistance, food safety, antibiotic utilization, nanoparticles, and tobacco use will be discussed.

- **Dr. Jackson**, “On the state of standardization of microbiome measurements”
  In 2016, the NIST has launched an initiative on standardization of microbiome measurements. This presentation will focus on the challenges and issues involved. The potential roles for informatics in this process will be discussed.

- **Dr. Chen**, “Emerging issues subcommittee on the role of microbiome in human health”
  Microbiome varies across individuals and is documented to interact with drugs and environmental chemicals. This is a specific example of factors beyond genetics that defines personalized response to such exposures. This presentation will discuss a new effort by HESI to foster collaboration on microbiome in toxicity, disease and drug interactions.

**Relevance of topic and anticipated audience:**

The White House precision medicine initiative, which is likely to shape the research funding policy in the next few years, specifically calls microbiome an important characteristic for Precision Medicine. In 2016, the White House Office of Science and Technology Policy has announced the Human Microbiome Initiative “to foster integrated study of microbiome across different ecosystems”. The initiative calls for supporting interdisciplinary research in microbiome and development of platform technologies to enable such research. With changing administration, the importance of microbiome as a precision medicine modality will likely to continue being recognized and valued. We anticipate that this panel will be interesting to attendees working in the translational informatics realm, specifically those focusing on precision medicine.

**Discussion questions:**
1. What resources to support translational microbiome science currently exist?
2. What key expertise is lacking or inadequately present on the microbiome arena?
3. What translational value does the microbiome hold and in what specific areas of medicine and health?
4. What are the national and regional centers for microbiome research and what opportunities for involvement exist?
5. How is microbiome science incorporated in biomedical informatics training?

**Learning objectives:**
1. Recognize the existing technologies to survey the human microbiome and the biological aspects they capture;
2. Understand the history and development of microbiome research;
3. Recognize the potential and limitations of host-microbiome data for precision medicine;
4. Identify key issues with standardization of measurement and data sharing of microbiome data;
5. Identify translational areas which can be positively affected by better characterization of human microbiome.

The organizer confirms that all participants have agreed to take part on the panel.
Redesigning the “Choice Architecture” of the EHR to Reduce Clinical Decision Support Burden
Jessica S Ancker, MPH, PhD,1 Sameer Malhotra, MD, MA,1,2 Yiye Zhang, PhD, MS,1
Adam Cheriff, MD1,2
1. Department of Healthcare Policy & Research, Division of Health Informatics, Weill Cornell Medicine, New York, NY; 2. Department of Medicine, Weill Cornell Medicine, New York, NY

Abstract
In this panel, experts will illustrate how the design of health information technology can be optimized for better decisions, with a specific focus on ways to minimize the need for alert-based clinical decision support. These design interventions exploit the technology’s “choice architecture,” a term from cognitive psychology which describes the way a system presents choices to decision-makers. (For example, the US “choice architecture” presents organ donation as an opt-in decision; other countries present donation as an opt-out decision in which anyone who does not sign an opt-out registry is eligible to be a donor.) Through three case studies, panelists will demonstrate how decisions can be improved by choice architecture in the context of electronic prescribing, order sets, and patient portals. After the panel, participants will be able to: define “choice architecture”; describe how “choice architecture” interventions can provide alternatives to clinical decision support alerts; analyze ethical implications of intervening in the “choice architecture”; describe several successful EHR “choice architecture” interventions.

Introduction
One of the central goals of medical informatics is to facilitate better medical decision making. A wealth of research and practice has examined ways to improve decisions through electronic clinical decision support (CDSS).1-3 Despite the successes of CDSS, its effectiveness may currently be limited by overuse. Contemporary research shows that clinicians now override or ignore more than 90% of alerts they receive.4,5 Alert effectiveness may be impaired by high rates of false alarms, delivery approaches that interrupt workflow, a reliance upon relatively effortful cognitive processes such as reading, and other design flaws.1,6-8 Combined with the sheer volume of alerts in contemporary systems, these failings lead to “alert fatigue”9-11 and habitual override behavior.12 Less intrusive approaches are needed if EHRs are to live up to their potential to support effective decision-making.

A powerful and relatively poorly exploited influence on decisions is the “choice architecture” of the system. “Choice architecture,” a term originating in cognitive psychology and behavioral economics, describes the ways in which a social or technological system presents choices to decision-makers.13 The same choice may be presented in many ways, and these ways strongly influence decisions.13-18

One feature that affects how people perceive decisions is the default option. In countries where all individuals are organ donors by default, those who do not wish to donate may sign an opt-out registry. Organ donation rates are far higher in these countries than in others (such as the US) in which the choice is presented to citizens as an opt in.15 Similarly, savings rates in 401(k) plans are highest when new employees are defaulted to participate but allowed to opt out.19 A meta-analysis shows that the effect of changing a default is large and robust, with an effect size that averages 0.36 (i.e., a 36% difference between two proportions).20

When defaults and other components of the choice architecture are thoughtfully examined and altered, they can provide unobtrusive “nudges” to promote good decisions without constraining choice. This didactic panel will present several viewpoints on the choice architecture of health information technology; demonstrate ways in which defaults can be exploited to improve medical decisions; and, importantly, illustrate situations in which defaults can reduce the workload burden of EHRs by replacing or minimizing the role of CDSS.

Moderator: Adam Cheriff, MD, MS, chief medical information officer, Weill Cornell Medicine

1. Redesigning Choice Architecture: How does it work, and is it ethical? (Jessica S. Ancker, MPH, PhD)

A customer downloads a new map app on his phone. The app has three audible narration settings: a woman’s voice, a man’s voice, and no narration. The first time the customer opens the app, the setting is defaulted to the woman’s voice, and the customer proceeds to use the female narration. In fact, the majority – and sometimes the large majority – of users will do the same. In this talk, we will discuss the three mechanisms through which the default setting exerts its effects on decisions.21 The first is effort: by definition, the default option is the easiest, and anyone who does not make a choice will end up with the default. The second is endorsement: the default is perceived as an
implicit endorsement by authority. The third is endowment: often, the default option is perceived as something owned by the decision-maker, and overriding a default may feel like giving up something that the he/she is entitled to.21

Any intervention to alter medical decisions must be ethical, and that requirement is particularly important with highly effective interventions such as “nudges” that do not fully depend upon conscious analysis by the decision-maker. In this talk, we will analyze whether and under what circumstances “nudges” might be unethical, i.e., threatening autonomy, dignity, or welfare. We will also discuss recent research showing that “nudges” do not require deception, suggesting that they may and in fact should be freely disclosed to decision-makers. Finally, we will examine the ethical applications of failing to thoughtfully design a system’s choice architecture.

2. Increasing the Generic Prescribing Rate through Defaults (Sameer Malhotra, MD, MS)

Generic medications are not only cost-effective but also improve patient adherence because of their lower co-pays. In determining how to encourage clinicians at our medical center to use more generics, we realized that education and persuasion have limited effectiveness in changing prescriber behavior, and CDSS alerts are already probably oversized. Instead, we redesigned our e-prescribing interface to automatically substitute generic equivalents for brand-name medications during order entry (while allowing a one-click override for those who wished to order the brand-name medication).22 In this talk, we will describe how we accomplished this intervention and report the retrospective cohort study conducted to assess its effect. We found that among drugs with generic equivalents, the proportion of generic drugs prescribed more than doubled, rising dramatically from 39.7% to 95.9% (a 56.2% increase; P < .001). The higher rate was sustained after the intervention, with virtually no clinician complaints. Over time, prescribers became more likely to search by the generic name rather than the brand name, suggesting a learning effect over time. We will place this project in context of similar work23 demonstrating the universality of this type of intervention.

3. Paving the Cowpath: Exploiting defaults to optimize efficiency in order sets (Yiye Zhang, PhD)

When clinicians use computerized provider order entry (CPOE), they generally have a choice between placing orders a la carte or with the help of an order set. Order sets are a powerful component of the EHR choice architecture. For example, they can provide unobtrusive “nudges” in favor of evidence-based practice if they are constructed to promote recommended practices. They can also reduce workload by making it easier to select multiple relevant orders with a single click.24 We will present recent work25,26 on setting the default options within order sets on the basis of analysis of EHR data to identify previous physician choices about order placement. Our research finds that number of mouse clicks and cognitive workload associated with current ordering practices can be reduced substantially across medical conditions and severity levels through the heuristic optimization of order set content and defaults, thereby contributing to more efficient care. Current work further shows that combining experts’ knowledge with data-driven evidence in setting default options may further improve both the efficiency and scientific validity of order sets.

4. Reducing Disparities Through Defaults (Jessica Ancker, MPH, PhD)

It is widely accepted that giving patients access to their medical records via portals may help them manage their healthcare. However, it is also well-known that patients from socioeconomically disadvantaged groups are less likely to take advantage of portals. This raises the possibility that health information technology may disproportionately benefit patients who are already educated or affluent enough to have computer access. In this presentation, we will describe a “choice architecture” intervention that massively reduced socioeconomic disparities in portal access at a federally qualified health center (FQHC).27 In 2011, a study demonstrated that white and insured patients were much more likely to use the portal. It was initially believed that these patients might be more literate or computer-literate. However, further analysis showed that the institution was disproportionately likely to offer portal access to these patients, and most patients who received an offer accepted it. The organization responded by abandoning this “opt in” model in which portal access had to be requested. Instead, the default was changed to an “opt out,” in which portal accounts were set up for all patients except those who requested not to have one. A subsequent 2015-16 study showed the steady elimination of disparities between black and white patients, and between Hispanic and non-Hispanic patients. Changing the “choice architecture” improved equity in access to information technology.27

Learning objectives: By the end of this discussion, participants will be able to: (1) Define “choice architecture”; (2) Describe how “choice architecture” interventions within the EHR may provide less intrusive alternatives to alert-based clinical decision support; (3) Analyze ethical implications of intervening in the “choice architecture” of health information technology; (4) Describe several successful EHR-based “choice architecture” interventions.

Statement: All participants have agreed to take part on the panel.
Discussion points:

1. Are “choice architecture” interventions deceptive? Are they manipulative?
2. When is it appropriate to promote optimal decisions through “choice architecture,” and when would it be more appropriate to promote decisions through more cognitively effortful interventions such as education?
3. Who is responsible for the “choice architecture” of the electronic health record?

Abstract

Over the past three decades, the growth of publications involving machine learning has grown in the healthcare literature [1]. More recently, to leverage the potential benefits of these machine learning based models, institutions have begun making investments in infrastructure to translate this academic research into clinical practice. Deployment and adoption of models in clinical practice is not trivial and many challenges and issues emerge during implementation. This panel will provide a broad view of the machine learning model pipeline through model inception, evaluation, deployment, adoption, and FDA regulation. Through a series of case studies, the panel will demonstrate the challenges and issues. The goal of this session is to form a body of work for best practices, establish a like-minded community, and demonstrate potential scientific research opportunities toward successful model deployment and adoption.

Learning Objectives

After participating in this session, attendants should be able to:

- describe challenges and issues in successful deployment and adoption of machine learning based models.
- describe operational principles supporting the production deployment of machine learning based models.
- describe the machine learning pipeline.
- define a strategy for promoting machine learning model adoption and engaging the clinical teams.
- describe methodology for evaluating the impact of these machine based models.
- describe the design of predictive analytics systems in anticipation of meeting FDA regulations.

General Description

Precision medicine [2] and precision delivery [3] are two emerging approaches to healthcare delivery. Both efforts propose to target care delivery toward those who can most benefit from an intervention. At its core, this targeting task is what every healthcare provider does when a patient walks into our offices. We gather patient data and allocate our resources (medicines, diagnostics, etc) to uncover and resolve underlying pathology. Precision medicine and precision delivery propose to expand this paradigm with omics and clinical data respectively.

Over many decades, researchers published papers and models with excellent discriminatory performance on multiple clinical problems. In the clinical domain, these models have typically been described as calculators. For example, PORT [4] and Reynolds [5] are two clinical calculators. Despite decades of literature, widespread adoption has been limited and a systematic deconstruction of the barriers and approaches to overcoming them have been limited. Multiple barriers may account for the limited adoption. One particular barrier was the difficulty in entering data into these calculators. With the advent of electronic health records and digital recording devices, this barrier is lower and it is now possible to build models more agilely from this data. Concurrently with the digitization of health data, massive gains in pattern recognition and machine learning have allowed massive analysis of this data. We are once again at a crossroads with many models being published and fewer being deployed.

Our premise is that barriers for pragmatic model implementation still exist between the academic research that demonstrates excellent discriminatory performance for multiple clinical problems and the translation of these models into routine practice. Naively it would seem easy to believe that translating a published model into practice is as easy as deploying a model on a server and feeding it variables and reporting the outcome. In practice, the challenges to
deployment and adoption of models are not trivial. This panel will highlight the lifecycle of a machine learning based model through the experiences of panelists deploying and implementing models at their respective institution. Through case studies, we will each highlight issues, challenges, and scientific research opportunities associated with deployment and adoption of clinical models.

**Description**

The panel will be organized as follows:

<table>
<thead>
<tr>
<th>Time</th>
<th>Speaker</th>
<th>Topic</th>
</tr>
</thead>
<tbody>
<tr>
<td>14 minutes</td>
<td>Aphinyanaphongs</td>
<td>Predictive analytics in medicine and the predictive model pipeline.</td>
</tr>
<tr>
<td>14 + 4 minutes</td>
<td>Draugelis</td>
<td>Knowledge management to enable consistent model performance and real-time predictive system from a vast and diverse data stream</td>
</tr>
<tr>
<td>14 + 4 minutes</td>
<td>Holmes</td>
<td>Data input validation and post-implementation evaluation.</td>
</tr>
<tr>

</tr>
<tr>
<td>14 minutes</td>
<td>Aphinyanaphongs</td>
<td>Panel Discussion with Audience.</td>
</tr>
</tbody>
</table>

Each panelist will anchor their content with a case study of a predictive model that they have built, deployed, or evaluated at their institution.

**Aphinyanaphongs:** Dr. Aphinyanaphongs is the Director of Clinical Predictive Analytics at NYU Langone Medical Center. His job is to build, deploy, monitor, and evaluate machine learning based models for optimizing clinical operations and care. His team includes data scientists and software engineers that build sustainable infrastructure to translate clinical needs and research findings into hospital solutions. Dr. Aphinyanaphongs will moderate the session and discuss the overall lifecycle of a predictive model. He will discuss NYU’s experience in producing model diagnostics to understand the internals of a congestive heart failure classification model.

**Draugelis:** Mr. Draugelis is Penn Medicine's Chief Data Scientist where he leads the exploration and development of predictive healthcare applications. Michael's previous position was Lockheed Martin's Chief Data Scientist where he led application development in Missile Defense, National Intelligence, Healthcare and Cyber Defense. He will discuss the importance and methods of knowledge event management to enable consistent performance predictive applications.

**Holmes:** Dr. Holmes is a Collaborative Scientist in the Department of Physiology and Biomedical Engineering. His research focuses on the fusion of heterogeneous datasets and advanced analytic techniques to improve diagnostics and therapeutics. He works with industry, scientists, and practitioners to develop optimized processing pipelines to generate findings in “useful” time. Dr. Holmes will discuss data provenance and quality of inputs to the predictive models in the context of Mayo’s Unified Data Platform. Additionally, he will discuss approaches to model evaluation with a case study of in-hospital patient monitoring.

**Mirhaji:** Dr. Mirhaji is Associate Professor of Systems and Computational Biology at Albert Einstein College of Medicine, and the Director of Clinical Research Informatics at Montefiore Medical Center. He will discuss challenges regarding integration of analytically informed workflow processes into delivery of care process in healthcare ecosystem, implementation science and human computer interaction aspects of introducing data driven decision support without distraction, disruption, or overloading providers, and multi-system integration and coordinations necessary to present a streamlined process. He will highlight the role of workflow integration,
education, human factors, interaction design that drive model adoption and ultimately the success of a predictive model through the case study of “Accurate Prediction of PROlonged VEntilation-APPROVE” project that predicts inpatient mortality and respiratory failure 48 hours in advance, and providing personalized best practice advisories just-in-time and through institutional EMR.

**Sahiner:** Dr. Sahiner is an Electrical Engineer by training and a senior scientist with the Office of Science and Engineering Laboratories at the Center for devices and Radiological Health at the FDA. He is the leader of the image analysis laboratory at the Division of Imaging, Diagnostics and Software Reliability, with a focus on the appropriate evaluation methodologies for computational algorithms used to aid medical practitioners in the interpretation of diagnostic device results. Prior to joining the FDA, he was an Associate Professor of Radiology at the University of Michigan. His research interests include computer-aided diagnosis, machine learning, image perception, clinical study design, and performance assessment methodologies. He will discuss the regulatory environment faced by machine learning based clinical models and how to factor in regulatory considerations while the models are being developed.

**Significance of panel topic and intended audience**

Data science and predictive analytics are taking increasingly large roles in health care. A plethora of research has demonstrated that machine learning models can identify patients for care prioritization and potentially reduce costs [6]. Translating these findings into actual practice is essential to realize their potential gains. Healthcare organizations have recognized this potential and are making investments in building infrastructure and teams. Thus, this panel topic is timely and needed. Our intended audience include machine learning model researchers who want to translate their papers into practice, data scientists within healthcare organizations, healthcare executives who want to assess infrastructure and conceptual concerns in making investments in predictive analytics, change managers and behavioral economists who can address the challenges of model adoption, user interface designers who build the end users experiences, and medical educators who train future health care providers.

**Discussion Questions**

- How do organizations manage the risk of deploying an unproven predictive model at a clinical institution?
- How do we incorporate predictive analytic education for our healthcare providers?
- Predictive models have existed for many years as calculators. These calculators are not widely used in practice even though they provide potentially significant prognostic information. What potential barriers prevented the adoption of calculators and are predictive models in the era of electronic health records any different?
- What mechanisms are possible to pool our collective knowledge and experiences in deployments to identify best practices?

**Participation Statement**

All proposed panelists have agreed to participate in the panel if the proposal is accepted.

Problem List 2.0

Joel R. Buchanan, MD\textsuperscript{1}, William L. Galanter, MS, MD, PhD\textsuperscript{2},
DuWayne L. Willett, MD, MS\textsuperscript{3}, Adam Wright, PhD\textsuperscript{4}
\textsuperscript{1}University of Wisconsin School of Medicine and Public Health, Madison, WI; \textsuperscript{2}University of Illinois Hospital \& Health Sciences System, Chicago, IL; \textsuperscript{3}University of Texas Southwestern Medical Center, Dallas, TX; \textsuperscript{4}Brigham \& Women’s Hospital, Boston, MA

Abstract

The value of a comprehensive, concise list of all a patient's active medical conditions to provide accurate "situational awareness" during clinical decision-making has long been recognized. EHRs offer the potential of centralizing the patient problem list, streamlining its maintenance, enhancing its accuracy, and providing flexible viewing to fit clinical information needs. Yet many practices and healthcare organizations today struggle with realizing these benefits. Why is that? What can be done to unlock this potential?

In this panel, we first briefly review the evolution of the problem list in its transition from paper to the electronic health record and summarize current challenges. Then we explore the use of clinical decision support and automated approaches for keeping up an accurate problem list. The recognized benefits of providing context-appropriate, problem-oriented views of relevant medical record information require both EHR technical capabilities and clinically-valid concept maps: we review both, and describe a project to develop the latter in the public domain. We then explore the wide range of potential applications for valid problem list representation of a patient’s health conditions, including clinical decision-making, clinical communication, quality measurement, registries, and clinical and translational research.

Description

The overall outline of the talk is given in the abstract. The panel will be organized as follows:

\begin{table}[h]
\centering
\begin{tabular}{|c|c|p{10cm}|}
\hline
\textbf{Time} & \textbf{Speaker} & \textbf{Topic} \\
\hline
10 min & Willett & Introduction, overview of current state of the Problem List in the EHR era \\
5 min & & Discussion and questions from audience \\
15 min & Galanter & Toward automated maintenance of the Problem List \\
5 min & & Discussion and questions from audience \\
15 min & Buchanan & Problem-Oriented View (POV) \\
5 min & & Discussion and questions from audience \\
15 min & Wright & Additional uses of the Problem List \\
5 min & & Discussion and questions from audience \\
15 min & Panel & General discussion and questions from audience \\
\hline
\end{tabular}
\caption{Organization of panel by segment length, speaker and topic.}
\end{table}

The specific topics covered by each presenter will be:

1. Willett (introduction): Introduce the topic and panelists, including a brief description of what each panelist will be talking about and their affiliations. Provide an overview of the history of using a problem list in medical records, its evolution in the EHR era including context within the EHR, and common current issues\textsuperscript{1}.

2. Galanter: Describe methods to help automate problem list documentation. Demonstrate the use of clinical decision support (CDS) to prompt clinicians to provide problems while ordering medications and labs, as well as other methods which use CDS to help or directly place problems\textsuperscript{2}. The design of this type of decision support will be discussed briefly with an emphasis on the types of orders which lend themselves to this method, contrasted to those that work less well. The use of CDS to clean problem lists will also be discussed.

3. Buchanan: Context-dependent views of EHR data are considered essential for success of the Problem Oriented Medical Record, and implementation of these views will require programming by vendors and
creation of content maps by customers. We have created a methodology for obtaining expert consensus on
these maps, and we plan to create 140 vendor-neutral, open source maps in the next phase of the project.

4. Wright: Give an overview of the range of uses of problem lists, including the core use of clinical care, as well
as clinical decision support, quality measurement, clinical and translational research, registries, supporting
teamwork and documentation. Dr. Wright will also discuss the impacts of inaccurate or incomplete problem
lists on each of these uses.

5. Panel: After the presentations, the panel will briefly discuss additional issues and then open for questions
from and discussion with the audience. Audience members will be invited to address questions to specific
panelists, or to the panel as a whole

Importance

The need for accurate digital knowledge of a patient's health conditions continues to expand rapidly. In addition to
its core benefit in providing complete clinical context for individual medical decision-making, knowing the list of a
patient's currently active health issues—their Active Problem List—now has become valuable in several other contexts
as well. The patient's list of active health conditions is now shared (a) with other organizations via Health Information
Exchanges, reflecting on the sender's clinical assessment, and (b) with patients via patient portals. When accurate,
this same list can also help automatically define sub-populations for clinical registries and electronic quality
measurements. Advanced analytics as well as clinical and translational research likewise benefit from an
unambiguous record of the patient's active health conditions.

Yet at the practical day-to-day level of medical practice, challenges remain with populating and updating the Problem
List, and with optimizing the display of problem-related medical information stored in the EHR in visualizations that
enhance clinical decision-making.

In this panel we summarize current challenges with the EHR problem list, and then offer perspectives from three
organizations on approaches to a) enhancing the population and grooming of the problem list, b) optimizing a problem-
oriented display of information to maximize the clinical signal-to-noise ratio for decision making, and c) harnessing
the value of knowing our patients' health conditions to drive improvements in patient and population health.

We believe this topic, along with an opportunity for open discussion and audience questions, will prove valuable for
medical informaticists, practicing clinicians, and anyone interested in secondary uses of EHR-derived data for quality
improvement and analytics.

Discussion Questions

1. How well is the problem list used currently at your institution, and does it vary between primary care and
specialists?
2. What incentives do providers at your organization have to maintain accurate problem lists? (e.g. P4P, part of
being a good team player, makes it easier to document, etc.)
3. What can leaders do to create a culture of problem list usage in their organizations?
4. What are the limits on the use of CDS for automated and semi-automated problem list placement?
5. What do clinicians and administrators think about trying to automate the problem list?
6. If indications are used for ordering labs and medications, is there still a need for problem concept maps to
drive an aggregate data display?
7. If we create problem concept maps for common problems, how can we encourage vendors to create the
necessary software?

Participation Statement

All proposed panelists are aware of this panel submission, and have agreed to participate in the panel if the proposal
is accepted.

Social Determinants of Health: Applied Informatics Approaches
Incorporating Context into Care

Hossein Estiri, PhD¹, Rachel Gold, PhD, MPh², Michael N. Cantor, MD³, Theresa Cullen, MD, MS⁴,⁵

¹Harvard Medical School, Boston, MA; ²Kaiser Permanente Northwest Center for Health Research, Portland, OR, and OCHIN, Inc.; ³NYU School of Medicine, NY, NY; ⁴Global Health Informatics, Regenstrief Institute, Indianapolis, IN; ⁵Indiana University School of Medicine, Indianapolis, IN

Abstract
There is substantial empirical evidence that many of the factors that contribute to health outcomes originate from outside of the conventional confines of the U.S. healthcare system. Social Determinants of Health (SDH) constitute the majority of these factors. The uptake of Electronic Health Record (EHR) systems offers great potential for addressing such socio-contextual determinants of health. Integrating SDH data into EHRs would provide invaluable information for healthcare organizations, helping to improve precision in diagnosis, treatment, and monitoring of disease and care management programs. Yet, the current healthcare system generally lacks the infrastructure to assimilate SDH data within clinical practice and research. This panel will discuss theoretical aspects and practical steps for developing informatics infrastructures to incorporate data on socio-contextual determinants into healthcare practice and research.

Keywords:
Social and Contextual Determinants of Health; Biomedical Informatics; Electronic Health Records; GIS

Introduction
Most determinants of health originate from the socio-contextual settings wherein we live (i.e., the social, cultural, historical, and economic settings, and the built, natural, and institutional environments), which are often outside the confines of disease-based healthcare.[1–6] The WHO defines social determinants of health (SDH) as “the conditions in which people are born, grow, work, live, and age, and the wider set of forces and systems shaping the conditions of daily life. These forces and systems include economic policies and systems, development agendas, social norms, social policies and political systems.” Since the early 2000s, several national advisory committees have highlighted the need for addressing SDH in clinical settings and made explicit recommendations on incorporating SDH into health care. However, in most cases, the U.S. healthcare system still lacks the resources and motivation needed to assimilate SDH into healthcare practice and related research.[7–9] As a result, many healthcare providers operate without fully understanding the challenges to optimal health that their patients may face, as those challenges fall outside of their historical purview.

Accountable Care Organizations and the Precision Medicine Initiative promote population health management both as a cost containment strategy and as a means of detecting disease earlier, understanding it better, and intervening more precisely. Electronic Health Record (EHR) systems are key to transforming health care from an episodic, reactive model to a more preventive, proactive system. To implement more efficient population health management, healthcare providers need point of care access to a full range of information about their patients. Yet while EHRs provide valuable information about clinical determinants of health and treatment effectiveness,[4] it is rare that they are configured to systematically capture SDH information.[3,10]

A few studies have recently applied geospatial technology to integrate SDH data with EHRs, arguing that integrating EHR data with SDH data would help healthcare organizations improve precision in diagnosis, treatment, and monitoring of disease and care management programs.[3,5,11] Attaining these potentials, however, is contingent on availability of health information technology that integrates EHR data with SDH. Also, little is yet known about best methods for synthesizing, interpreting, and intervening on SDH. We lack empirical evidence on the clinical utility of SDH data – i.e., evidence that SDH can be directly applied in clinical interventions / decision-making. In addition,
data sharing, governance, and privacy concerns introduce new challenges that discourage healthcare organizations from integrating data from outside into their clinical repositories.

This panel is sponsored by the AMIA Social Determinants of Health (SDH) discussion group.

**Discussion Questions:**

- Who are the social and institutional actors/stakeholders, and their roles and relationships in a context-informed healthcare system (i.e., one in which patients’ social and cultural context is considered in clinical care decisions)?
- What are available/potential sources of social and contextual information, and related data integration technologies?
- Can distributed clinical data networks facilitate integration of EHRs with SDH data?
- What is needed to incorporate the integrated SDH data into clinical processes?
- What is known about how patient-reported or contextual SDH data can be used in clinical practice?

**The Panel**

This panel seeks to discuss practical steps and opportunities for developing informatics infrastructures to incorporate socio-contextual determinants data into healthcare practice and research. For this panel, participants will describe their experience in integrating EHR data with social and contextual data and will discuss lessons learned, informatics requirements, and decision support needs that can be applied in real-world clinical settings.

**Dr. Estiri** will use the social and ecological theory as an organizing framework to identify and discuss social and institutional actors/stakeholders, elements, and their interactions in a context-informed healthcare system. Based on this framework, he will discuss informatics questions that need to be addressed to operationalize such a system. He will describe the experience, as well as socio-technical challenges and opportunities, of architecting an informatics infrastructure for incorporating social and contextual data into Electronic Health Records (EHR) from a large-scale distributed clinical data network at HMS.

**Dr. Gold** will discuss her team’s pilot study of the development and implementation of EHR-based tools for collecting and acting on patient-reported SDH data. This is the first federally-funded study of strategies for SDH data collection among adult patients in the primary care community health center setting – a setting with highly vulnerable patients, where SDH have profound impacts. This talk will describe implementation barriers and lessons learned in this pilot study; these lessons may be informative to others seeking to implement patient-reported SDH data collection. Dr. Gold will also discuss her team’s theoretical model for using SDH to augment clinical data, and their plans for future research on how to use such data to connect primary care teams to community services that might address SDH.

**Dr. Cantor** will discuss the experience of NYU Langone Medical Center’s efforts around capturing and acting on individual and community-level SDH, and efforts on integrating the two. For individual-level determinants, he will discuss NYULMC’s work with New York State’s DSRIP (Delivery System Reform Incentive Payment) program which aims to improve care for Medicaid patients. NYULMC has taken several different approaches to both capture and integrate individual-level SDH into treatment and care management approaches, including partnering with and referring patients to community-based organizations. NYULMC is also using community-level SDH both within its network and as part of the NYC-CDRN, our local instance of PCORnet. We are using publicly-available, census tract level data, captured in the FACETS (https://github.com/mcantor2/FACETS) database, to evaluate the impact of community-level determinants on various medical outcomes.

**Dr. Theresa Cullen** will discuss her experience with developing screening tools for SDH and associated analytics in Indian Health Service. Starting in 2004, the Indian Health Service, at the behest of tribal communities, responded to community needs to capture data on domestic violence as well as sexual assault. Dr. Cullen will describe how SDH screening tools, developed in conjunction with endabuse.org (formerly the Family Violence Prevention Fund), were integrated into RPMS, the Indian Health Service electronic health record. This process, a joint effort between tribal communities and the Indian Health Service, is a model for shared decision-making with communities. Screening tools included attention to safety, including ‘opt-out’ options, non-inclusion of screening data on health summaries as well as extra security requirements for aggregating and exporting the data. Screening rates for
domestic violence are tracked; outcome reports are generated by tribal communities but are not available for research or publication without tribal IRB approval.

Following the panelists’ presentations, the moderator will start the discussion by asking a few questions to help the audience understand the available data and technology resources, and socio-technical challenges for integrating social and contextual data with EHRs. We will then open the floor for a discussion of the practical informatics steps and possibilities for addressing social and contextual data in healthcare research and practice.

**Learning Objectives**

After participating in the session, the attendant should be able to:

- Identify elements (i.e., actors/stakeholders, technology, and interactions) of a context-informed healthcare system.
- Describe available data and technology resources for integrating social and contextual data into EHRs.
- Discuss possibilities, challenges, and concerns related to integration of social and contextual data with EHR data.

**Panel Organizer Statement**

All participants have agreed to take part in the panel.

**Conflict of interest**

The participants have no conflict of interest to declare.

The Data and Research Center of the All of Us Research Program: Framework for a National Cohort Program and Research Opportunities

Robert J Carroll, PhD¹, Joshua Mandel, MD², Karthik Natarajan, PhD³, Scott Sutherland⁴, Joshua C Denny, MD MS¹

¹Vanderbilt University Medical Center, Nashville, TN; ²Verily, Cambridge, MA; ³Columbia University, New York, NY; ⁴Broad Institute of MIT & Harvard, Cambridge, MA

Abstract

The Precision Medicine Initiative All of Us Research Program is a national effort to recruit and engage at least one million participants who consent to provide health information (including data from health surveys, electronic health records, and baseline physical measures), biospecimens, and to be recontactable in the future. The Data and Research Center (DRC) sits at the confluence of all of these varied data and, in collaboration with the many All of Us partners, has been creating a framework to shape and support biomedical research in the future. This panel will discuss a number of primary topics including operations support, the back end data structure, EHR data ingest, processing, and curation, and the researcher tools and public facing sites with a number of interwoven secondary topics including principles driving the creation of the All of Us Research Program, the ethical, legal, and social implications of the effort, and the privacy and security framework for protecting participants and their data. We are interested in engaging the AMIA community in discussions around the plans to engage and protect participants and empower this community of researchers.

Overview

In 2015, President Barack Obama first introduced his vision for the Precision Medicine Initiative (PMI) during his State of the Union Address. With a goal to recruit and engage one million participants representing the diversity of the United States, the PMI All of Us Research Program has received bipartisan support and has been an important focus of the National Institutes of Health. After months of work by individuals across a broad set of fields, a set of working recommendations were presented. The All of Us Research Program was launched in 2016 with a number of grants addressing key areas of the project including recruitment sites, a biobank, a participant technologies center, and the data and research support center (DRC). All of these groups are collaborating on solving the many barriers to creating such a large, nationwide cohort. As members of the DRC, the panelists have been involved in the many aspects of this project, including operations support, the back end data structure, EHR data ingest, processing, and curation, and the researcher tools and public facing sites. Josh Denny from Vanderbilt will be the moderator for this panel.

Operational Support

Robert Carroll will present on the topic of the DRC’s role in operational support for the All of Us Research Program starting with an overview of the participant enrollment process. The design, feedback, and implementation approach of the research associate facing HealthPro Portal used for in person enrollment will be the primary focus for this segment. Concerns around data sharing and visibility on a national program will be discussed in addition.

Raw Data Import and APIs

Josh Mandel will introduce the data storage architecture, domain models, and APIs that support the DRC. The discussion will incorporate a set of motivating use cases outlining communication requirements between the DRC and other All of Us stakeholders (Participant Technology Center, Biobank, and healthcare provider organizations). This topic will also include an overview of the use of the Fast Healthcare Interoperability Resources (FHIR) standard within the DRC, as well as the security model that protects participant data.

¹Precision Medicine Initiative, PMI, All of Us, the All of Us logo, and The Future of Health Begins With You are service marks of the U.S. Department of Health and Human Services.
Aggregation of EHR Data

Karthik Natarajan will present on the ingestion, processing, and curation of electronic health record data for the All of Us program. Topics of interest include the Observational Medical Outcomes Partnership Common Data Model (OMOP CDM), the Observational Health Data Sciences and Informatics (OHDSI) collaborative and its open-source toolkit, and solutions to integrating multiple implementations of the OMOP CDM into a single, usable dataset. Additionally, this topic will cover the quality control processes employed on such data in order to deliver high-quality EHR data for researchers.

Data Use and Research Support

Scott Sutherland from the Broad Institute of MIT & Harvard will present on public facing and researcher tools. This segment will include public dashboards, researcher support, tools available in the researcher portal, and data access mechanisms. Special focus will be given to the privacy and security policies and how researchers can access and use the data from the All of Us Research Program.

Relevance

Simply by the merit of being one of the largest programs initiated by the United States National Institutes of Health, the All of Us Research Program is likely to be of interest to a diverse set of attendees. In addition, each topic appeals to a broad, potentially different, set of informatics researchers. Implementation and evaluation of an operational electronic support system, the design of interoperable systems communicating health data using a number of major current standards, the management and quality control of multi-site EHR data, and the design and availability of a researcher portal are all key areas of interest to AMIA members. It is currently anticipated that roll out of research tools using this data may be available, providing some introduction to the pipeline and data available (or soon to be available) for use generally.

Discussion Questions

1) Since the All of Us Research Program will be delivering many petabytes of data into a cloud-based scalable computing environment, what kinds of tools should we provide to minimize the need to download data to local systems.
2) What are the opportunities and concerns with integrating health data from a number of systems, including differing EHR sources, participant self report data, and other national systems?
3) Are there sources of participant level data that would be useful to integrate within the DRC for use by researchers?
4) Are there sources of reference data that would be helpful to provide in a research environment?
5) What level of quality control for the various types of data would be helpful? How can the DRC flexibly provide accurate data without excluding or preventing certain types of research, eg on noisier data?
6) What types of studies would be easily enabled in this framework?
7) Are there studies which would be difficult to perform in the current scheme? How could those be facilitated?
8) In what ways can data be provided back to participants that would encourage engagement in the program?

Participation Statement

All participants have agreed to take part in this panel presentation.
“My work will surely speak for itself:”
Visibility, Networking, and Self Promotion in Informatics
Sponsored by the Women in AMIA Taskforce

Wendy W. Chapman, PhD 1, Murielle Beene, DNP, MS, MPH, MBA, RN-BC, PMP, FAAN 2, Omolola Ogunyemi, PhD3, Genevieve B. Melton, MD, PhD 4, Laura K. Wiley, PhD 5
1 University of Utah, Salt Lake City, UT, 2 US Dept of Veteran Affairs, Atlanta, GA, 3 Charles R. Drew University of Medicine and Science, Los Angeles, CA 4 University of Minnesota; University of Minnesota Health and Fairview Health Services, 5 University of Colorado Anschutz Medical Campus.

Abstract. Women and men interested in better understanding how to obtain leadership positions and to enhance leadership opportunities for women within our field should attend this interactive panel sponsored by the Women in AMIA Taskforce. Women continue to be under-represented in leadership positions in medicine and within informatics. Contributing factors include a person’s confidence level and degree of networking. Our objective is to discuss the confidence and networking differentials between men and women and to share strategies for reconciling the fear many women (and some men) have of appearing over-confident with the need for self promotion and visibility needed to achieve positions of leadership and increase impact. The panel will focus on four areas:
(1) Selling yourself: the confidence spectrum; (2) Climbing the ladder: Academic career progression; (3) Women in the C-Suite; (4) Strategies for Students.

Intended Audience: The intended audience for the panel discussion includes all biomedical informaticists (both men and women) who are interested in obtaining leadership positions themselves and in enhancing leadership opportunities for women within our field. This topic is timely as we seek to increase the proportion of female nominations for awards and of leadership positions within our field.

Introduction of the Topic.
Women continue to be under-represented in leadership positions. In fact, men with moustaches outnumber women in medical school leadership. An informal survey of women in informatics leadership showed that 43% of NLM training programs have female PIs, 21% of CTSAs have a female BMI Core director, and only 10% of BMI departments have a female chair. Confidence level is potentially a contributing factor to this gap. Research shows that across the world men overestimate their intelligence, whereas women underestimate theirs. This confidence differentiation influences whether individual seek for or accept leadership opportunities.

259
Moreover, differences in displays of confidence affects reception by peers and other leaders. Male qualities are often equated with leadership qualities. Because people “commonly misinterpret displays of confidence as a sign of competence, we are fooled into believing that men are better leaders than women.”

**Aim of Discussion.** Our objective is to discuss the confidence differential between men and women and to share strategies for reconciling the fear many women (and some men) have of appearing over-confident with the need for self promotion, networking, and visibility needed to achieve positions of leadership and increase impact.

Panel presenters will provide background, share personal experiences, and lead interactive discussions with the audience on the following four topics:

1. **Selling yourself: the confidence spectrum (Wendy Chapman).** The motto of many women is “My work will surely speak for itself.” As much as we hope that may be true, the path to leadership requires promoting one’s work and one’s personal abilities, and women on the whole are less successful at this.
2. **Climbing the ladder: Academic career progression (Omolola Ogunyemi).** Is there a best approach to working towards promotion? How do we balance leadership opportunities with building our research labs? And what role do sponsors play?
3. **Women in the C-Suite (Genevieve Melton-Meaux).** There are a variety of leadership opportunities in health care settings. How many women are in the C-Suite? What are the particular challenges in this setting, and how do women make themselves more visible for these types of positions?
4. **Strategies for Students (Laura Wiley).** Leadership qualities can be learned and practiced from the very beginning of informatics studies. How can students effectively network and self promote to improve their visibility to broader informatics community? What opportunities are there for female students in AMIA leadership?

**Contributions of Each Speaker:** All participants have agreed to take part on this panel.

**Murielle Beene, DNP, MS, MPH, MBA,** is the CNIO and acting director, Office of Informatics and Analytics, Department of Veterans Affairs. Dr. Beene is the first CNIO for the Veterans Health Administration and has been a CNIO since 2009 and a nurse since 1996. Dr. Beene will moderate the interactive panel.

**Wendy Chapman, PhD, FACMI,** is the chair of the Department of Biomedical Informatics at the University of Utah. She discovered biomedical informatics serendipitously and fell in love with the field. Since receiving her PhD in 2000, Dr. Chapman was a faculty member at the University of Pittsburgh then UC, San Diego. She returned to her alma mater as the department
chair. Dr. Chapman serves as an elected member of the AMIA Board of Directors, as the chair of the AMIA Student Paper Awards Committee, and as the Chair of the Women in AMIA Taskforce. Dr. Chapman will discuss the role of confidence in career advancement. She will discuss research on gender differences in confidence, will describe some personal experiences, and will suggest an approach to confidence for women.

**Omolola Ogunyemi, PhD**, is Director of the Center for Biomedical Informatics at Charles R. Drew University of Medicine and Science (CDU) and an Associate Professor in the Department of Preventive and Social Medicine. She was introduced to the field of Biomedical Informatics while a computer science graduate student at the University of Pennsylvania. She served as an informatics faculty member at Brigham and Women’s Hospital for over seven years before joining the faculty at CDU. She is a member of the Women in AMIA Taskforce Steering Committee and AMIA’s Membership and Outreach Committee. Drawing on her background as a reviewer for NLM, NIBIB and AHRQ research grants and her experience serving on appointments and promotions committees, she will talk about career advancement strategies and potential pitfalls.

**Genevieve Melton-Meaux, MD, PhD,** is Chief Health Information Officer for Fairview Health Services and University of Minnesota Physicians. At University of Minnesota, she is an Associate Professor of Surgery, Core Faculty in the Institute for Health Informatics, and co-directs the Natural Language Processing-Information Extraction Program. After studying computer engineering and mathematics as an undergraduate, she went to medical school and while there was introduced to informatics and surgery. With experience as a successful academic surgeon, informatics researcher, and healthcare administrator, Genevieve will discuss administrative leadership in health care settings, research around women in the boardroom, and factors for success.

**Laura Wiley, PhD,** is an Assistant Professor in the Division of Biomedical Informatics and Personalized Medicine at the University of Colorado School of Medicine. She recently completed a PhD in human genetics (2016) and Master’s in biomedical informatics (2014) at Vanderbilt University. She is currently the student representative to the AMIA Board of Directors, Chair of the Working Group Steering Committee, and a member of the Women in AMIA Taskforce. Previously she has served as Chair of the Student Working Group and as a member of the AMIA Public Policy Committee. Dr. Wiley will discuss how students can effectively network and self promote to improve their visibility to broader informatics community. She will also describe ways that students can become involved in AMIA leadership (all of her listed AMIA roles began while she was still a student).
The Hashemite Kingdom of Jordan is located in the Middle East at the crossroads of Asia, Africa, and Europe with a population of over 9 million. In 2009 under the patronage of His Majesty King Abdullah II Bin Al Hussein, Electronic Health Solutions (EHS) was founded to advance the healthcare sector in the country through its flagship program Hakeem. The Hakeem program facilitates efficient, high-quality healthcare in the Kingdom through the nationwide implementation of an Electronic Health Record (EHR). Jordan selected an open source version of VistA. The Jordanian version of VistA, a collaboratively supported free and open platform adopted from World VistA, is currently in use in over 104 facilities (primary healthcare clinics, comprehensive healthcare clinic, and hospitals) across various public healthcare authorities in the Jordan Ministry of Health, Royal Medical Services, and King Hussein Cancer Center. The benefits of open, collaboratively developed health information technologies (HIT) have been well described, and strongly advocated for over the past decade. Many have found it difficult to successfully initiate, grow, and maintain these initiatives. The Jordan experience with WorldVistA EHR provides a potent reminder of the possibilities and promise of open source HIT as well as the possibilities and impact of full spectrum HIT in low and middle income countries (LMIC).

Keywords

Global Health, Clinical Information Systems, Clinical Systems Implementation

Introduction and Background

This panel is designed to share the experience of the last eight years of health information technology in Jordan from the vantage point of a non profit government supported health information technology company (EHS) that has helped guide the development, deployment, implementation, and assessment of a nationwide roll-out of an EHR within Jordan. This panel will discuss the history of the decision and the benefits that have accrued due to the use of an open source version of VistA (WorldVistA EHR) which has been customized and modified to meet the need of the various Jordanian public healthcare sectors.

The HIT solution, Hakeem, is based upon the Veterans Health Information Systems and Technology Architecture (VistA), an enterprise-wide information system used throughout the United States Department of the Veteran Affairs (VA) medical system. The Hakeem VistA-based structure selected based upon the needs of the country. VistA was customized and modified to meet Jordanian regulations, language, culture and standards. Members of EHS, the nonprofit organization supporting the HIT initiative, coupled with healthcare team members and other stakeholders, identified the local health sector needs and requirements for a customized implementation of VistA. EHS successfully developed needed functionality, implemented quality tests to ensure the capacity and efficiency of the system (i.e. drug information, localization, etc.) and developed robust deployment and implementation capacity. Ultimately, EHS has become a pioneer, locally, regionally and globally, in developing a technology solution for the national public health sector in low and middle income countries.

In 2017, the Hakeem initiative is engaged in the deployment of the Hakeem (VistA) open EHR in more than 75 new sites across the Jordanian public healthcare sectors. This scale of a project, leading to over 70% of the population...
receiving care at a facility that has deployed Hakeem by the end of 2017, represents successful collaboration between multiple stakeholders who shared the vision of transforming and sustaining a continuously improving healthcare system in Jordan by leveraging technology. EHS stakeholders include the Ministry of Health, Ministry of Information and Communications Technology, Royal Medical Services, King Hussein Cancer Center, Private Hospital Association, The Royal Health Awareness Society, and the King Abdullah II Fund for Development. Over the past eight years, EHS and its various stakeholders have worked side-by-side to elevate the healthcare process and achieve health equity by providing easy access to a complete electronic health record for patients of healthcare facilities within the Hakeem implementation network. This work reflects shared responsibilities and processes such as vision and mission, governance, technologies, industry standards, principles, and the gathering and utilization of resources. This shared commitment has helped ensure efficient access to vital patient information, resulting in improved patient care quality. Jordan is an exemplary example of a middle-income nation that has actualized improving a country’s health status through a commitment to health information technology. Jordan stands at the precipice of the next stage of data use - embracing the continuum of data maturity with a commitment to a complete analytics and business intelligence framework. The lessons learned from Jordan’s experience are important to global as well as US national health informatics work.

Panel Description

Dr. Terry Cullen will facilitate a panel discussion on the history and current status of VistA within Jordan. This panel will help the audience better understand the importance of open source software, the many collateral benefits that emerge from them, and the potential for using the Jordanian experience to help inform other health information technology journeys. The panel will include a review of how a decision was made to select VistA, and the various implementation activities and the factors that contributed to the current success. The panel will also discuss the historical and future management strategies employed by project leadership, which will provide details on the nuanced decision-making that has proven fundamental to the initiative’s success. These experiences and lessons learned from this global health informatics initiative are applicable to not only HIT development and implementation initiatives working under fiscal and human constraints, but to other countries who are embracing a commitment to health system strengthening and resiliency with limited resources. Anticipated audience includes those interested in enterprise wide deployments of HIT, those interested in the use of open source software, and AMIA members interested in seeing a successful mature HIT deployment in a LMIC.

Panel

Health Information Technology (HIT) in Jordan: Why VistA? (Feras Kamal)

Mr. Feras Kamal will present on the history of Jordan’s decision to use HIT to improve care at a national level, as well as the choice of VistA as the solution for this need. Mr. Kamal will share the last nine years of experience, culminating in the current situation where the Hakeem program supports care provision to over five million patients from all over Jordan. The Hakeem system enables healthcare professionals in clinics as well as hospitals to care for patients through electronically accessing the patient’s medical records from within participating health facilities by simply entering the patient’s national ID number (a unique identifier for all patients receiving treatment within the public healthcare sector). The creation of a HIT system responsive to the clinical needs of Jordan, as well as an integrated approach to deployment and implementation of a cloud based HIT solution, has proven to be a successful model for the Jordanians health care system. Mr. Kamal will also discuss the challenges of deployment in a middle income country, as well as Jordans approach to security, privacy and confidentiality within the VistA deployment.

The Benefits of VistA (Nancy Anthracite)

A technical overview of the various VistA packages which have been implemented, as well as the packages currently in development and packages that have received extensive customization to enhance usability (Pharmacy GUI + Dental Package), will be presented. The Hakeem Team has developed a package enhancement process that is low cost, supports the needs of Jordan and can be a model for other countries. The panel presentation will emphasize lessons learned by EHS, including predictive factors for the success of an open source electronic health records deployment on a national level as well as a successful open source health information technology community.

Looking Forward – Analytics and Business Intelligence (Theresa Cullen)
EHS is a case study in how to use open source technology to improve health status of a country. As a result of the successful deployment of the Hakeem program, EHS has moved to the next phase of data use with a commitment to quality and business intelligence. Following a rigorous alternative review, EHS elected to use an open source dB, Maria, for their ABI platform. Currently in its infancy, this platform is designed to support the production of key performance measures as well as multiple data marts. Ideally, EHS will soon produce national level indicators and measures that reflect the needs and priorities of the Kingdom. Plans for the future, as well as the use of analytics and business intelligence to drive future implementation projects and improve health quality and safety, illustrate the data continuum and a comprehensive HIT model for LMIC countries.

Increasing attention to health system strengthening and resiliency, data collection, aggregation and data use and the constraints of focusing on monitoring and evaluation data in LMIC reinforces the need for deploying and integrating affordable HIT systems that can support big data and analytics/business intelligence. The Jordanian example is a case study in a country’s commitment to improving the health status of its citizens through the use of HIT.

Discussion Questions

1. What are the top three benefits and challenges of open source HIT systems for global health IT?
2. What differences exist between the US based HIT and ABI maturity models and HIT and ABI maturity models in LMIC?
3. How can AMIA leverage the lessons learned from Jordan to benefit the US HIT and health informatics community?
4. What can AMIA do to assist the global health informatics community?

Panel Organizer Statement: All participants have agreed to take part in the panel and discuss the topics as outlined above.

Opportunities and Challenges for Development, Implementation, and Investigation of Acute Care Patient Portals (ACPP): Recommendations from the ACPP Task Force

Anuj K Dalal, MD,1 Sarah Collins, RN, PhD,1 Victoria L Tiase,2 MSN, RN-BC, Kristin O’Reilly, RN, MPH,4 S. Ryan Greysen, MD, MHS, MA5

1Brigham and Women’s Hospital, Boston, MA, 2New York-Presbyterian Hospital, New York, NY, 4Beth Israel Deaconess Medical Center, Boston, MA, 5University of Pennsylvania Health System, Philadelphia, PA

Abstract

The adoption of patient portals has been predominantly in ambulatory settings—use for acute and post-acute care is a rapidly emerging field. An Acute Care Patient Portal (ACPP) task force consisting of stakeholders from early adopter institutions has identified opportunities and challenges for use of patient portals to improve the acute and post-acute care patient experience and is creating a road map to advance this evolving field. This interactive panel will discuss key findings and recommendations from the ACPP 2020 conference that engaged a national group of stakeholders. Session participants will discuss and vet recommendations, refine a road map for development, implementation, and investigation, and identify future directions for innovation.

General Description

The use of patient-facing technologies to engage patients and care partners is viewed as a strategy to achieve better outcomes, improve satisfaction, and optimize healthcare delivery.1 Healthcare systems have been adopting patient portals at an accelerated rate, driven in part by the Meaningful Use (MU) program. Forthcoming legislation—the Caregiver Advise Record and Enable (CARE) Act—will require hospitals to engage care partners more formally in the acute and post-acute care setting. However, the vast majority of use has been limited to the ambulatory setting—use in the hospital and care transitions settings is nascent at best.2 Nonetheless, hospitalized patients represent a vulnerable population with unmet information and communication needs—and there remains the task of promoting self-management after discharge. Although preliminary evidence is encouraging, there is little consensus regarding the development, implementation, and investigation of acute care patient portals.2,3

As part of the Libretto Consortium supported by the Gordon and Betty Moore Foundation, we created an Acute Care Patient Portal (ACPP) task force consisting of early adopter institutions. Early work identified stakeholder perspectives on current practices for acute care patient portals.4 These findings have generated broad interest and culminated in a national conference in June 2016 in Palo Alto, CA: Acute Care Patient Portals 2020: Opportunities and Challenges for Development, Implementation, and Innovation. Participants included CMIOs, CNIOs, clinicians, healthcare executives, policy officials, representatives from electronic health record vendors, patient advocates, and others. Meeting transcript and notes were synthesized, summarized, and reviewed by task force members. Using a group consensus approach, we identified three main themes from our panel of patient advocates—cognitive support, respect and boundaries, and patient and family empowerment—that should help drive future implementation and innovation efforts in a patient-centric manner. From the perspective of the multiple stakeholders engaged during the conference, the ACPP task force identified a set of priorities for development, implementation, and investigation.

This interactive panel will engage a wide variety of participants (clinicians, researchers, CMIOs, CNIOs, etc.) in a range of topics based on the collective work of the ACPP task force. Panelists will discuss recommendations from the ACPP 2020 national conference and share lessons learned from individual institutions. Participants will be encouraged to share experiences from their institutions to corroborate, refute, and refine recommendations, and identify new directions for innovation and investigation.

Addressing the discussion topics below, panel members will present a recommendation in context of their perspective, institutional experience, and involvement in the ACPP task force, and engage audience members in a
robust discussion to elicit participants’ opinions, experiences, and practices.

**Discussion Topics**

- What are sustainable approaches to engage patients and care partners in the acute and post-acute care setting?
- What strategies can be employed to sustain use of the patient portals across the continuum of care?
- How do we leverage patient portals to improve the patient experience and maximize value?
- What outcomes should be used to measure the impact of patient portals over the acute episode of care?
- What are the interoperability and standards necessary to facilitate adoption?
- How should institutions integrate patient portals across the enterprise? Is integration with the ambulatory patient portal the best approach for all institutions?
- What is the role of patient portals in promoting self-management and patient-provider communication during hospitalization and after discharge?
- How do we ensure equitable access securely? Is bring your own device (BYOD) practical, secure, and feasible?
- What are the advantages and disadvantages of hospital-issued versus a BYOD strategy?
- Should we leverage patients’ social networks and existing social media profiles to share with providers?
- What policies should be in place to drive development, innovation, adoption? How do we deal with “portal proliferation” from a policy perspective?
- What policies should be in place regarding sharing of data (test/study results, mental health data) with patients and care partners? What is the role of patient-generated health data?
- How will a new emphasis on APIs (application programming interfaces)–driven by Meaningful Use–impact patient engagement, and how should portals support or supplement this trend? How do we leverage the growth of wearable technologies?

**Moderator:** Anuj K Dalal, MD is an Associate Physician within the Hospital Medicine Unit, Division of General Medicine at Brigham and Women’s Hospital (BWH). He is an Assistant Professor at Harvard Medical School and Fellow of Hospital Medicine. He completed the Program in Clinical Effectiveness at Harvard School of Public Health, and holds a Graduate Degree in Medical Informatics from Oregon Health & Science University. He has expertise in designing, implementing, and evaluating innovative HIT strategies to improve the delivery of care in the inpatient and transitions setting. He has worked on multiple initiatives, including innovative projects to improve communication of clinically significant test results, optimize care team communication, and facilitate patient engagement with an overall goal of improving patient safety, quality, and healthcare value. He co-led the BWH PROSPECT (Promoting Respect and Ongoing Safety through Patient-centeredness, Engagement, Communication, and Technology) effort to design, develop, implement, and evaluate a novel acute care patient portal to engage patients and care partners. He has co-led the ACPP task force to disseminate findings from the Libretto Consortium and the ACPP2020 national conference. **He will provide an overview of the emerging field, review key opportunities and challenges to improve the acute and post-acute patient experience, highlight key recommendations from the ACPP2020 workshop, and introduce panel members.**

**Panel Members**

**Sarah Collins, RN, PhD** is a Senior Clinical and Nurse Informatician at Partners eCare, a researcher within the Division of Internal Medicine at BWH, and an Instructor in Medicine at Harvard Medical School. Dr. Collins received her Bachelor of Science in Nursing from the University of Pennsylvania and holds a PhD in Nursing Informatics from Columbia University. She is an experienced critical care nurse. She was a National Library of Medicine Post-Doctoral Research Fellow at Columbia University’s Department of Biomedical Informatics. Her research and applied clinical informatics work focuses on modeling, developing, and evaluating standards-based, collaborative informatics tools to further patient safety, knowledge development, clinical decision-support, and coordinated patient-centered care. Dr. Collins was first author of a 2011 JAMIA publication titled: Policies for Patient Access to Clinical Data via PHRs: Current State and Recommendations. Currently, she is leading the MySafeCare research project at BWH. MySafeCare is an application for patients and care partners to electronically submit safety concerns while in the hospital for real-time review via clinical dashboards. This AHRQ funded work includes integration of MySafeCare with the acute care patient portal at BWH. She has co-led the ACPP Task Force to disseminate findings from the Libretto Consortium and the ACPP2020 national conference. **She will discuss potential new directions for informatics research based on recommendations from the workshop.**
Victoria L Tiase, MSN, RN-BC is Director, Informatics Strategy at New York-Presbyterian Hospital. She received a BS in Nursing from the University of Virginia and the MS in Nursing Informatics from Columbia University. She serves on the AMIA Nursing Informatics Working Group Board and recently complete a fellowship in the Alliance for Nursing Informatics Emerging Leaders Program. She is currently responsible for planning, organizing, and implementing a range of clinical information technology projects related to electronic health record adoption and meaningful use, clinical workflows, patient engagement, and care coordination. She will discuss institutional strategies to sustain adoption and use of patient portals in acute care settings, including EHR integration.

Kristin O’Reilly, RN, MPH, is currently Manager of Network Medicine at athenahealth. Previously she held the position of Manager of Critical Care Quality at the Beth Israel Deaconess Medical Center (BIDMC). She holds a Master of Public Health in Health Services, Management, and Policy from Tufts University. Prior to working in healthcare quality, she served as a front-line clinical nurse at the Massachusetts General Hospital for five years. This unique combination of formal training and real-world healthcare experience has made her exceptionally effective as a project leader in Critical Care Quality and Safety. At BIDMC she oversaw a large portfolio of grant funded initiatives intended to reduce preventable harm in critical care incorporating informatics, patient engagement and systems science. This portfolio includes the development, design and rollout of an acute care inpatient portal for use in the intensive care unit. She will address recommendations for future investigation to address knowledge gaps, challenges, and emerging opportunities drawing upon her experience designing and implementing an acute care patient portal.

S. Ryan Greysen, MD, MHS, MA is a practicing hospitalist, NIH-funded investigator, and Chief of Hospital Medicine at the University of Pennsylvania. His research focus is on improving engagement of care for hospitalized older adults and interventions to improve post-discharge continuity of care including novel uses of patient-centered technology such as tablets and wearable mobility sensors. Dr. Greysen’s mixed-methods evaluation studies have leveraged advanced quantitative and qualitative techniques to inform health policy at the intersection of mobile health, hospital medicine, and geriatrics. His ongoing work expands this bedside coaching with portals and integrates mobility sensors to engage older adults/caregivers in goal-setting to avoid complications such as functional decline during hospitalization. He will discuss opportunities and challenges for effectively engaging vulnerable populations (such as older adults) in use of acute care portals and related applications (such as mobility sensors connected to the EHR via APIs) to improve patient experience and outcomes.

Acknowledgements: The work of the Acute Care Patient Portal Task Force was supported by the Gordon and Betty Moore Foundation. Additionally, we thank the members of the planning and steering committee for their participation and contributions to this effort.

Abstract

The Observational Health Data Sciences and Informatics collaborative (OHDSI, pronounced ‘Odyssey’) aims to create reliable scientific evidence through large-scale analysis of observational health data from around the world. OHDSI promotes the translation of this work to improve clinical research and medical decision-making. In the proposed panel, members of the community will discuss how OHDSI is working to support clinical research efficiency as well as support evidence sharing for medical decision-making by adopting the FHIR integration. To ensure transparency and reproducibility in our research, we have created shared knowledge artifacts such as phenotype libraries. In the proposed panel, we will discuss our approach to building shareable knowledge assets, conducting research using these assets, and supporting dissemination beyond the OHDSI community.

Organizer: Jon D. Duke, MD, MS

Background and Panel Description

The Observational Health Data Sciences and Informatics collaborative (OHDSI, pronounced ‘Odyssey’) was formed in 2013 with the goal of creating reliable scientific evidence through large-scale analysis of observational health data from around the world.¹ To advance this goal, OHDSI has had to rapidly expand its scientific, technical, and community infrastructure. OHDSI has now grown to over 200 participants from 17 countries. Across the collaborative, there are 55 databases covering over 650 million patient lives that have been transformed into a common data model. OHDSI has conducted multiple international network-based observational research studies using this infrastructure. In this panel we will focus on efficiency of evidence generation, and on translating large scale analytics into clinical solutions. We will report back on the results of a two day face to face meeting and hackathon from March 2017 as well as describe the development of the OHDSI on FHIR framework designed to facilitate the integration of OHDSI predictive models into clinical decision support. By the end of this panel, attendees will gain an understanding of the issues and approaches to sharing of large-scale observational research with clinicians.

Panel Importance and Target Audience

The target audience includes health informaticians, clinical and health services researchers, health IT leaders (e.g., CMIOs), implementation scientists, epidemiologists, biostatisticians, and data scientists. This panel will provide attendees with insight into the opportunities and challenges of conducting reproducible research across diverse datasets as well as a clear path for sharing research results outside the OHDSI network. The proposed panel illustrates how international collaborative research can be conducted in a transparent and reproducible fashion; and in the process generate large scale shared resources.²

Presentations

An Informatics Framework for Systematic Clinical Research across Observational Data Network (P. Ryan)
Observational healthcare data from electronic health records and administrative claims can be used to explore and test clinical hypotheses and generate aggregate evidence that can meaningfully inform medical decision-making.
While the community has seen tremendous advances in technical infrastructure, data standards, and statistical computing over the past decade, the paradigm for conducting clinical research has largely remained stagnant: a researcher poses a question about a particular clinical phenomenon (such as an exposure-outcome relationship), seeks to find a dataset that can be used to test the hypothesis, generates results that confirm or refute the hypothesis, drafts a publication that interprets the findings, rinses and repeats. Each clinical research project is a one-time journey, often inefficient but rarely reproducible. Other forms of replication - applying similar methods to different data, or different methods to the same data - to assess the robustness of clinical findings are difficult to coordinate and execute. The OHDSI community has been actively developing and testing informatics frameworks to facilitate the clinical research process - replacing the bespoke approach with a systematic pipeline to consistently guide researchers from research conception through protocol development through analysis implementation through network execution through results coordination. We have applied this process across questions of clinical characterization, population-level estimation, and patient-level prediction with the aim to the efficiency, accuracy, and reproducibility of observational analyses. In this talk, we will share the experiences and lessons learned from executing clinical research questions across the OHDSI network using this framework.

**Large-Scale Dissemination of OHDSI Prediction Models via FHIR Integration (J. Duke)**

One of the strengths of the OHDSI analytics environment is its predictive modeling engine known as PatientLevelPrediction (PLP, www.github.com/OHDSI/PatientLevelPrediction). PLP is an R-based package for generating predictive models using a large set of covariates such as all drugs, diagnoses, procedures, demographics, and comorbidity indices. PLP incorporates a range of machine learning techniques for feature selection and model generation. Current outcome models include logistic regression, random forest, gradient boosting machine (GBM), naive bayes, k-nearest neighbors (KNN), and multi-layer perceptron (MLP). While generating high-performing models is a key step in advancing the value of observational data, model generation alone is insufficient. Indeed, these models must be applied to individual patients and delivered at the right time and place (e.g., point of care) to improve medical decision-making. Dr. Duke will discuss the development of the OHDSI on FHIR framework designed to facilitate the integration of OHDSI predictive models into clinical decision support. This framework wraps PLP-based predictive models into RESTful APIs that ingest standard FHIR resources (e.g., medications, conditions), transiently converts the data to OMOP CDM format, and generates an individual patient prediction. This framework allows any FHIR-enabled EHR to incorporate OHDSI-based predictive models without the need to maintain an OMOP database. We will discuss how the OHDSI on FHIR framework can be used to expand evidence dissemination in clinical and research settings.

**Large-Scale Electronic Phenotyping (N. Shah)**

One of the first steps in using EHR data for research is to reliably identify a cohort of patients that have a condition of interest or a phenotype. Typically, methods for identifying patients with a given phenotype have relied on rule-based definitions. Recently, statistical learning approaches have also been employed for electronic phenotyping. Here the rate-limiting step is manual creation of training sets for statistical learning approaches. Given the heterogeneity of the data models in use, missing data values, and differences in standardization, in commercial EHR systems phenotype definitions are difficult to port across different EHR systems and institutions. Developing such definitions against common data models is one way to create reusable phenotype definitions. In the OHDSI community, we have demonstrated that by using semi-automatically assigned, and possibly noisy labels in training data, it is possible to build phenotype models that are comparable to rule-based phenotype definitions. The key intuition is that the large volume of training data which can be collected using an automated labeling process, can compensate for the inaccuracy in the labels. This presentation will discuss our effort to scale electronic phenotyping methods to build a library of 100 phenotype definitions for the OHDSI community for shared use. We will describe our experience in creating such phenotype definitions at scale. We will discuss automated mechanisms to evaluate the validity of phenotype definitions; and review the progress made at the OHDSI face to face meeting and hackathon held March 17-18 2017.

**Large-Scale Incidence Rates (G. Hripcsak)**

The large-scale calculation of incidence rates serves as a first step toward a comprehensive biomedical knowledge base. For every given drug, condition, procedure, etc., we can calculate the incidence of all other drugs, conditions, procedures, etc. Such a knowledge base is easily understandable, requires no assumptions, is efficient to calculate,
and is straightforward to visualize. The challenge is that incidence does not assign causality and is subject to many forms of confounding. We can see the probability of something happening but not the probability of improving it. For example, a condition that begins frequently when a drug is taken may be a side effect of the drug or may be part of the indication for the drug. Stopping the drug may or may not remove the condition. Nevertheless, the information is useful. Incidence rates can serve as upper bounds to side effect rates, and they can be interpreted in the context of deeper medical knowledge, such as whether a condition is likely to be part of a drug’s indication. As we move to large-scale causal assessments, incidence rates will remain an important foundation to interpret the causes. For example, something that is highly causal but very low incidence may not be of concern. OHDSI is calculating all-by-all incidence in a set of large databases and making it available to the public.

Discussion Questions

- What are the main challenges associated with disseminating evidence?
- What is the value of reusable knowledge assets such as phenotype libraries?
- How can phenotype performance be consistently evaluated across diverse institutions?
- What are the barriers to disseminating predictive models?
- How can FHIR be used to connect evidence to providers in diverse clinical settings?
- How can large-scale incidence rate enable better care or better research?
- What are the limitations of large-scale incidence rates.
- What motivates large collaborative studies?

Assurance
The organizer Jon D. Duke vouches that all listed participants have agreed to take part on the panel.

An Overview of Emerging Real-World OpenHIE Use Cases: Successes, Challenges, and Future Opportunities

Shaun Grannis, MD, MS, FACMI1, Eric-Jan Manders, PhD2, Carl Leitner, PhD3, Annah Ngaruuro, MS4, Jack Bowie, ScD5

1Indiana University and the Regenstrief Institute, Indianapolis, IN; 2Centers for Disease Control and Prevention, Atlanta, GA, USA; 3PATH, Chapel Hill, NC, USA; 4ICF International Inc., Rockville, MD, USA; 5Apelon Inc., Hartford, CT, USA.

Abstract

A growing international collaborative of diverse organizations and people have formed a community to develop open processes and technologies to support essential clinical data sharing needs of low and middle income countries throughout the world. OpenHIE (Health Information Exchange) is a global initiative convening communities of practice, implementers, and reference software components that together support national-level health information sharing activities. In this panel we will describe multiple real-world use cases supported by OpenHIE’s operational infrastructure, and will discuss the evolving community process, opportunities for broader collaboration, and future development plans. Learning objectives for the panel include: understanding the basic elements of a component-based eHealth architecture for low and middle-income countries, as exemplified by OpenHIE; describing specific use cases supported by OpenHIE; and identifying potential barriers and solutions for implementing specific health information exchange use cases for low and middle-income countries.

Introduction

Healthcare systems and public health practice rely on information and communication methodologies and tools for enabling the optimal use of data and information for action. Recent pandemics have further emphasized the need for information derived from flexible, standards-based, and interoperable electronic health information systems. Experience has shown that application of information and communication technologies (ICTs) for health, i.e., eHealth, especially in a global, interconnected world, requires strong leadership at the strategic and implementation levels to develop a sustainable model. To address this need, OpenHIE has emerged over the last two years, and numerous countries in Africa and Asia have engaged in the initiative. OpenHIE is a community of individuals and organizations who are committed to serving the underserved by bringing responsible technical architectural solutions to support large-scale electronic health information sharing. The OpenHIE community welcomes all and is represented by government agencies, private sector companies, academia, and non-governmental organizations contributing to the development of an open source, globally relevant health information exchange (HIE). Information sharing has become increasingly central to improving healthcare systems and health outcomes, The OpenHIE community seeks to share our experience and lessons learned with those interested in data sharing regardless of setting. This session will leverage the perspectives shared by attendees to inform future trajectory for health information architectures and data sharing use cases.

The 66th World Health Assembly (WHA) proposed a progressive new agenda in support of the health information architectures for it’s member states. WHA resolutions implored global health and informatics experts to support member states as they developed their national eHealth strategies through a multistakeholder and multisectoral approach including national authorities, relevant ministries, relevant private sector parties, and academic institutions. In parallel, a broad consortium of donors, stakeholders and development partners developed the nine Principles for Digital Development to serve as a set of living guidelines meant to inform the design of technology-enabled development programs. Both OpenHIE and this proposed panel respond to these calls to action, which furthers the dialogue around the effective, real-world implementation of health information architectures via community of practice models.

OpenHIE Introduction (Grannis)

OpenHIE’s mission is to improve the health of the underserved through open, collaborative development and support of country driven, large scale health information sharing architectures. The initiative is multifaceted and includes a flexible component-based architecture to support a diverse set of health information exchange clinical workflows. As
chief architect of OpenHIE, Dr. Grannis will serve as moderator and will provide an overview of the OpenHIE architectural elements, the reference software components and document artifacts, and the inclusive community model. The panelists will highlight use cases that illustrate the broad use of the OpenHIE construct to improve care and outcomes.

**Integrating Standard Terminologies: OpenHIE Terminology Services (Bowie)**

As developing countries contemplate comprehensive eHealth strengthening strategies, a primary function of a fully functional health information exchange is to aggregate, normalize, and communicate diverse healthcare information among disparate sources for various use cases. As data from different systems is exchanged and used outside its originating system, it is challenging to maintain the original meaning of the data. The use of standard definitions, terminologies and ontologies provides a technical language that can enable the data to have meaning outside its originating system.

This presentation will describe the role of one of the critical components of OpenHIE: the Terminology Services (TS). The TS component of the OpenHIE architecture provides a centralized source for the HIE’s standards and definitions, including terminologies, ontologies, dictionaries, code systems, and value sets. We will discuss the value of standardized data representations and the difficulties inherent in their adoption, particularly in the context of low and middle-income countries. We will describe examples of TS integration with other OpenHIE architecture components. The presentation will conclude with a discussion of TS integration in a variety of current OpenHIE implementations, touching on issues of required clinical and demographic domains, selection of national and international standards, and ongoing governance of the overall standards environment.

**The DATIM experience supporting indicator reporting (Ngaruro)**

The President's Emergency Plan For AIDS Relief (PEPFAR) is a U.S. governmental initiative to address the global HIV/AIDS epidemic, strengthen health systems, and help save the lives of those suffering from HIV. Its reach is global and includes partnerships with many countries. To manage information generated in participating countries, PEPFAR’s Data for Accountability, Transparency and Impact Monitoring (DATIM) system seeks to build a health information exchange infrastructure to enable data exchange among PEPFAR in-country teams, implementing partners and Ministries of Health. To accomplish this, the DATIM initiative has begun implementing various components of the OpenHIE architecture. We will discuss the DATIM use case, the experience and challenges, and value of implementation of the OpenHIE architecture from a programmatic and system perspective as well as the value proposition for stakeholders. Further, we will describe the minimum set of technologies necessary to accomplish the DATIM use case as well as how a discussion around the use of other HIE component to enrich and enhance the data exchange infrastructure.

**mHero: Supporting health workers for routine care and Ebola crisis care (Leitner)**

We will describe how the OpenHIE framework has been used to support sustainable health information systems by exploring a two-way SMS communication platform called mHero. mHero has been deployed in West Africa as part of the USAID Ebola Grand Challenge to link existing routine health worker registry and facility information systems (iHRIS and DHIS2) to provide integrated scalable tools to reach health workers in support of both routine health services crisis response situations. We will discuss the enabling environment needed to move a digital health intervention from a pilot to a national scaling implementation.

We will describe how factors including a participatory design processes, the installation of comprehensive governance structures, the inclusion of mHero in written eHealth policy, and investments in Ministry human resources and ICT capacity have produced a strong sense of local ownership of mHero. Participants will learn how an approach using OpenHIE simplifies the deployment of complex integrated health information systems and the technological tools that can be managed by ministries of health even in severely resource-constrained settings.

**HIV case-based surveillance (Manders)**

In many countries, the national response to the global HIV epidemic has contributed to the development of health information systems. With an initial focus on reporting program performance metrics, stakeholders recognize that system architecture and design considerations are critical to sustainability and successful implementation at scale. One such consideration is health information exchange, and the preference to achieve it through standards-based interoperability.
For the context of a country that has a substantial and growing footprint of facility-based EMR systems, we focus on leveraging the OpenHIE framework to implement EMR-based HIV case surveillance. We use the OpenHIE architecture to create a reporting channel to transmit selected clinical counter data of public health interest to a centralized data repository. Data transmission is based on clinical trigger events, and uses a standards-based message format. An OpenHIE client registry component can be used to support record linkage for patients who seek health services from different facilities, resulting in more accurate client counts for reporting. Security controls support the implementation of data access policies. Our aim is to leverage OpenHIE to facilitate program planning and public health decision-making from patient level data without the requirement to establish a fully developed shared health record for care coordination. The reusable architecture can accommodate interoperable systems for laboratory reporting, vital registration, and data sources that originate from paper registers for more complete data analysis.

**Discussion Questions**

1. What are the key elements of a component-based eHealth architecture supporting low and middle-income countries?
2. How can elements in component-based eHealth architecture be orchestrated to support specific data exchange workflows?
3. What are potential barriers to implementing specific data exchange use cases?
4. What key non-technical factors can enable successful implementation of data exchange workflows?
5. How can terminology services integrate into an overall eHealth architecture?
6. What lessons learned from implementing Health Information Exchange in the US could translate to LMIC settings?

**Panel Organizer Statement:** All participants have agreed to take part in the panel and discuss the topics as outlined above.

**Disclaimer:** The findings and statements in this report are those of the authors and do not necessarily represent the official position of the Centers for Disease Control and Prevention.

Clinical Decision Support in the Era of Precision Medicine

Panelists
Barry Blumenfeld, MD, MS1, Joni L. Rutter, PhD2,
Eliot Siegel, MD3, Linda Wedemeyer, MD, RN, MS4

Moderator
Michael A. Grasso MD, PhD3

1RTI International, Raleigh, NC, 2National Institutes of Health, Bethesda, MD, 3University of Maryland, Baltimore, MD, 4Veterans Health Administration, Los Angeles, CA

Abstract
The All of Us Research Program from the Precision Medicine Initiative will create new opportunities and challenges for clinical decision support (CDS). An important goal of the program is to create a research cohort of at least one million U.S. volunteers, which will be used to develop customized approaches to treat diseases and improve health. This panel will discuss new opportunities and challenges for CDS using the large research cohort. This panel, which was organized by the AMIA Clinical Decision Support Working Group, brings together leaders from government, academia, and industry with diverse backgrounds in Biomedical Informatics.

Background
During his 2015 State of the Union address, President Obama announced a new Precision Medicine Initiative (PMI). Renamed the All of Us Research Program, its goal is to develop new approaches to treat diseases and improve health customized by an individual’s genetic, environmental and lifestyle characteristics1,2,3. The program received initial funding of $215 million, which was allocated to NIH to build a large national cohort and to support cancer genomics. The Precision Medicine Initiative, PMI, All of Us, the All of Us logo, and The Future of Health Begins With You are service marks of the U.S. Department of Health and Human Services.

One long-term goal of the All of Us Research Program is to create a research cohort of at least one million U.S. volunteers4, who will contribute genetic data, lifestyle and environmental information, biological samples, and links to their electronic health records (EHRs). This new All of Us cohort will be unique in its balance of participants, reflecting the diversity of the U.S. population based on age, gender, ethnicity, geography, social characteristics, and health status. The program is a partnership between the cohort participants, health care providers, and the research community, to work together to develop prevention and treatment strategies with greater precision.

Similar large cohorts have been created, for example, IMS Health nation cohort of three million primary care patients in United Kingdom’s National Health Service5. In addition, the U.S. Veterans Health Administration manages research data on roughly thirty million veterans through the VA Informatics and Computing Infrastructure (VINCI)6, and is currently developing the Million Veteran Program to study genetic influences on health and disease7.

Introduction
This panel will discuss new opportunities and challenges for CDS in light of the All of Us Research Program. A wealth of new knowledge is expected to flow from the initiative. However, its effective use in clinical care depends heavily on its incorporation into CDS applications and tools. The barriers to such use are many. The provision of CDS will hinge on the development and deployment of new knowledge environments based upon flexible data models and extensive use of standard-based ontologies and terminologies8. Access will depend on wide scale adoption of standardized application programming interfaces. Current rule-based systems used in EHRs for most CDS systems might not be adaptable to the types of data and conditions represented by genomic data, nor is it known if they can scale for the very large numbers of data points represented by mutations and deletions in large genome datasets9. Other challenges include a lack of data independence, as well as complexity, quality, and integration10. Additionally, at the
point of care, such knowledge must be displayed in user-friendly formats so that physicians, laboratory personnel, nurses, researchers, and other end-users can enter data, access information, and understand the output.

**Topics for Discussion**

Clinicians are already dealing with a knowledge explosion that exceeds their capacity for absorption. The addition of genomic knowledge will only strain their capacity further. CDS has the potential to bridge the gap between the promise and realization of precision medicine, but it depends on progress in multiple arenas. The goal of this panel is to discuss these challenges and barriers, and to relate possible solutions. Panelists will address the following topics:

- Research goals and the timeline of the All of Us Research Program.
- The role of CDS and participants as partners in achieving the All of Us Research Program goals.
- Enabling CDS in the All of Us cohort: Knowledge engineering, implementation, and measurement.
- Using CDS in the All of Us cohort to drive a learning system.
- Challenges and barriers to the effective use of CDS within large cohorts.
- Real-world CDS experiences and lessons learned from other efforts.

**Panel Organizers**

This panel is sponsored by AMIA Clinical Decision Support Working Group.

- Yang Gong, MD, PhD, Chair.
- Barry Blumenfeld, MD, MS, Vice Chair.
- Michael A. Grasso, MD, PhD, Immediate Past Chair.
- Eric Pan, MD, MSc, Past Chair.
- Laura S. Crawford, MIS, Member-At-Large.

**Intended Audience**

The intended audience includes clinicians, researchers, and other informatics professionals who have an interest in healthy living, health policy, disease management, clinical decision support, and electronic health record integration.

**Speaker Contributions**

**Barry Blumenfeld, MD, MS - Senior Physician Informaticist, RTI International**

Barry Blumenfeld is a Senior Physician Informaticist at RTI International. He currently serves as the principal investigator for the AHRQ sponsored Patient Centered Outcomes Research Clinical Decision Support Learning Network. He is an authority on CDS and clinical documentation, and has led the design of systems in both academic and commercial settings. Other areas of expertise include health care analytics, health care information standards, interoperability, and knowledge management. He is also the current Vice Chair of the AMIA Clinical Decision Support Working Group. Dr. Blumenfeld will discuss the value of knowledge sharing and CDS in clinical practice, and the role of the All of Us cohort in knowledge engineering and management.

**Joni L. Rutter, PhD - Director of Scientific Programs, All of Us Research Program, The Precision Medicine Initiative, NIH**

Joni Rutter is the Director of Scientific Programs within the All of Us Research Program of the Precision Medicine Initiative at the National Institutes of Health. She leads the scientific, programmatic development, and implementation efforts to build a national research cohort of one million or more U.S. participants to advance precision medicine. She is internationally recognized for her work in basic and clinical research in human genetics and in the study of genetic and environmental risk factors focusing on the fields of cancer and addiction. She received her Ph.D. from Dartmouth Medical School and completed a fellowship at the National Cancer Institute. Her primary scientific objective is to integrate genetic principles with environmental influences to increase our understanding of how individual and societal influences impact health and disease. Dr. Rutter will discuss the All of Us cohort efforts and its application to CDS.

**Eliot Siegel, MD - Professor, University of Maryland School of Medicine**

Eliot Siegel is a Professor and Vice Chairman in the Department of Diagnostic Radiology and Nuclear Medicine, and Chief of Imaging Services for the VA Maryland Healthcare System. He has been recognized internationally for his
work in imaging informatics, served as the National Cancer Institute Cancer Biomedical Informatics Grid (caBIG) Imaging Workspace lead, and is a designated informatics lead within the national VA network. He is a fellow of the American College of Radiology and of the Society of Imaging Informatics in Medicine. His areas of interest and responsibility at both the local and national levels include digital imaging and PACS, telemedicine, the electronic medical record, informatics and artificial intelligence systems. Dr. Siegel will discuss related CDS efforts with large cohorts, including the IBM Watson program and caBIG.

Linda Wedemeyer, MD, RN, MS - Physician Informatician, VA Greater Los Angeles Healthcare System

Linda Wedemeyer is a Physician Informatician within the Veterans Health Administration Office of Informatics and Information Governance. She is part of the Clinical Decision Support team in Knowledge Based Systems. Her work includes CDS and health IT evaluation at the VA, and health IT standards development for the American Academy of Ophthalmology. She is working on a model for CDS evaluation and on standardized, shareable CDS knowledge artifacts. She has also been responsible for writing metrics to determine the impact of interoperability and health IT modernization on healthcare processes and outcomes. Dr. Wedemeyer will discuss real-world CDS experiences within the VA system, and the availability of large clinical repositories within the VA system.

Michael A. Grasso, MD, PhD – Assistant Professor, University of Maryland School of Medicine

Michael Grasso is an assistant professor of Emergency Medicine, Internal Medicine, and Computer Science at the University of Maryland School of Medicine. He practices Emergency Medicine at the Baltimore VA Medical Center, is board certified in Clinical Informatics, and is Director of the University of Maryland Clinical Informatics Group. He is currently working with the national clinical repository from the Veterans Health Administration. He is developing new approaches to knowledge representation and reasoning, which can be optimized for very large clinical repositories. The clinical focus for this work includes several chronic diseases, prescription opioid abuse, and quality improvement in Emergency Medicine. Dr. Grasso will be the panel moderator.

Participation Statement
All of the panelists have agreed to participate if the panel is selected for the AMIA 2017 Fall Symposium.

Successes and Challenges in Developing and Implementing Electronic Informed Consent Tools for Research

Panelists
Christopher A. Harle, PhD1, Hyeoneui Kim, RN, MPH, PhD2, David R. Nelson, MD3

Moderator
Kenneth W. Goodman, PhD, FACMI4

1Indiana University and Regenstrief Institute, Indianapolis, IN; 2University of California, San Diego, CA; 3University of Florida, Gainesville, FL; 4University of Miami, Miami, FL

Abstract
The U.S. health care system’s increased adoption and use of electronic health records (EHRs) over the past decade has increased the utility of health records for research. With these technological changes, new approaches and systems are needed to efficiently and appropriately inform patients about and consent them to participate in research, especially research that uses their electronic health information. In this panel, three researchers from different disciplines will describe three novel efforts to develop, implement, and evaluate point-of-care electronic systems that administer broad research consent. These systems span multiple institutions, are integrated with institutional EHRs, and involve consent for research re-contact and patient sharing of health records and bio-samples for research. At the conclusion of this panel, audience members will be able to: (1) discuss technological, process, and ethical challenges and keys to success in designing electronic consent tools for point-of-care use, (2) describe operational and technical challenges and keys to success in integrating research consent tools with EHRs and other enterprise information systems, and (3) critique qualitative and quantitative approaches to evaluating the effectiveness of electronic informed consent tools.

Introduction
The U.S. health care system’s increased adoption and use of electronic health records (EHRs) over the past decade has increased the utility of electronic health information for clinical research. EHR systems serve as direct and indirect, via integrated warehouses and registries, sources for researchers to analyze phenotypic, treatment, and outcomes data for patients over time, across care settings, and across organizations. EHRs can be used to identify patients for clinical trials and linked to biosample data for genomics research.1, 2 In addition, where racial and ethnic minorities are often underrepresented in clinical research,3, 4 EHRs may contain more representative data. Indeed, it has been suggested that failure to make efficient use of EHRs for research is itself an ethical failure.5

Given the expanded content and uses of EHRs, a key question is whether new approaches are needed to ensure ethical obligations are met when informing and consenting patients about research that uses their health information. However, while ethically appropriate approaches to informing and consenting patients are critical, research institutions also demand efficient approaches for administering broad research consents, and integrating and sharing consent and research data with partner organizations. Therefore, electronic applications for consenting patients at the point of care may provide an ethically appropriate, patient-centered, and efficient approach to involving patients in research. Compared to traditional paper-based consents, well-designed interactive electronic consent tools may be better at allowing patients to explore personally-relevant information and communicate granular consent preferences, and allowing research institutions to integrate consent data with other clinical and research data.

Why this Panel is Timely and Urgently Needed
This panel involves an interdisciplinary group of clinicians and researchers who will be discussing a timely topic with important policy, administrative, and research informatics implications. In recent years, the Department of Health and Human Services (HHS) prioritized improved knowledge and policies related to the increased scale and scope of electronic health information use in research. In 2014 and 2015, this led the National Institutes of Health (NIH) to request grant applications on Ethical Issues Related to Consent for Research Using Clinical Records and Data. This panel will discuss two of the projects funded by this request. Furthermore, in early 2017, HHS finalized updates to the Common Rule,6 the primary regulation that protects research participants. Several of the Common Rule updates aim to overcome the concern that informed consent processes are administratively and legally
burdensome, and not designed to help people make informed decisions about participating in research, including sharing their health information for research. Therefore, this panel will discuss the potential for electronic informed consent tools to integrate with clinical research information systems and support consent processes. We expect the panel will attract clinicians, information technology administrators, and informatics researchers interested in developing and leveraging electronic tools for efficient and patient-centered research.

General Description of the Panel
In this panel, three researchers from different disciplines will describe three novel efforts to develop, implement, and evaluate point-of-care electronic systems that administer research consent. These systems span multiple institutions, are integrated with institutional EHRs, and involve patient consent for research re-contact and sharing of health records and bio-samples for research. The panelists will describe technological, process, human, and ethical keys to successes and challenges in designing, implementing, and rigorously evaluating electronic consent tools.

Panelists
Dr. Harle is an Associate Professor of Health Policy and Management at Indiana University and Affiliated Scientist at the Regenstrief Institute’s Center for Biomedical Informatics. He is also currently a Co-Principal Investigator on the NIH-funded study “An Interactive Patient-Centered Consent for Research Using Medical Records.” In this panel, Dr. Harle will describe findings from this study, which aims to design and evaluate an interactive electronic informed consent application that asks patients for consent to use their identifiable health record data in research. The application is designed to be efficient for use in clinical practice settings while also enhancing patient trust and flexibly meeting their information needs, as compared to traditional paper-based consents. First, Dr. Harle will describe patient preferences and information needs related to electronic research consent. These were identified during a series of 42 think-aloud interviews conducted during a mock electronic consenting process. Second, Dr. Harle will describe the successes, challenges, and results of a randomized experiment examining how the interactive and trust-enhancing features of an electronic consent application affect peoples’ satisfaction with an electronic consent process, understanding of the consent, perceptions of coerciveness, and trust in medical researchers.

Dr. Kim is an Associate Professor of Biomedical Informatics at the University of California, San Diego. She is also currently a Co-Principal Investigator on the NIH-funded study “iCONCUR: informed CONsent for Clinical data and Biosample Use for Research.” In this panel, Dr. Kim will describe findings from this study, which aims to guide the development and implementation of informed consent management systems that elicit patient preferences for clinical data sharing based on what data are shared and who the recipients of shared data are. First, Dr. Kim will describe the successes and challenges involved in developing, pilot testing, and establishing feasibility of a web-based informed consent tool that allows patients to express granular preferences for the use of their EHR data in research. Second, Dr. Kim will describe the second phase of iCONCUR, where consenting options are refined and survey functions are expanded to incorporate the care dependents of the main survey respondent. The current status of the iCONCUR tool will be demonstrated and preliminary results of the phase two survey will be shared.

Dr. Nelson is a Professor of Medicine, Assistant Vice President for Research, and Director of the NIH-funded Clinical and Translational Science Institute (CTSI) at the University of Florida (UF). In this panel, Dr. Nelson will describe the UF’s Consent2Share program. The Consent2share program encompasses processes and electronic consent systems that ask patients at the point-of-care for their consent to be re-contacted about research studies in which they may be eligible to participate. The Consent2Share program was pilot tested in an internal medicine and medical specialties practice and subsequently rolled out at an enterprise level for both pediatric and adult patients. First, Dr. Nelson will describe successes and challenges in Consent2Share’s rollout and integration with UF’s Epic EHR system, integrated data repository, and i2b2 system. Second, Dr. Nelson will describe Consent2Share’s value in supporting clinical trial recruitment, including relative yield of different recruitment strategies.

Dr. Goodman is a Professor of Medicine, Director of the University of Miami School of Medicine’s Institute for Bioethics and Health Policy, and co-founder of the North American Center for the Study of Ethics and Health Information Technology. He is also past chair of the Ethics Committee of AMIA and co-founder of the Ethical, Legal and Social Issues Working Group. Dr. Goodman will moderate this panel, discuss overlapping themes in the panelist presentations, and lead the audience discussion.

All participants have agreed to take part on the panel.
Learning Objectives
At the conclusion of this panel, audience members will be able to:

1. Discuss technological, process, and ethical challenges and keys to success in designing electronic consent tools for point-of-care use.

2. Describe operational and technical challenges and keys to success in integrating research consent tools with EHRs and other enterprise information systems.

3. Critique qualitative and quantitative approaches to evaluating the effectiveness of electronic informed consent tools.

Discussion Questions
The panelists will encourage in-depth discussion from the audience. Several discussion questions are listed below:

1. What ethical obligations do researchers have to inform and consent patients regarding the use of their health record data for research? How has that obligation evolved with widespread EHR adoption, increasing health information exchange, and new forms of personal health data that are stored in EHRs?

2. For what types of research and patients can well-designed electronic informed consent tools serve as an effective substitute for in-person consent processes? What are the potential legal, ethical, and operational strengths and weaknesses of replacing in-person informed consent with electronic tools?

3. What are the appropriate metrics for assessing the value and impact of electronic informed consent tools on research activity?

4. What challenges have audience members’ institutions faced when considering, developing, implementing, and using electronic informed consent tools?

A Structured Approach to Measuring Individual Nurse’s Contribution in Patient Outcomes

Ellen M. Harper, DNP, RN, MBA, FAAN¹, Catherine H. Ivory, PhD, RNC-OB, RN, BC ², Lisa A. Moon, BSN, CCMC, LNC, PhD², Amy Garcia, DNP, RN, CENP ⁴
¹University of Kansas, Kansas City, KS, ²Vanderbilt University, Nashville, TN, ³ University of Minnesota, Minneapolis, MN, ⁴ Cerner Corporation

Abstract

Nurses are key drivers of patient outcomes as well as a significant cost center in any healthcare setting. How do we measure nursing care value – or more importantly, the unique value each nurse contributes to patient outcomes? At the most basic level of definition, value is the relationship between outcomes of care and the costs to produce that care. These two basic elements of cost and outcome are measured using the individual patient as unit of analysis. Traditional hospital outcome metrics are measured in terms of length of stay, the presence or absence of adverse events such as infection, fall, or pressure ulcer, or inpatient mortality. However, the volume of data generated by clinical and operational electronic health records (EHRs), permits the examination of short term changes in patient outcomes attributable to nursing care. EHR data allows measurement of both the patient response to treatments or nursing interventions, at the individual nurse level and correlate both with nurse characteristics such as education and experience levels. This didactic panel will describe the methodological approach taken by the Nursing Value Expert Workgroup to structure, define, abstract and evaluate discrete data from disparate electronic systems to measure nurse’s contribution to patient outcomes.

Introduction

Nurses are key drivers of patient outcomes as well as a significant cost center within any healthcare setting¹². How do we measure nursing care value – or more importantly, the unique value each nurse contributes to patient’s outcomes? At the most basic level of definition, value is the relationship between outcomes of care and the costs to produce that care³⁴. These two basic elements of cost and outcome are measured at the individual patient unit of analysis, for example, what is the total nursing care time and costs to care for a patient with acute pneumonia and what are the patient’s outcomes of the care? Conversely, we do not measure care cost and outcomes at the individual nurse level. Traditional metrics of hospital outcomes are measured in terms of length of stay, potential adverse events such as infection, falls, pressure ulcer or inpatient mortality⁵. However, the volume of data generated by clinical and operational electronic health records (EHRs), permits the examination of short term changes in patient outcomes attributable to nursing care⁶. Discrete electronic data allows measurement of both the patient response to treatments or nursing interventions, at the individual nurse level and correlate both with nurse characteristics such as education and experience levels. This didactic panel will describe the methodological approach taken by the Nursing Value Expert Workgroup to structure, define, abstract and evaluate discrete data from disparate electronic systems to measure nurse’s contribution to patient outcomes.

Nursing care is a practice discipline and occurs between one nurse and a person, family, or community. Nurses can be linked to individual patients within the EHR in several ways (e.g., the nurse-patient assignment or other data that capture touch points such as bar coding for medication administration or recording an assessment in a patient’s home or clinic documentation⁷). These data can provide new and unique opportunities to measure nursing care in several different dimensions (e.g., the 1:1 relationship of a nurse caring for a patient, the impact of many nurses on the outcomes of care for a single patient, or the potential to investigate similar outcomes across many nurses and many patients across many different settings⁸).

This didactic panel will describe the structured methodology and work products of a Nursing Value Expert Workgroup⁹¹⁰, organized through the Nursing Big Data to Knowledge initiative¹¹. The expert workgroup is a component of ongoing efforts of a National Action Plan to ensure that nursing data is captured in EHRs and other information systems – and that the data is available in shareable and comparable formats so that clinicians, nursing administrators, researchers, policy makers and others can use it to gain useful, actionable insights. The aim is to ensure that nursing data is used to inform changes leading to better outcomes, lower cost and an improved patient and staff experience.
Objectives

1. Develop a national consensus model to measure patient-level nursing intensity and costs per patient in multiple care settings to support the continuum of care and to produce objective measures of nursing care value.

2. Develop new nursing business intelligence and analytic tools that will utilize the rich clinical, operational, financial, and quality/safety outcome data currently available to measure and compare nursing care value.

3. Develop and test new nursing financial models to bring transparency to support risk sharing within Accountable Care Organizations, value-based purchasing, and pay-for-performance models.

The panel will include presentations on the following 4 topic areas:

1. Presentation of the recently published Value Based Nursing Data Model which demonstrates the relationships across disparate electronic data and primary key (relationships). The Value Based Nursing Data Model is EHR agnostic and venue setting neutral to support the continuum of care.

2. Processes used to develop a data dictionary that structurally and operationally defines individual nursing value data elements mapped to standardized terminologies, such as SNOMED CT and LOINC. We will describe efforts to use existing definitions from established dictionaries such as the Centers for Medicare/Medicaid Services (CMS), the Nursing Management Minimum Data Set (NMMDS), the National Database of Nursing Quality Indicators (NDNQI) and others, to eliminate redundancies. We also propose a framework to harmonize recognized terminologies that describe nursing interventions, processes and outcomes, that recognizes facility preferences but permits data sharing and benchmarking. Finally, we propose value sets for standards organizations, to approve and use for the measurement of nursing care across inpatient, outpatient, home care and public health domains.

3. Development of User Stories used to deconstruct complex nursing scenarios into a standardized set of features, item responses and data elements. The User Stories use conventional agile information technology processes. The tool intentionally links the identified user story features to the Value Based Nursing Data Model. This approach provides a standardized process that can be used to describe nursing value for data analytics and business intelligence purposes.

4. Presentation of the results of the pilot study site used to test the work products. The research questions- Do the characteristics (certification, education, nursing experience, and experience on the unit or service line) of registered nurses assigned to care for a patient significantly impact patient care and outcomes, including cost? How does the workload of the individual nurse impact the outcomes of the patient? Additionally, presentation on the preparation of a multi-site study which includes the Nursing Value Data Warehouse (NVDW) and business intelligence to facilitate research on the value of nursing across the continuum of care.

The presentation will demonstrate how we can use discrete data to improve efficiency, effectiveness, productivity, performance, and quality, to achieve exceptional outcomes of nursing care.

Discussion questions:
What strategies can be used to define and categorize data elements used to measure nursing value?

What discrete data elements can be used to measure both the patient’s response to treatments or nursing interventions, at the individual nurse level and correlate with nurse characteristics such as education and experience levels?

How can user stories be used to deconstruct complex nursing interactions so that they might be tested as part of an approved data model to measure nursing value?

Can we leverage patient and nurse level data to identify new micro-costing methods, to predict patient care trajectories that improve outcomes of care, and link nurses and patient to identify best nursing outcomes?
Conclusion
The imperative is to better understand how nursing care is expended for each person/patient and measure the specific costs of that care, associated with defined outcomes. Prior research measures nursing care in the aggregate, such as average number of nurses on a unit or nursing skill-mix on a unit. This presentation will describe the ample data in emerging EHRs and other electronic systems and how it can be used to quantify nursing care at the individual nurse level. The structured methodology presented provides a model for usable and actionable information that can be the basis to improve the quality and efficiency of nursing care delivery systems. Such actionable information provides understanding of how to optimize nurse staffing and assignment patterns that will improve outcomes by aligning individual nurse’s characteristics (experience, education, certification) to individual patient’s needs. The nursing value model, data dictionary, user stories and their corresponding analytic and business intelligence tools will provide a mechanism for the use of data sensitive to the practice of nurses in big data and value-based measurement, providing a metric by which the unique value of nursing contribution in patient outcomes can be measured.

Working Group Affiliation: Endorsement of this panel presentation is provided by the Nursing Informatics Working Group (NIWG).

Clinical Informatics in Medical Education: Innovations from the AMA Accelerating Change in Medical Education Initiative

William R. Hersh, MD1, Susan Skochelak, MD2, Anderson Spickard, MD3, Blaine Takesue, MD4, Paul Gorman, MD1

1Oregon Health & Science University, Portland, OR; 2American Medical Association, Chicago, IL; 3Vanderbilt University, Nashville, TN; 4Indiana University, Indianapolis, IN

Competence in clinical informatics is required of all 21st century health professionals. This panel will describe efforts to bring clinical informatics competencies, curricula, and integration into medical school curricula in the context of the American Medical Association initiative, Accelerating Change in Medical Education. After an overview of the initiative by one panelist, the other three will describe specific projects in curriculum development in clinical informatics for medical students, data-driven monitoring of medical student achievement and progress, and the development and use of a teaching electronic health record.

Modern physicians, nurses, and other health care providers must have knowledge and skills in applying modern informatics tools, from the electronic health record to information and knowledge retrieval systems [1]. They must have a practical understanding of key informatics issues that impact clinical practice, including privacy and security, clinical decision support, patient safety, and more.

In 2013, the American Medical Association (AMA) launched an initiative called Accelerating Change in Medical Education (ACE), with the aim of creating “medical schools of the future” [2]. The AMA awarded five-year grants to 11 medical schools to undertake innovations in medical education. An additional 21 schools were brought into the consortium in 2016, although funded at a lower level. The foci of the awardees was diverse and included projects to introduce competency-based education and lifelong learning, shorten the duration of medical school, and expand curricula beyond traditional basic and clinical sciences. One focus across the consortium has been to expand curricula under the rubric of health systems science (also known as healthcare delivery science or the “third science”) [3], including the publication of a new textbook on the topic [4].

Four of the original 11 grantees had components of clinical informatics in their project plans, and a subgroup of interest focused around aspects of clinical informatics in the curriculum. Each of the four medical schools had distinct projects, yet they collectively addressed a spectrum of key issues related to implementing competencies in clinical informatics medical training. The four institutions included Indiana University, New York University, Oregon Health & Science University (OHSU), and Vanderbilt University.

Although the development of competencies and curricula in clinical informatics for clinicians is not limited to physicians, the AMA ACE initiative has provided unique resources to enable aspects of clinical informatics in the training of health professionals that can be adapted to other health professionals besides physicians. The overall goal of the panel is to share the projects and lessons learned from the initiative to inform other efforts and stimulate potential collaboration. The panel will begin with an overview of the AMA ACE initiative, which sets the context for three of the grantees to describe their work. Each panelist will speak for 12-14 minutes and leave at least 30 minutes for audience interaction to provide feedback on work done and engage in dialogue for collaboration going forward.

This panel is timely and relevant given the increasing role that informatics plays in the lives of clinicians, especially the near-universal adoption of electronic health records in the United States and increasing engagement and use by patients, researchers, and other of information technologies.

Dr. Skochelak will be the initial speaker and will present a big-picture view of the AMA ACE consortium. She will then drill down to describe the relevance of clinical informatics to the consortium and describe AMA efforts to lead innovation in medical education across the country.

Dr. Hersh will next describe efforts at Oregon Health & Science University (OHSU) to thread clinical informatics throughout the four years of a newly revised MD curriculum. He will discuss initial efforts to establish competencies in clinical informatics for medical education and then detail how the curriculum has been implemented. He will also
describe barriers and challenges, which include the critical need for student assessments, managing competition for curricular time, and engaging students who are technology-savvy but possess very little understanding of its optimal and appropriate use in healthcare.

Dr. Spickard will then discuss how Vanderbilt has implemented a restructured curriculum in which medical student learning is competency-based, individualized, and situated in the workplace. He will describe innovative means of gathering student performance information through the electronic health care record and mobile assessment applications. He will share lessons learned after 4 years of implementation of a robust electronic portfolio system that collects and displays student data for analysis to inform individual and programmatic success.[5].

Finally, the Regenstrief Institute at Indiana University developed an electronic health record (EHR) designed specifically to support education. Dr. Takesue will describe the implementation and use cases of the teaching EHR (tEHR) at Indiana University and several other undergraduate and graduate health professions schools. He will discuss challenges in using real, misidentified data for education. He will also discuss the challenges in developing and executing a clinical informatics curriculum in schools without a robust clinical informatics tradition.

Dr. Gorman will serve as the panel moderator and also share his experiences when appropriate concerning implementation of clinical informatics curriculum at OHSU.

Although discussion with the audience will be attendee-driven, we propose some questions to facilitate participation:

- What strategies have we used to successfully address the challenges of incorporating informatics concepts and competencies?
- How are we using the EHR educationally?
- How can clinical information systems and specially designed systems be used to capture student performance data?
- How can these methods be transported to other disciplines?
- What strategies have we used to successfully address the challenges of incorporating informatics concepts and competencies?
- How can clinical information systems and specially designed systems be used to capture student performance data?

This topic is timely and urgent because competence in informatics is not limited to informatics professionals. All health care professionals must have skills and knowledge in informatics to practice optimally in the 21st century. Although focused on medical school curricula, this panel will provide insights and methods applicable to all health care professionals. The panel will likely draw an audience not only of educators, but all conference participants who are concerned with the informatics competence of health care professionals generally.

The panel organizer (WRH) states that all participants have agreed to take part on the panel. A CV for each presenter (“NIH-style” bio-sketch is preferred) is provided.

The Best of Imaging Informatics Research 2017

Panelists: William Hsu, PhD1, Charles E. Kahn, Jr., MD, MS2
1Department of Radiological Sciences, University of California, Los Angeles, CA;
2Department of Radiology and Institute for Biomedical Informatics, University of Pennsylvania, Philadelphia, PA

Abstract
The field of imaging informatics is rapidly advancing in its ability to address challenges related to clinical big data and harnessing this information for precision medicine. In the past year, the field has experienced growth in a variety of areas including machine learning (learning from imaging data for diagnostic and prognostic predictions), radiomics (the generation of high-dimensional features from images), patient-oriented sharing and communication of images and image-derived findings, and the growth of the use of imaging beyond radiology. Novel approaches go beyond pixel data to integrate imaging with other biomedical data, standardize imaging workflows, and improve the quality and utility of image-derived information in clinical practice. In this session, we will review key advances in imaging informatics research published this past year.

Overview
Biomedical informatics spans a spectrum from basic to applied research, and from molecular to population scale. Imaging informatics is a discipline that focuses on improving patient outcomes through the effective use of images and imaging-derived information in research and clinical care. As the storage and display of multidimensional image data have become commonplace, imaging informatics has evolved from primarily characterizing information from pixels and voxels in images to integrating evidence from images and other biomedical data sources to provide a systems-level understanding of disease etiology and progression. These developments have underscored the need to engage individuals from different disciplines to address shared challenges in managing heterogeneous datasets, developing common standards, and interpreting multiscale evidence for precision medicine. This session provides attendees with a topical review of new and interesting developments in imaging informatics in areas of quantitative image analysis, image annotation and markup standards, data curation and integration with clinical, pathology, and genomic datasets, deep learning and machine learning for clinical decision support, and patient-oriented image sharing. We expect this session to appeal to AMIA attendees given its emphasis on shared challenges and techniques such as data standards, information extraction, annotations, and predictive modeling that are broadly studied and applicable across the biomedical informatics field.

Methods
We will perform a broad search of relevant papers published in the past twelve months using targeted PubMed, Web of Science, and Google Scholar queries. To ensure coverage, we will also review articles published in Radiology, Radiographics, Journal of the American Medical Informatics Association, Journal of Biomedical Informatics, and Journal of Digital Imaging, Journal of Pathology Informatics, Neuroimage, Medical Image Analysis, and Academic Radiology. Abstracts will be reviewed and ranked by the two panelists with disagreements discussed. Identified articles will also be supplemented by a call for nominations from luminary imaging informatics groups, including the AMIA Biomedical Imaging Informatics Working Group, the Radiology Informatics Committee of the Radiological Society of North America (RSNA), the Commission on Informatics of the American College of Radiology, and the Board of Directors of the Society for Imaging Informatics in Medicine (SIIM).

Drs. Hsu and Kahn will present the best of research in ontologies, structured data capture, decision support, radiomics, data integration and predictive modeling, novel healthcare applications, and other science focusing on data other than the images themselves. The content will be divided between the two panelists based on the final set of papers that are identified as a result of the selection process.

Panel Organizer Statement
The panelists listed above have agreed to present the material and lead a discussion. A similar session will be presented at the RSNA annual meeting in December 2017. This session is supported by RSNA, SIIM, and the AMIA Biomedical Imaging Informatics Working Group.
Can the Clinical Information Modeling Initiative (CIMI) Enable the Semantic Interoperability Promise of Fast Healthcare Interoperability Resources (FHIR®©)?

Stanley M. Huff, MD⁠¹, Julia Skapik, MD, MPH⁠², Claude Nanjo, MPH, MAAS⁠³
¹ Intermountain Healthcare, Murray, UT, ² Department of Biomedical Informatics, University of Utah, Salt Lake City, UT, ³ Office of the National Coordinator for Health IT (ONC), Washington, D.C., ⁴ Cognitive Medical Systems, San Diego, CA

Abstract As implied directly in its name, the Health Level 7 (HL7) Fast Healthcare Interoperability Resources (FHIR) standard is intended to enable semantic interoperability. However, the base FHIR-defined classes (known as FHIR “resources”) do not have sufficient specificity to enable such interoperability. Constrained versions of those classes (known as FHIR “profiles”) are intended to provide sufficient specificity to support the semantically interoperable exchange of clinical data. However, multiple, semantically inconsistent FHIR profiles on the same topic can and have been developed; there is no governance around profile development; many profiles are still insufficiently specified to enable semantic interoperability; there is no mechanism to ensure consistency between FHIR profiles; and vendor support for FHIR has focused primarily on resources and not profiles, and are therefore potentially (and likely) inconsistent with one another. HL7 CIMI is working with the FHIR team to address these problems and to enable FHIR to be truly semantically interoperable. This panel will be an interactive discussion to address two questions: first, is FHIR capable of supporting true semantic interoperability without an effort such as CIMI? And second, is CIMI the answer to FHIR’s challenges in this area?

Description Dr. Huff will serve as the moderator and introduce each of the panel members. He will then provide a brief overview of the topic (5 min). Dr. Skapik will provide a position statement that FHIR is a highly promising platform for interoperability but that it alone is insufficient for achieving true semantic interoperability (10 min). Dr. Huff will provide a position statement that CIMI and its model-driven approaches are essential for achieving true semantic interoperability (10 min). Mr. Nanjo will provide a position statement that CIMI can be leveraged by the FHIR community to enable true semantic interoperability (15 min). These position statements will be followed by an interactive panel discussion (50 min) on the proposed position statements and will be moderated by Dr. Huff.

Intended Audience The intended audience for this interactive panel are developers and implementers of the FHIR standard, including EHR vendors, clinical informaticists, standards developers, and healthcare leaders and policy makers.

Introduction of the Topic As noted explicitly in its name, The HL7 FHIR standard is intended to enable semantic interoperability. The primary focus of the FHIR standard to date has been on its definition of classes such as Condition, Encounter, Patient, and Observation, which are known as FHIR “resources”. However, FHIR resources alone do not have sufficient specificity to enable semantic interoperability. In particular:
- **FHIR resources may not represent important concepts.** For example, the Patient resource lacks a race attribute, which is commonly used in the U.S. This situation is due to FHIR resources not including attributes unless they are commonly collected globally.
- **FHIR resources make most attributes optional.** Because FHIR resources can be used in a wide variety of contexts, most attributes are optional. For example, the value of an Observation is optional in FHIR.
- **FHIR resources have minimal terminology constraints.** Because FHIR resources are intended to be used in a wide variety of contexts, terminology constraints are minimal in nature. For example, codes to identify Observations, Conditions, Procedures, and Medications can use any terminology, including local or vendor-specific codes.
- **The FHIR “Basic” resource, combined with FHIR’s limitless “extension” capability, allows any data structure to be represented in any number of ways while remaining “FHIR compliant.”** For example, a Basic resource with tires, doors, and an engine can be defined to represent a car and would be considered completely FHIR compliant, as would a Basic resource with a windshield, drivetrain, and hood ornament.
As a consequence, for example, an EHR vendor returning laboratory results as an Observation can be fully compliant by using a vendor-specific, or even implementation-specific, code to represent a lab and by omitting the value completely. It should be clear, then, that on its own, saying that one supports FHIR resources is practically meaningless in terms of semantic interoperability.

In order to address this interoperability challenge, FHIR allows the definition of more specific versions of the resources as FHIR Structured Definitions, more commonly known as FHIR “profiles”. These profiles can specify, for example, that a U.S. laboratory result observation must use LOINC for its code and use UCUM as its units of measure.

Despite the potential promise of profiles, in practice they are insufficient for achieving semantic interoperability. In particular, multiple, semantically inconsistent FHIR profiles on the same topic can and have been developed; there is no governance around profile development; many profiles are still insufficiently specified to enable semantic interoperability; there is no mechanism to ensure consistency between FHIR profiles; and vendor support for FHIR has focused primarily on resources and not profiles, and are therefore potentially (and likely) inconsistent with one another.

HL7 CIMI was established to rigorously and consistently define the semantics of clinical information models. The HL7 CIMI Work Group has been working with the HL7 FHIR team to address challenges to semantic interoperability and to enable FHIR to be truly semantically interoperable. In particular, CIMI is developing models from which FHIR profiles can be auto-generated, and it is establishing governance on the selection of a preferred model and associated FHIR profile among multiple semantically equivalent representations of the same information.

**Aim and Expectations of the Discussion**

The aims of the discussion are to (i) inform the AMIA audience on the interoperability limitations of FHIR and work that is currently underway to address it and (ii) obtaining constructive criticism and feedback on the proposed approach from the audience.

**Contribution of Each Speaker**

Dr. Huff is Professor (Clinical) of Biomedical Informatics at the University of Utah, and the Chief Medical Informatics Officer at Intermountain Healthcare. He is currently a co-chair of the LOINC Committee, and a co-chair of the HL7 CIMI Work Group. He will moderate the panel and make the case for CIMI as the basis of semantic interoperability in health care.

Dr. Skapik is an internist and Medical Officer at ONC. She has been working with ONC for the past several years on clinical quality standards, terminology, policy and programs. The culmination of the standards work is the Clinical Quality Framework, which has taken disparate clinical quality measurement and clinical decision support standards and moved them into a unified modular stack within FHIR. She hopes that this work, when fully integrated with a robust data element specification and detailed clinical models like CIMI, could form the basis for a unified clinical data model that will enable seamless but consistently meaningful data capture by end users and a basis for future health IT certification. She will make the case that FHIR alone is insufficient to achieve true semantic interoperability.

Mr. Nanjo is Chief Scientist at Cognitive Medical Systems, and he has been a leader in the development of FHIR profiles for the purposes of clinical decision support and electronic clinical quality measurement. He is also developing tooling to allow CIMI models to auto-generate FHIR profiles. He will make the case that CIMI can enable FHIR to achieve true semantic interoperability.

**Why this Topic is Timely and Controversial**

FHIR is rapidly being advanced as a panacea to semantic interoperability in health care. However, early and deep adopters of the FHIR standard, including the members of this interactive panel, have identified significant issues with achieving semantic interoperability using FHIR alone. This issue is particularly timely because important stakeholders including healthcare leaders, vendors, and policy makers may be advancing FHIR without a full understanding of its current limitations. Addressing this issue will be critical for achieving the promise of interoperability envisioned by the FHIR community. This topic is controversial because many stakeholders are under the impression that FHIR alone can achieve semantic interoperability.
Participation Statement
All panelists have agreed to participate in the panel if it is accepted.
Big Data in the Intensive Care Unit*

Andrew James, MBChB¹, Mohammad Adibuzzaman, PhD², John Zaleski, PhD³, Peter Haug, MD⁴
¹Department of Paediatrics, University of Toronto, CA, ²Regenstrief Center for Healthcare Engineering, Purdue University, Indiana, USA, ³Bernoulli, USA, ⁴Homer Warner Center, Intermountain Healthcare and Department of Biomedical Informatics, University of Utah, USA

Moderator
Soojin Park, MD⁵
⁵NY Presbyterian Hospital and Columbia University College of Physicians and Surgeons

Abstract
Big data has brought much promise for discovery of treatment and therapies, drug safety, and the care delivery processes by identifying which treatment would work best for which patients. NIH has recently taken the initiative, ‘All of Us’, to collect one million or more patients’ data (electronic health records (EHR), imaging, genomics, environmental data, etc.) over the next few years. The intensive care unit represents a unique data source in this context, with carefully captured detailed high volume data from different systems such as EHR, electrocardiogram, blood pressure, infusion pumps, and photoplethysmogram, among other data. However, the mere availability of data does not translate into knowledge or improved outcome. Questions remain on what data is needed, how to integrate these high volume data with high throughput infrastructure for near real-time decision making by the clinicians. In this panel, we present our work in integrating this heterogeneous high volume data with state of the art technologies for retrospective analysis and near real-time decision making with different systems such as Medical Information Mart from Intensive Care Unit (MIMIC III) and Artemis: both from technological and clinical perspectives.

Panel Description
The panel addresses the technological challenges to overcome the gap between large volume of data collection and useful applications with the data. The discussions would focus on high throughput analysis, both real time and retrospective, and specific clinical applications of such systems in the domain of prediction of sepsis, multivariate alarm generation, and diagnosis and treatment of pneumonia.

Brief description of each panelist’s discussion
1. The Artemis Project: Real-time intelligent data analysis in the NICU. Andrew James, MBChB
   Enormous data is collected in the ICU setting from different sources such as nursing notes, infusion pumps, and physiological data from as many as sixteen different streams. Clinicians often are overwhelmed with the volume of data, and cannot make data driven decisions because of the gap between data collection and necessary tools for real-time data analysis and visualization. For example, it is very common for critically ill babies to have significantly abnormal variation in the measured parameters minute by minute that are not recorded in the medical record. Motivated by this need, the Artemis project was initiated to develop the necessary software and hardware tools for real-time continuous ingestion of high volume data for robust temporal analysis to identify variations that are temporally associated with conditions of interest. As a use case, the early diagnosis algorithm for onset of neonatal sepsis, which is a leading cause of morbidity, is illustrated.

2. An integrated high throughput open access analysis platform for the MIMIC database for retrospective analysis. Mohammad Adibuzzaman, PhD
   Medical Information Mart for Intensive Care (MIMIC) database is a well-known database in the scientific community for detailed data captured from an intensive care unit and freely available for research and collaboration. Although this database is a great resource for scientific analysis, it is not straightforward to do a holistic analysis of the clinical

* Sponsored by the Intensive Care Informatics Working Group
In this talk, we present a new cloud based model for collaborative access, exploration, and analyses of the MIMIC III database for translational clinical research (1). The proposed model addresses the significant disconnect between data collection at the point of care and translational clinical research. It addresses problems of data integration, pre-processing, normalization, analyses (along with associated compute back-end), and visualization. The proposed platform is general, and can be easily adapted to other databases. The pre-packaged analyses toolkit is easily extensible, and allows for multi-language support. The platform can be easily federated, mirrored at other locations, and supports a RESTful API for service composition and scaling.

3. Multivariate real-time data can provide insight into cascades towards adverse events. John Zaleski, PhD

In recent years focus has been on alarm signal reduction in critical care and, more recently, general care floors regarding mitigation of false alarm signals and other non-actionable alerts to clinical staff, to both mitigate alarm fatigue and improve patient safety. Alarm signals, in general, provide reactive mechanisms for indicating a potential problem with patients. Yet, oftentimes the trends leading towards the resulting alarm signal can be detected earlier through an understanding of the behavior of measured signals that, individually, may not be interesting. Yet, when taken together, paint a picture of deterioration that can be used to suggest earlier intervention to head off an adverse event. One area in particular is that of opioid-induced respiratory depression, and the interaction between patient respiratory drive, the onset of CO2 narcosis, and the detection of trending events. This talk illustrates the case for using multi-variate data through real-time measurement to indicate trending behavior that can lead towards adverse events.

4. Impact of electronic clinical decision support tool with high volume data for diagnosis and treatment of pneumonia. Peter J Haug, MD

The talk illustrates the usefulness of big data systems in clinical settings for the diagnoses and treatment of specific clinical problems, such as pneumonia and sepsis, from the experience of Intermountain Healthcare. Despite evidence that guideline adherence improves clinical outcomes, management of pneumonia patients varies in emergency departments (EDs) and ICUs. Motivated by this problem, the effect of a real-time, electronic clinical decision support tool that provides clinicians with guideline-recommended decision support for diagnosis, severity assessment, disposition (including recommending ICU admission), and antibiotic selection is presented(2, 3).

Learning Objective

After participating in this panel, the attendant should be able to:

1. Identify the technological challenges to integrate and analyze high volume data in ICU setting, both for real time and retrospective analysis.
2. Identify the need for such systems in care delivery process.
3. Learn about specific clinical applications of such systems, in the domain of prediction of sepsis, multivariate alarm generation, and prediction of pneumonia.

Biography of the panelists

1. Andrew James, BSc, MBChB, MBI, FRACP, FRCPC

Dr. Andrew James is the Interim Clinical Director, Neonatal Intensive Care Unit at The Hospital for Sick Children, and an Associate Professor, Department of Paediatrics, Faculty of Medicine, University of Toronto. He obtained his medical degree from the University of Auckland, Auckland, New Zealand and trained in neonatology at National Women’s Hospital, Auckland and The Hospital for Sick Children, Toronto, Canada. Dr James has a graduate degree in biomedical informatics from the Department of Medical Informatics and Clinical Epidemiology, Oregon Health & Science University, Portland, Oregon. He has also completed the Certificate in Continuing Studies in E-Learning, School of Continuing Studies at the University of Toronto. Dr. James’ current activities include knowledge representation, the visual display of information, predictive analytics, and advanced clinical decision support. He is co-lead for the Artemis Project: a collaborative, multidisciplinary, international team that is developing advanced clinical decision support applications for the early identification of late onset neonatal sepsis, the recognition and classification of neonatal spells, the recognition of pain, the recognition of sleep/wake cycling in newborn infants and the quantification of retinal exposure to oxygen. Other active projects include the structured representation of the
clinical care of the newborn infant by SNOMED CT; the development of SNOMED RefSets for disorders of the newborn infant; and the ontological representation of the clinical care and disorders of the newborn infant.

2. Mohammad Adibuzzaman, PhD

Mohammad Adibuzzaman is a research scientist at the Regenstrief Center for Healthcare Engineering located in Purdue University, Indiana. His research interest includes mathematical model development and big data system for understanding of healthcare data for better patient outcomes. He has a PhD in Computational Sciences from Marquette University. He received his Master’s degree in Computational Sciences in 2012 from the same university. Before going to Marquette, he worked as a Junior Research Assistant at the National University of Singapore and as a Software Engineer in Bangladesh. He also worked as an Oak Ridge Institute of Science and Engineering (ORISE) Fellow at the U.S. Food and Drug Administration in 2013 and 2014.

3. John Zaleski, PhD

John Zaleski, PhD, CAP, CPHIMS, is Chief Analytics Officer of Bernoulli, a leader in real-time connected healthcare. Dr. Zaleski brings 21 years of experience in researching and ushering to market devices and products to improve healthcare. He received his PhD from the University of Pennsylvania, with a dissertation that describes a novel approach for modeling and prediction of post-operative respiratory behavior in post-surgical cardiac patients. Dr. Zaleski has a particular expertise in designing, developing, and implementing clinical and non-clinical point-of-care applications for hospital enterprises. Dr. Zaleski is the named inventor or co-inventor on seven issued patents related to medical device interoperability. He is the author of numerous peer-reviewed articles on clinical use of medical device data, information technology and medical devices and wrote three seminal books on integrating medical device data into electronic health records and the use of medical device data for clinical decision making, including the #1 best seller of HIMSS 2015 on connected medical devices.

4. Peter J. Haug, MD

Dr. Peter J. Haug earned his MD from the University of Wisconsin, Madison. Currently he is a Medical Informatics Director and a member of the Homer Warner Center for Informatics Research at Intermountain Healthcare and is a professor in the University of Utah’s Department of Biomedical Informatics, where he is involved in research and postgraduate education. His expertise includes the following: the study of tools for natural language processing in medicine; the evaluation of probabilistic decision support systems for use in the health-care process; the development of computer-based tools to deliver detailed medical protocols; and various applications of data mining to assist in the development of innovative medical software. Previously, he developed components of two different medical information systems. Currently, he is focusing on the construction of environments designed to support applied informatics research and to support the testing of innovative tools for implementing decision support in active clinical settings. His research explores natural language processing to extract clinical information from medical documents, sharable approaches to representing decision support logic, models of disease capable of informing clinical care, and secondary uses of data collected in the course of care. Joining the department in 1983, Professor Haug, MD, is a Fellow of the American College of Medical Informatics, and co-chairs the Arden Syntax Working Group, Health Level VII. He is certified by the American Board of Internal Medicine and the National Board of Medical Examiners.

Big Data to Knowledge (BD2K) and the Application of Metadata

Guoqian Jiang, MD, PhD1, Walter Campbell, PhD, MBA2, Timothy Clark, PhD3, Cui Tao, PhD4, Mark Musen, MD, PhD5

1Mayo Clinic, Rochester, MN; 2University of Nebraska Medical Center, Omaha, NE; 3Massachusetts General Hospital, Boston, MA; 4University of Texas Health Science Center – Houston, Houston, TX; 5Stanford University, Stanford, CA

Abstract
Clinical and translational research studies increasingly involve the manipulation of large datasets. There is a critical need to develop metadata-driven informatics technology to both lower the effort required for, as well as incentivize the process of applying metadata in clinical and translational research. The NIH Big Data to Knowledge (BD2K) initiative seeks to develop an interactive data ecosystem through adopting the FAIR principles (i.e., data must be findable, accessible, interoperable and reusable), and is supporting various technology platforms in these contexts to make it easier for researchers to share their data with the community so that it can broadly benefit the community. This thematic panel will highlight five projects funded through the BD2K initiative that are developing technology infrastructure and tools for metadata management, standardization and applications. Attendees will learn about novel open source metadata informatics platform, and how data/metadata standards are used in data sharing platforms. Attendees can engage with panelists on metadata challenges and potential solutions in support of clinical and translational research applications.

Introduction
Clinical and translational research studies increasingly involve the manipulation of large datasets. There is a critical need to develop metadata-driven informatics technology to both lower the effort required for, as well as incentivize the process of applying metadata in clinical and translational research. The NIH Big Data to Knowledge (BD2K) initiative seeks to develop an interactive data ecosystem through adopting the FAIR principles (i.e., data must be findable, accessible, interoperable and reusable), and is supporting various technology platforms in these contexts to make it easier for researchers to share their data with the community so that it can broadly benefit the community. This thematic panel will highlight five projects funded through the BD2K initiative that are developing technology infrastructure and tools for metadata management, standardization and applications.

The use of data standards plays a key role in these applications of metadata as existing and emerging data standards can enhance comparability and consistency of heterogeneous data sources. The data standards used in these projects include clinical data standards such as HL7 FHIR and ONC national standards, the data citation standards such as JDDCP, and vocabulary standards through biomedical ontology services and developments. The use cases and application domains included in some of these applications are generic (e.g., focusing on broad clinical and translational research studies) whereas some applications are very specific (e.g., focusing on data regulation and citation).

Metadata Topics
In this panel, we highlight five metadata technology development projects that describe various platforms to demonstrate the informatics platform and framework applying metadata that would drive data discovery in the era of rapidly accumulating big data. These initiatives are described briefly below:

1. **Tools for indexing clinical research metadata using HL7 FHIR (Guoqian Jiang)**

   Fast Healthcare Interoperability Resources (FHIR) is an emerging HL7 standard; it leverages existing logical and theoretical models to provide a consistent, easy to implement, and rigorous mechanism for exchanging data between healthcare applications. However, currently the toolbox that enables HL7 FHIR as a global data model to standardize clinical research metadata is very limited. We aim to provide a scalable standards-based framework that enables effective and efficient big data integration and semantic sharing leveraging emerging Semantic Web technologies. In this panel, we will present the methods and tools we are developing at Mayo Clinic for indexing clinical research metadata, including 1) a semantic data element repository for managing metadata in HL7 FHIR; 2) a schema.org extension for enabling
2. Deploying ONC National Standards in Support of Metadata for Big Data Research Warehouse Management of Repurposed Laboratory, Pathology and Patient Findings Data from the EHR (Walter Campbell)

The Patient Centered Outcome Research Network (PCORnet) seeks to support large scale, multi-site outcomes research through collection and aggregation of data across a broad array of medical centers. Central to the success of PCORnet is the ability to perform federated data queries across numerous heterogenous clinical data warehouse (CDW) instances. Researchers at UNMC propose the use of ONC standards as metadata as a mechanism for normalizing data across multiple, diverse CDW’s. In this panel, we will present how UNMC deployed ONC standards metadata into its i2b2-based CDW including the complex polyhierarchies of SNOMED CT and RxNorm to support federated queries across PCORnet sites. Included in this discussion is the development and deployment of an observables ontology for pathology data, as well as, the current status of software tooling developed and available for ONC metadata deployment in an i2b2 environment.

3. JDDCP-Compliant identifiers and Metadata for Biomedical Publishers and Data Repositories (Timothy Clark)

The BD2K-sponsored Data Citation Implementation Pilot (DCIP) was run from late 2015 through 2017 in conjunction with bioCADDIE, a project to develop a data discovery index for biomedicine. DCIP’s goal was to develop, enable and encourage adoption of a common model for data to be archived in robust repositories, cited in publications, identified by globally unique persistent identifiers, and discoverable by search engines and indexers. DCIP’s methodology was to convene expert groups of early adopters across several communities to develop common specifications and initiate adoption, while coordinating with metadata harvesters and standards bodies. This talk will briefly report on the metadata and identifier approaches that developed out of the DCIP program and how they can support more robust, reusable and translatable biomedical research.

4. Metadata Applications On Informed Content To Facilitate Biorepository Data Regulation And Sharing (Cui Tao)

The application of suitable metadata in support of the complex set of regulatory, legal, privacy and security requirement processes and information flows involved in regulated research is a field in an early phases of development. The complicated legal and technical requirements involved in the processes challenge our ability to effectively build information systems that support sharing of research data, specimens and other research artifacts at scale. Our project is trying to develop suitable machine-based metadata representation and automatic annotation of regulatory processes focusing on informed consent forms and the associated documents. Our approach will presumably provide a formal and computable basis for data sharing and information release policies.

5. Intelligent Authoring of Metadata for Translational Research (Mark Musen)

The Center for Expanded Data Annotation and Retrieval (CEDAR) is developing methods to ease the authoring of the metadata needed to annotate data sets from experiments in translational research. Using community-derived metadata standards and controlled terms from biomedical ontologies, CEDAR offers a Web-based platform that simplifies the development of complete, comprehensive metadata. CEDAR has been deployed in several real-world settings, and we will discuss user experiences with the technology. We also will discuss how CEDAR-based software might assist with the authoring of metadata for more clinical applications.

This panel is timely and relevant given the urgent need to share clinical research data to facilitate clinical and translational data discovery and analytics, and advance our understanding of human health and disease. Initiatives such as the precision medicine and cancer moonshot will spur the generation of large datasets. We need appropriate tools and technologies applying metadata to manage and analyze these to inform clinical research and patient care.

Discussion questions

1. What would you like to see in a research-data sharing platform?
2. What types of metadata/data should be shared?
3. What metadata tools will be most useful to help your translational research?
4. What are your most critical metadata/data sharing challenges?

Learning Objectives

1. Attendees will learn about novel open source metadata informatics platform
2. Attendees will learn about how data/metadata standards are used in data sharing platforms
3. Attendees can engage with panelists on metadata challenges and potential solutions in support of clinical and translational research applications

Organizer statement: All speakers have agreed to attend AMIA 2017 Annual Symposium and participate on this panel.

Acknowledgement

The five metadata projects highlighted in this panel proposal are supported by the following NIH Awards: U01 HG009450 (PI: Jiang); U01 HG009455 (PI: Campbell); 3U24 AI117966-02S1 (PI: Ohno-Machado), U01HG009452 (PI: Clark); U01 HG009454 (PI: Tao); and U54 AI117925 (PI: Musen).
Enabling Knowledge-Driven Care at Scale through CDS Hooks and the FHIR Clinical Reasoning Module

Kensaku Kawamoto, MD, PhD, MHS¹, Kevin Shekleton,² James Doyle³, Bryn Rhodes⁴, Howard R. Strasberg, MD, MS⁵

¹Department of Biomedical Informatics, University of Utah, Salt Lake City, UT,

³Epic Systems Corporation, Verona, WI,
⁴HarmonIQ Health Systems Corporation, Orem, UT,
⁵Wolters Kluwer Health, San Diego, CA

Abstract

Interoperable clinical decision support (CDS) holds great promise for ensuring that patients receive the best care possible based on the latest medical knowledge. Building on prior efforts at standards-based CDS interoperability, as well as rapid adoption of the HL7 FHIR standard by the EHR vendor community, various stakeholders including EHR vendors, knowledge vendors, and healthcare systems are working together to enable interoperable knowledge-driven care through the CDS Hooks and FHIR Clinical Reasoning specifications. These specifications are being harmonized into a single unified HL7 specification, and the goal of this unified specification is to enable EHR systems to both (i) invoke external CDS Web services and (ii) consume external knowledge artifacts such as order sets, rule specifications, and documentation templates in a standard manner. In this panel, the latest developments will be discussed by leaders of this effort from the EHR vendor community, the CDS knowledge vendor community, the standards development community, and the healthcare provider community. The panel will demonstrate interoperable CDS implemented on multiple EHR platforms using this approach. The panelists will also describe key challenges and lessons learned, solicit feedback from the audience, and describe planned future work to continue advancing health and health care through interoperable CDS.

Description

The panel will be organized as follows:

<table>
<thead>
<tr>
<th>Time</th>
<th>Speaker</th>
<th>Topic</th>

</tr>
<tr>
<td>15 min</td>
<td>Kawamoto</td>
<td>Health care system perspective</td>
</tr>
<tr>
<td>20 min</td>
<td>All</td>
<td>Panel discussion with audience</td>
</tr>
</tbody>
</table>

Dr. Strasberg will serve as the moderator and introduce each of the panel members and their organizations. Dr. Strasberg will then describe why CDS interoperability is needed, briefly summarize prior work, and outline challenges to achieving interoperable knowledge-based care. This overview will be followed by presentations by the panelists, who will describe the unified FHIR-based standards for CDS interoperability (Rhodes); provide EHR vendor perspectives for supporting these CDS interoperability standards (Shekleton and Doyle); and describe how interoperable CDS can and is improving patient care at the healthcare delivery system level (Kawamoto). Panelists will also showcase interoperable CDS using this standard approach. These presentations will be followed by a panel discussion with the audience moderated by Dr. Strasberg.
Strasberg: Dr. Strasberg is VP of Medical Informatics at Wolters Kluwer Health, a leading CDS knowledge vendor with CDS solutions such as UpToDate® and Medi-Span®. He is co-chair of the HL7 CDS Work Group. Dr. Strasberg leads Wolters Kluwer’s efforts in interoperable CDS. Dr. Strasberg will provide an overview of why CDS interoperability is needed to enable knowledge-driven care at scale. He will also provide a brief history of prior standardization efforts upon which the present initiative builds, and he will discuss key challenges to CDS interoperability.

Rhodes: Mr. Rhodes is EVP of Advanced Consulting at HarmonIQ Health Systems Corporation, a health IT company focused on interoperable solutions to improve patient health. Mr. Rhodes is also the principal subject matter expert for the Clinical Quality Framework (CQF) initiative sponsored by the Office of the National Coordinator for Health IT (ONC) and the Centers for Medicare and Medicaid Services (CMS) to enable interoperable CDS and electronic clinical quality measurement at scale. Mr. Rhodes will describe the unified FHIR-based CDS interoperability specification, which represents a unification of the CDS Hooks and FHIR Clinical Reasoning specifications. This unified specification is anticipated to be balloted as an HL7 standard in September 2017. This unified specification supports both (i) the sharing of CDS capabilities through Web services and, equally importantly, (ii) the sharing of CDS knowledge artifacts (e.g., event-condition-action rules, order sets, and documentation templates) as FHIR resources. The sharing of CDS knowledge artifacts involves the use of the HL7 Clinical Quality Language (CQL) expression language, and the sharing of CDS capabilities through Web services can leverage CQL or any other expression language. Both CDS interoperability approaches utilize the FHIR data model and profiles, which are expected to continue to evolve through the work of various HL7 Work Groups including the HL7 Clinical Information Modeling Initiative (CIMI) Work Group.

Shekleton: Mr. Shekleton is a Vice President and Distinguished Engineer at Cerner Corporation. Mr. Shekleton is the Project Lead of the multi-stakeholder CDS Hooks initiative, which has brought together a diverse group of EHR vendors, CDS knowledge vendors, and healthcare systems around the vision of interoperable CDS. Mr. Shekleton will describe Cerner’s strategy and roadmap for supporting interoperable CDS, which includes providing production-level support for CDS Hooks in its product lines. He will also show examples of interoperable CDS solutions operating in the Cerner environment using these interoperability specifications, and he will provide his thoughts on the future of interoperable CDS at Cerner and across the industry, including his thoughts on how standards-based CDS knowledge artifacts could potentially be supported by EHR vendors such as Cerner.

Doyle: Mr. Doyle is a senior Software Developer and a leader of CDS development and initiatives at Epic, including Epic’s efforts in the area of standards-based CDS interoperability. He will describe why Epic sees value in CDS interoperability, and how Epic is seeking to support the best care possible for every patient through the sharing of best clinical practice and the latest medical knowledge. Mr. Doyle will describe Epic’s strategy and roadmap for interoperable CDS and will provide examples of interoperable CDS solutions operating in the Epic environment. Mr. Doyle will also provide his thoughts on the future of interoperable CDS at Epic and across the industry, including how CDS interoperability could be supported not just through services but also through the sharing of interoperable CDS knowledge artifacts such as rule definitions and order sets.

Kawamoto: Dr. Kawamoto is Associate Chief Medical Information Officer, Assistant Professor of Biomedical Informatics, Director of Knowledge Management and Mobilization, and Chair of the CDS Committee at the University of Utah. Dr. Kawamoto is also co-chair of the HL7 CDS Work Group and co-Initiative Coordinator for the ONC/CMS-supported CQF initiative. Dr. Kawamoto also co-leads the University of Utah’s Interoperable Apps and Services (IAPPS) initiative, which is a multi-stakeholder effort to enable standards-based, interoperable applications and software services to improve health and health care. Dr. Kawamoto will describe why interoperable CDS is urgently needed to enable the ubiquitous availability of advanced CDS across healthcare delivery systems. He will then describe how the University of Utah is supporting the standards described in the panel through an open-source implementation of a CDS Hooks adapter for the Epic EHR platform, as well as through OpenCDS (www.opencds.org), an open-source CDS framework that provides support for standards-based CDS delivery. Dr. Kawamoto will also show how the University of Utah is leveraging these standards to improve patient care and the physician experience, including through the use of these CDS interoperability approaches within SMART on FHIR applications interfaced with the Epic EHR. Dr. Kawamoto will also discuss key lessons learned and the work that remains in achieving optimized patient care supported by effective, comprehensive, and interoperable CDS.
**Strasberg:** Dr. Strasberg will lead a moderated discussion with the audience. The objectives of this discussion will be to answer questions from the audience, engage in a stimulating exchange of ideas, and gain further insights on the topic from audience members’ collective experiences. The questions listed below will be used to stimulate this discussion.

**Significance of panel topic and anticipated audience**

Effective CDS is critical for ensuring that patients receive optimal patient care and for healthcare systems to survive and thrive in a value-based payment environment. While history has shown that it is not feasible for individual healthcare organizations to develop the breadth and depth of effective CDS needed for realizing the full potential for knowledge-driven care, the unified CDS Hooks/FHIR Clinical Reasoning specification holds the potential to finally realize this vision given the strong support it is receiving from major EHR vendors such as those represented in this panel. Thus, it is imperative for biomedical informaticists seeking to improve the quality and value of health care to gain knowledge and insights into this important and rapidly progressing area of clinical informatics and health care delivery.

**Discussion questions**

- What areas of clinical medicine do you think can benefit most from interoperable CDS?
- What recommendations do you have for standards development and implementation in this area?
- What gaps do you see in the current interoperability frameworks offered by EHR systems?
- What can be done to facilitate order mapping from external CDS systems to local order catalogs?

**Participation statement**

All proposed panelists have agreed to participate in the panel if the proposal is accepted.
Are EHRs “Overloading” Health Professionals? Issues, Advances and New Directions from Cognitive Science and Usability Engineering

Andre W. Kushniruk, Ph.D., FACMI 1, Elizabeth Borycki, Ph.D.1, Yalini Senathirajah2, Darren Hudson3

1 School of Health Information Science, University of Victoria, Canada
2 SUNY Downstate Medical Center, Brooklyn, New York, USA
3 Department of Critical Care Medicine, University of Alberta, Canada

Abstract

Issues about the usability and safety of electronic health records have come to the fore. Reports of systems that user find difficult to use, interfere with healthcare workflows and that make them feel “cognitively overloaded” continue to be reported. The concept of “cognitive load” emerged from the cognitive literature several decades ago and refers to the amount of mental effort required to carry out tasks. In areas such educational design the concept has proven useful, as well as in other areas such as aviation and cockpit design. However, far less work in cognitive load has been applied in the area of human factors in healthcare. In this panel presentation, experts from the United States and Canada will explore the concept of cognitive load, including its definition, its measurement and its implications, for improving the usability and safety. Implications for the design and testing of a wide range of health information systems and technologies will be explored. The learning objectives include increasing awareness of cognitive load, understanding the concept, understanding how it can be measured, and understanding what can be done to decrease “cognitive overload”.

Introduction

Usability testing and clinical simulations can provide data that can be used to assess not only the usability of health information technology (HIT), but also the impact of systems on the cognitive processing of end users of these systems 1-3. Despite increased consideration nationally and internationally about the usability of HIT, reports of unusable, difficult to work with and unsafe HIT continue to be reported worldwide. One major complaint is that these systems may be difficult to use under real contexts of use where there may be time constraints, missing data, and stressful conditions. Working with HIT under these conditions might be difficult and users still complain about inability to process information presented by HIT and potential negative impact on workflow, decision making and reasoning 4.

A concept that has emerged from the cognitive literature is that of cognitive load. Cognitive load refers to the amount of mental effort being used in working memory to carry out tasks. The theory emerged from research in problem solving and the work of John Sweller in the 1980s 5. It has since been applied in design and evaluation in areas ranging from education to aerospace. For example, the NASA Task Load Index has been used to assess the cognitive load of carrying out tasks using technology in a range of areas from combat aviation, commercial aviation, office workers and electrical power groups. Related measures of workload have begun to be applied in medical specialties such as critical care medicine, anesthesia, emergency medicine, pharmacy and nursing health records 6-9. Applying such measures hold promise to help in understanding critical human factors issues with systems such as electronic health records and to help in decreasing the potential for error due to cognitive overload 10. A number of authors have begun to argue that cognitive overload may be responsible for many of the usability, workflow and safety problems being reported in the literature 10. With the increased triggering of system generated medical alerts, complex user interfaces and less than optimal screen designs in HIT, the potential for cognitive overload increases and is beginning to be recognized as being a major problem (and as a major underlying source of many usability and safety issues in healthcare today). As a result, there is a need to develop effective measures of cognitive load that can be used to compare HIT, select systems and to understand when HIT user interfaces and displays need to be reconfigure to reduce cognitive load and resulting potential for technology-induced error in healthcare.
In this panel, experts from Canada and the United States will describe their work in applying assessment of cognitive load to leading to improved user interface design, improved user interaction and safer systems in healthcare. A particular focus of the panel will be on the impact of cognitive load on the inadvertent introduction of technology-induced error, and how methods from human factors and usability engineering can be applied to assess the impact of cognitive load on medical error in order to mitigate such negative impact. This is a new perspective from which to view cognitive load as the literature on technology-induced error in HIT is barely a decade old and needs to be integrated with work on assessing cognitive load. New approaches are needed in the context of making HIT safer from the impact of cognitive load on technology-induced error, which will be discussed and will be a focus. The panelists will also engage the audience in a discussion of the impact and importance of this essential human factors issue (and growing concern) in the design, use and selection of healthcare information systems. The intent will be to make the audience aware of the critical importance of considering cognitive load in understanding problems with system usability and safety and to provide practical ways of measuring cognitive load.

Panelist Presentations:

Andre Kushniruk, Ph.D., FACMI (moderator and panelist) will describe the concept of cognitive load and relate it to the design and usability of a range of healthcare information systems. He will provide a background to the concept from the cognitive literature and will review areas in healthcare information systems where concepts and methods from cognitive science have been applied in an attempt to improve healthcare user interfaces by understanding, measuring and decreasing the cognitive load of health professionals using these systems. He will draw on examples from the area of usability and human factors in healthcare, including the application of a method known as rapid low-cost in-situ usability testing as a way of assessing the impact of systems on users’ cognitive processes and assessing the impact of systems on cognitive load in order to mitigate error and make HIT safer.

Elizabeth Borycki, Ph.D. will describe the integration of “clinical simulations”, i.e. simulations involving in-depth qualitative study of humans (e.g. nurses, doctors) conducted “in-situ” (i.e. in real hospital settings) with simulations that are “computer-based”. The approach involves several phases. First complex human interactions with systems such as medication order entry are analyzed by giving representative users scenarios which are recorded in-situ (i.e. in actual healthcare settings, including recording of user interactions with interfacing technologies – e.g. bar coding). The data from these studies of humans interacting with systems in highly realistic conditions are then analyzed to assess cognitive load and the likelihood of medication error given the presence of specific user interface and design features. Finally, the results from such analysis can be fed into computer-based simulations to form the basis for further modeling and forecasting of impact of systems on a larger scale and over time. The approach can also be used to assess the impact of specific design features that may be causing cognitive load and that may be responsible for causing technology-induced error. It is argued that a range of usability testing and simulation methods can be practically used in conjunction in order to identify user issues and dramatically decrease cognitive load and the risk of technology-induced error, and increase the potential benefits of healthcare information systems.

Yalini Senathirajah, Ph.D. will describe her work in developing composable user interfaces that allow for more flexibility in designing and deploying EHR user interfaces, in an effort to decrease cognitive load of these systems and to arrive at new ways of measuring cognitive load. Almost all current EHR systems have information location fixed by the vendor, with menu-based navigation and information access. This has the result that the user must usually traverse multiple screens and scroll, zoom, pan, and take other actions to view all relevant parts of the record. This ‘display fragmentation’ has consequences for cognitive load as the user must then remember information in mind between screens, loading working memory and also imposing visual and hand coordination requirements. A different ‘composable’ approach in which the relevant data are assembled on the same screen via flexible user-controlled UI can be used to decrease the cognitive load as well as discover better information aggregation and interaction design meeting user needs. Methods of studying cognitive load (such as with eye tracking) and assessing and redesigning EHR UI will be discussed.

Darren Hudson, M.D., M.Sc. will describe his work in integrating the NASA task load index to assess workload in electronic health records. Few studies have specifically studied workload in electronic medical records even though there increased workload is cited as a frequent cause of dissatisfaction. The NASA task load index can be used to understand the factors that impact on the perceived workload associated with the use of electronic medical records in order to make them safer. It is easy to administer and produces consistent results. The NASA task load index is also able to distinguish between different groups of subjects within a study and demonstrates face validity.

Topic Rationale: Issues related to poor usability and potential for introduction of technology-induced error continue to be reported worldwide as HIT such as EHRs are deployed and become ubiquitous. Theory and methods emerging from human factors in the area of measuring cognitive load will become increasingly important to
understand and apply in health informatics to increase the potential benefits of systems and decrease the potential for cognitive overload and associated negative effects on usability and safety of the systems we deploy. Health informatics professionals require better methods for identifying issues related to cognitive load and to formulate approaches to mitigating impact of cognitive load.

**Learning Objectives:** After participating in this panel, attendees will be able to understand issues related to cognitive load in the design, use and testing of HIT such as EHRs. They will also have learned about how cognitive load can be measured in relation to using HIT, and how cognitive overload can be identified and mitigated.

**Discussion Questions:**
- Are currently available vendor based systems causing health professionals to feel they are overloaded or overwhelmed?
- What is the impact of cognitive overload on health IT safety and ultimately patient safety?
- Are negative impacts of systems on workflow related to the health professionals’ ability to process increasing complexity and amounts of information being made available electronically?
- Does the concept of “cognitive load” help to explain the type of end user issues complaints related to lack of fit with workflow, too much information to process in a reasonable time, poor usability etc.?
- What methods can be used to assess cognitive load involved in using HIT?
- How could methods for assessing cognitive load be used to improve system design and customization and provide input when deciding amongst HIT products during procurement?

**Participant Agreement Statement:** All participants have agreed to participate in this panel.

**Keywords:** user-computer interface, patient safety, usability, cognitive load, system evaluation

**Panel Participant Details:**
- **Andre W. Kushniruk**, MSc., Ph.D., FACMI, Professor and Director, School Health Information Science, University of Victoria, Victoria, BC, Canada Email: [andrek@uvic.CA](mailto:andrek@uvic.CA)

Accelerating Evidence Into Practice: AHRQ’s Clinical Decision Support Initiative

Edwin A. Lomotan, M.D.1, Dave deBronkort, S.B.2, Barry Blumenfeld, M.D.3, Robert McCready, M.S.4
1Agency for Healthcare Research and Quality, Rockville, MD; 2 Society for Participatory Medicine, Nashua, NH; 3 RTI International, Research Triangle Park, NC; 4 The MITRE Corporation, Bedford, MA

Abstract
The Agency for Healthcare Research and Quality (AHRQ) has launched an ambitious multi-component initiative with two primary aims: to accelerate the movement of evidence into practice through clinical decision support (CDS) and to bring CDS closer to becoming more shareable, standards-based, and publicly-available. This panel will discuss progress thus far and visions for the future based on lessons learned. The initiative includes: 1) The Patient-Centered CDS Learning Network, which is building a community for engaging patients, clinicians, CDS developers and implementers, professional societies, and other stakeholders; 2) CDS Connect, which is building prototype infrastructure for sharing CDS, including a CDS authoring tool and a national CDS repository; 3) research grants to develop new CDS and to scale existing CDS to new sites and systems; and 4) evaluation. Audience members will learn how the Patient-Centered CDS Learning Network is engaging stakeholders to explore and advance the concept of “patient-centered CDS,” how to contribute and use shareable CDS artifacts through CDS Connect and its repository, about current grants and funding opportunities to move evidence into practice on a wider scale, and how to participate in the overall initiative.

Introduction
The time between evidence generation and incorporation into clinical practice continues to be problematic. Clinical decision support (CDS), as a component of quality improvement and when properly implemented, has the potential to accelerate the movement of evidence into practice. This process may be further expedited by tools and infrastructure that facilitate sharing of CDS among developers, implementers, and target audiences such as patients, clinicians, health care organizations, and others stakeholders dedicated to improving health care quality. In 2016, the Agency for Healthcare Research and Quality (AHRQ) launched an ambitious multi-component initiative, with two primary aims: 1) to accelerate the movement of evidence into practice through CDS and 2) to make CDS more shareable, health IT standards-based, and publicly-available.

Panel Description
This didactic panel will feature the leads of the initiative and provide a patient advocate’s perspective. Panelists will focus on progress thus far and visions for the future based on lessons learned. Additional information can be found at http://cds.ahrq.gov.

Edwin Lomotan, M.D., serves as Chief of Clinical Informatics for the Division of Health IT in the Center for Evidence and Practice Improvement at AHRQ. He will provide background for the CDS initiative, including its legislative mandate and requirements, its overall purpose and aims, and will describe the collaborative effort the initiative represents across several Federal agencies. Dr. Lomotan will also moderate the panel.

Barry Blumenfeld, M.D., is a Senior Physician Informaticist at RTI International and serves as the Principal Investigator for the Patient-Centered Clinical Decision Support (PCCDS) Learning Network. He will describe the Learning Network’s efforts thus far, including its Analytic Framework for Action developed through multi-stakeholder input, which places CDS into the context of a learning cycle addressing patient engagement, development, implementation, measurement, legal, governance, marketplace, and policy factors (see Figure 1). Dr. Blumenfeld will also describe the Learning Network’s efforts to advance the concept of “patient-centered CDS,” which extends CDS beyond its traditional focus on clinicians to include CDS-enabled, shared decision-making with patients.
Robert McCready is a Senior Principal Healthcare Systems Engineer at the MITRE Corporation and serves as the Project Lead for CDS Connect, the AHRQ-funded contractual effort to build prototype infrastructure for sharing CDS. Mr. McCready will describe a new national CDS repository, CDS Connect. CDS Connect allows CDS developers and stewards to contribute to a curated, online library of CDS artifacts (see Figure 2). CDS artifacts range from computer-interpretable, guideline recommendation statements encoded in the HL7 draft standard, Clinical Quality Language, to resources to guide CDS implementation, results of CDS testing, and links to primary research evidence. CDS Connect also allows CDS implementers to view, download, sort, and provide feedback on the library of CDS artifacts. Mr. McCready will describe a CDS authoring tool that aims to improve the efficiency and interoperability of CDS between systems and technologies. Finally, he will describe the development of CDS in the area of cholesterol management, chosen as the clinical domain for the first year of the contractual effort, as a proof-of-concept for developing standards-based CDS, testing CDS in a live clinical environment, and contributing to CDS Connect for public use of the artifacts.
Dave deBronkart, S.B., known on the internet as “e-Patient” Dave, is a leading evangelist for patients having active partnerships with their clinicians, both through sociological advancement (empowerment and role change) and by recognizing and leveraging new competencies that become available when patients connect with information and with peers on the internet. He will provide a patient advocate’s perspective. Mr. deBronkart serves on the Advisory Council for the PCCDS Learning Network and on a working group for CDS Connect.

Relevance to Annual Symposium Theme and Importance of the Topic

Our proposed panel fits directly into the theme of the AMIA 2017 Annual Symposium, “Precision Informatics for Health: The Right Informatics for the Right Person at the Right Time.” The right information for the right person at the right time are three of the “Five Rights of CDS,” which are woven throughout the AHRQ initiative. CDS Connect helps developers and implementers find what is relevant for health care providers and their patients. A national repository of publicly-available CDS artifacts has never before existed. Further, the PCCDS Learning Network has identified “patient-centered CDS” as its central focus. It has engaged a wide range of stakeholders – patients, clinicians, CDS and other health IT developers, Federal agencies, payers, and more – to explore what it means for CDS to be relevant to and incorporate patient preferences and for CDS to reflect shared decision-making with patients and their families.

As part of CDS Connect, MITRE has developed CDS in the area of cholesterol management. The CDS provides an assessment of cardiovascular risk and applicable recommendations, which can be viewed by both patients and clinicians in real-time. Going beyond simple alerts and reminders, the tool facilitates shared decision-making by enabling informed discussions to guide medication management and other treatment decisions that are reflective of patient preferences.

The concept of “precision informatics” depends on knowing what is precisely relevant to patients and making those preferences actionable. The AHRQ CDS initiative is exploring and developing tools and infrastructure to advance CDS forward in this regard. The anticipated audience will include patients (or patient advocates), CDS developers and implementers, other health IT developers (e.g., EHR vendors, vendors of population health platforms that may support CDS), Federal agencies, and clinicians.

Discussion Questions for Audience Participation

We anticipate the panel will generate discussion in a wide range of areas, from the technical aspects and standards for CDS development to further exploration with the audience how CDS Connect may serve their organizations and their patients. Discussions questions may include:

- What does “patient-centered CDS” mean to you?
- Would contributing artifacts to CDS Connect by you (or your organization) be valuable? What about using artifacts made available through CDS Connect? Why or why not?
- How might the artifacts and the authoring tool enable you to develop CDS more efficiently?
- How can the PCCDS Learning Network continue to build the CDS community? What do you see as pressing CDS issues that should be addressed moving forward?
- How can we incorporate feedback from both patients and clinicians into patient-centered CDS so that the CDS artifacts and their development continuously improve in a learning health system?

Author statement

All authors have agreed to take part in the panel.

A Spoonful of Structure Helps the Workload Go Down: Modeling Clinical Cognition in Inpatient Documentation Tools

Panelists: Subha Airan-Javia MD\textsuperscript{1,2}, Evan Orenstein, MD\textsuperscript{3}, Eric Shelov, MD MBI\textsuperscript{2}, Kai Zheng, PhD\textsuperscript{4}

Moderator: Mark V. Mai, MD MHS\textsuperscript{3}

\textsuperscript{1}University of Pennsylvania Health System, Philadelphia, PA; \textsuperscript{2}Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA; \textsuperscript{3}Department of Biomedical and Health Informatics, Children’s Hospital of Philadelphia, Philadelphia, PA; \textsuperscript{4}Department of Informatics, Donald Bren School of Information and Computer Sciences, University of California Irvine, Irvine, CA

Abstract

As inpatient care has grown in complexity and front-line clinicians (FLCs) must create and update a larger volume of information, inefficient and fragmented documentation systems put hospitalized patients at risk of harm from communication errors. In addition to writing and updating admission notes, progress notes, and discharge summaries, FLCs must also update plans of care and problem lists in their handoffs—often independently. Further, the information therein is generally locked in free-text, which cannot be easily reused for clinical decision support. With this duplicative workflow, FLCs struggle to maintain high quality notes and handoffs, and discrepancies between information documented between the two are known to occur. Problem-oriented documentation tools from electronic health record vendors have begun to address these issues by mandating coded problem names and allowing users to specify a block of information as historical. However, these tools lack the granularity required to optimize task management and handoffs. In this didactic panel, we will review the successes and failures of structured and flexible documentation systems, describe strengths and weaknesses of a vendor approach to problem-oriented documentation, and discuss novel models that organize clinical reasoning documentation into discrete elements that can be reused to improve clinical workflow.

Description

The tension between structured and free-text data in clinical documentation has limited the promise of the electronic health record (EHR). Information quality for secondary re-use is more complete when clinical data are structured at the time of data entry, however few structured documentation systems have demonstrated ongoing adoption and dissemination due to limited expressivity, user interface complexity, poor integration, and the differing goals of busy clinicians and administrators. Inpatient documentation represents a missed opportunity to leverage structured data for workflow enhancement. In addition to admission notes, progress notes, and discharge summaries, inpatient front-line clinicians must create and update written handoffs and problem lists to optimize patient outcomes. These tools must be independently updated, and the information therein is generally locked in free-text, which cannot be easily reused for clinical decision support. FLCs struggle to maintain high quality notes and handoffs, and discrepancies between information documented in the handoff and recorded in the electronic health record (EHR) are known to occur. Resolving this tension requires a sufficiently flexible system where clinicians can divine downstream workflow benefits from structuring data at the point of entry. In this didactic panel, we will review successes and failures of structured and flexible documentation systems, describe vendor approaches to problem-oriented documentation, and discuss novel models that allow users to tag clinical reasoning elements to improve clinical workflow.

Some early efforts to promote structured data entry demonstrated increased data quality and provider satisfaction for specific use cases such as SISCOPE for reporting gastrointestinal endoscopy. However, more generalized efforts ranging from the Structure-Meta Knowledge formalism to OpenSDE subsequently struggled to sustain adoption due to decreased efficiency in data entry and difficulty balancing limited expressivity with an excessive number of data elements. More recent approaches have recognized the importance of tolerating flexibility through structure-enhanced narratives and tightly integrating documentation with clinical workflow. The chronological order of studies on effective documentation strategies suggest a paradigm shift from an expert focus to end user focus, from a one-size-fits-all solution to customization, from a strong preference on structured data to a balance between structure and expressivity, and from individuals to teamwork.
In this environment, EHR vendors have begun to develop inpatient documentation strategies that explicitly connect the problem list with note documentation while allowing users to create individual problem plans through free text or note templates. Simultaneously, wiki-style free-text handoff sections allow for team collaboration, although these sections are often disconnected from other documentation tools. New methods may allow for some degree of parsing information that can be reused for different user-tasks. While this solution does not yet fulfill all user goals in inpatient documentation, it encourages the use of reference terminologies for the problem list and bypasses many obstacles of a third-party solution including integration, authentication, and the long-term need for local maintenance and associated institutional resources. We will discuss strategies for using vendor-based functionality to reduce inpatient documentation redundancy. Nonetheless, custom systems based on a more detailed model of clinical cognition may offer new strategies for minimizing redundancy and facilitating inpatient workflow.

At the University of Pennsylvania, analyses of communication failures and tasks during clinical handoffs led to the development of a home-grown, interdisciplinary handoff system. Carelign© is a responsive web application with a mobile interface being used in production at four of five hospitals within the University of Pennsylvania Health System. It utilizes an overarching, constantly changing care plan which can then be used for handoffs, progress note assessment and plans and hospital course summaries for discharge transitions. It pairs objective data with the qualitative handoff utilizing HL-7 messages, direct database queries, and web services/APIs. Carelign’s© care plan functionality uses discrete, collapsible data elements organized in a way that facilitates rounding, critical thinking, and list management. Key features include the ability to archive information, tag items as anticipatory guidance, arrange the care plan by problem priority or by system, view tasks for all problems by time due, create progress note content, and filter views based on provider role and context. For example, overnight cross-covering providers are able to limit their view to a one-liner, anticipatory guidance, and overnight tasks for the patients they are covering, with one touch access to drill down into more detailed information about the patient’s history and the ability to enter information from the same view that writes back to the overall care plan. The system handles almost 5000 unique weekly users with ~50,000 weekly sessions, and internal medicine residents reported significantly higher satisfaction and safer written handoffs with Carelign©, as well as a near-significant improvement in workflow efficiency.

At the Children’s Hospital of Philadelphia, cognitive engineering methods including artifact analysis and directed stakeholder interviews have informed the development of a markdown-based handoff application. Snap Chart (Signout to Note Assessment and Plan) leverages existing written handoff culture to give structure to free text at the point of data entry. It uses common annotations to identify data element types as the user is entering them, then parses that information into a data model representing elements of clinical reasoning (e.g. differential diagnosis, current therapy, anticipatory guidance, etc.). This model can then populate a note assessment and plan as well as workflow tools that can read and write to the data model such as a to-do list, an IPASS-compliant handoff, or a graphical user interface. By taking advantage of frequent habits, such as beginning a line of text with a “#” that will contain the name of a problem, the application suggests standardized terminology or autocompletes to existing patient data. This approach provides structure to unstructured text with the primary goal of streamlining the workflow of the providers responsible for data entry and upkeep. It also yields concepts that can drive clinical decision support and billing.

Learning Objectives

- Understand how the inpatient care plan is distributed across multiple documents and how data can be re-used to improve workflow and avoid inconsistencies.
- Review the successes and failures of structured and flexible documentation systems.
- Describe the strengths and shortcomings of vendor-based tools to address these problems.
- Discuss new approaches to documentation that structure impressions and plans into a data model that can be filtered into workflow tools optimized for provider role and context.

Description of panelist contributions

Mark Mai is a Pediatric Resident Physician in his 3rd year at The Children’s Hospital of Philadelphia and incoming Clinical Informatics Fellow. He is also a co-founder of Snap Chart, a markdown-based web application that allows clinicians to tag elements of their plan to facilitate rapid data entry, internally consistent inpatient documentation, and context-specific displays of information. He will serve as moderator of this panel.

Kai Zheng is Associate Professor in the Department of Informatics at the Donald Bren School of Information and Computer Sciences, Associate Adjunct Professor in the Department of Emergency Medicine, and Co-Director of the Center for Biomedical Informatics at the Institute for Clinical and Translational Science of the University of
California, Irvine. He will present a systematic review of the literature on successes and failures in structured and flexible clinical documentation and describe lessons for future work.

**Eric Shelov** is Associate CMIO, Medical Director for the Inpatient Electronic Health Record, and Attending Physician in the Division of General Pediatrics at The Children’s Hospital of Philadelphia. He will present the problem created by independent workflows for different inpatient documents and describe the strengths and shortcomings of a vendor-based solution.

**Subha Airan-Javia** is Associate CMIO at the University of Pennsylvania Health System, Director of Handoff and IT Education for the Internal Medicine residency program and Assistant Professor of Clinical Medicine at the Perelman School of Medicine. She is also the founder of Carelign©, a responsive web application with an intuitive presentation of real-time clinical data and an interactive, editable, electronic handoff with full mobile functionality. She will discuss how Carelign© organizes the care plan to reduce redundancies and improve communication.

**Evan Orenstein** is a Clinical Informatics Fellow at The Children’s Hospital of Philadelphia. He is also a co-founder of Snap Chart, a markdown-based web application that allows clinicians to tag elements of their plan to facilitate rapid data entry, internally consistent inpatient documentation, and context-specific displays of information. He will discuss the cognitive engineering methods that led to the data model underlying Snap Chart and discuss approaches to structuring free text using autocompletion tools at the point of data entry.

**Discussion of anticipated audience**

We believe this panel will be of interest to a wide variety of attendees including clinicians and trainees interested in streamlining documentation workflow, administrators and CMIOs looking to maximize the utility of clinical documentation and improve quality of care, and informatics researchers interested in increasing the proportion of structured data in the electronic health record.

**Expected discussion**

1. What are the challenges in integrating new approaches to documentation into vendor-based electronic health records and how can we avoid the creation of a “shadow chart”?
2. How should documentation interfaces be designed to optimally capture clinical reasoning and display easily digestible summaries for clinical users?
3. What are barriers to implementation of new documentation strategies in clinical practice?
4. How can we maximize structured data in the electronic health record for secondary consumption?

**Statement of participation:** All panelists have agreed to take part in this panel.

The PCORnet Learning Cycle

Keith Marsolo, PhD1, Bradley Hammill, DrPH2, Laura Qualls, MS2, Jeffrey Brown, PhD3, Lesley Curtis, PhD2
1Cincinnati Children’s Hospital Medical Center, Cincinnati, OH; 2Duke Clinical Research Institute, Durham, NC; 3Harvard Pilgrim Health Care Institute, Boston, MA;

Abstract

The National Patient-Centered Clinical Research Network (PCORnet) is a distributed network-of-networks, where partners transform data from electronic health record (EHR) and claims data sources into a Common Data Model. In order to ensure that the underlying data are suitable for use in network queries, PCORnet employs a robust data characterization process. The tools and processes that support PCORnet are not static, however. They are constantly being refined in response to stakeholder needs as well as the findings from analytic queries and characterization results. This panel will describe the Learning Cycle that informs the activities of the PCORnet Distributed Research Network Operations Center (DRN OC) and will highlight the relationship between the PCORnet CDM, the Data Characterization process, the findings of the PCORnet Demonstration Projects, and downstream analytical tool development. In addition, the panel will discuss how all of these findings are communicated out to network participants and other stakeholders. Attendees will gain an understanding of why these components are all necessary to the successful operation of a distributed research network, and recognize how similar Learning Cycles can be used to improve the quality and reproducibility of any network’s research.

General description of panel

Distributed research networks (DRNs) are critical components of the strategic roadmaps for agencies like the National Institutes of Health and Food and Drug Administration as they seek to move towards large-scale systems of evidence generation (1). The promise and sustainability of these systems hinges on the ability to extract usable, high-quality data from sources like the electronic health record (EHR), claims and others that are fit to support translational, interventional, and observational research initiatives. There are several active DRNs in the United States, including the Sentinel Initiative (formerly Mini-Sentinel) (2, 3), the Health Care Systems Research Network (HCSRN) (formerly the Health Maintenance Organization Research Network (HMORN))(4-6) and the National Patient-Centered Clinical Research Network (PCORnet) (7, 8). While these DRNs all have different operational characteristics, they share some commonalities. The first is that each network utilizes a common data model (CDM) to ensure that all partners (network participants) represent their data in a standardized manner. The second is that the data stay local, and the queries or analyses are distributed. The analytical tools differ by network, but are generally tailored to leverage the available data and to support the major use cases or study designs of interest. What they do have in common is that typically only the results, in the form of aggregate counts or summary statistics, are sent back to the requestor (9, 10). Therefore, before conducting any analysis, it is important to first understand the quality of the data that are to be queried to ensure that the results returned by each partner are valid and trustworthy (11). To that end, many DRNs have developed data characterization routines which are used to summarize missing values, outliers, and frequency distributions, and they also ask partners to complete surveys about the provenance of their data (3, 11). The characterization results then help inform an investigator’s decision about whether a dataset is suited to answering a given research question.

These activities do not occur in a silo, however, but inform one another. Data characterization routines may uncover variability in how network partners are populating certain elements of the network’s CDM. Study-specific analyses may uncover quality issues that are masked by a data characterization package that is designed to provide a broad assessment on data quality. Such findings can have a number of downstream impacts. For instance, variability in the population of the CDM may result in specific guidance to partners on how they should structure their extract-transform-load procedures and to the analytic teams on how they should structure their queries. Quality issues uncovered through study-specific characterization routines may result in changes to the base characterization process, or modifications to the network’s CDM in order to better represent the data in question. All of this then has an impact on the design and developmental roadmap of the analytical tools that support the network. In this manner, a DRN follows a learning cycle with a goal of continuous improvement, which can be linked to a number of metrics, such as overall data quality or query throughput. To that end, this panel will describe the Learning Cycle that informs the activities of the Distributed Research Network Operations Center (DRN OC) of the PCORnet Coordinating Center.
PCORnet is a distributed network of networks, comprised of 13 Clinical Data Research Networks (CDRNs) and 21 Patient-Powered Research Networks (PPRNs). PCORnet’s CDM network partners include health systems, ambulatory care clinics, and health plans, which contribute electronic health record data, billing system data, and other electronic health data such as clinical registries and health insurance claims. Altogether, these CDMs operate more than 80 individual datamarts, which contain data on tens of millions of patients standardized to the PCORnet CDM. The DRN OC of the PCORnet Coordinating Center is responsible for characterizing the datamart(s) of each network partner and evaluating the data’s fitness-for-use across a broad research portfolio through a foundational data characterization process. Data characterization is designed to complement any of the CDRNs’ internal data quality efforts while generating meaningful, actionable information for the CDRNs, Coordinating Center, sponsor, and other stakeholders. In particular, these results are used to inform the development and deployment of the analytical query tools that support the network, which includes both rapid, prep-to-research queries, as well as observational and comparative effectiveness studies. While the foundational data characterization process does not necessarily determine whether a given datamart is fit-for-use in a specific research study, the results inform study planning decisions, including what to include in the more comprehensive study-specific data characterization routines. These routines are executed prior to the main study analyses, and help assess the quality of the outcomes and variables of interest for the cohort in question.

Panelist presentations

Laura Qualls is a Project Leader at the Duke Clinical Research Institute (DCRI) and is responsible for the implementation of PCORnet’s foundational data characterization process. She will provide an overview of the current process and illustrate how it has evolved over time. In addition, Ms. Qualls will share selected results for the current data characterization cycle and explain how they are used to inform the query activities of PCORnet.

Keith Marsolo is an Associate Professor in the Division of Biomedical Informatics at Cincinnati Children’s Hospital Medical Center. He is a co-investigator in the PCORnet Coordinating Center’s DRN OC where he provides faculty oversight for the efforts related to data characterization and the PCORnet CDM. He will describe how the results of the initial data characterization cycle led to the creation of a document that provides implementation guidance to network partners as they populate the PCORnet CDM. Dr. Marsolo will also cover the process used to update this “Implementation Guidance” and how the material is disseminated and communicated to stakeholders.

Bradley Hammill is a Faculty Statistician at the DCRI. He is a co-investigator on the PCORnet Demonstration Study, Aspirin Dosing: A Patient-centric Trial Assessing Benefits and Long-Term Effectiveness (ADAPTABLE), a pragmatic clinical trial that is comparing the effectiveness of two different daily doses of aspirin to prevent heart attacks and stroke in patients with heart disease (12) as well as a study that transformed Medicare fee-for-service claims data into the PCORnet CDM and tested linkage rates between PCORnet patients and Medicare beneficiaries. Dr. Hammill will provide a high-level overview of these activities and describe how his findings led to changes in the PCORnet CDM specification and implementation guidance, as well as the foundational data characterization process.

Jeff Brown is an Associate Professor in the Department of Population Medicine at the Harvard Pilgrim Health Care Institute. He is a co-lead of the DRN OC and oversees the team responsible for the fulfillment of PCORnet queries and for the development and support of the PCORnet analytical query tools. He will provide an overview of the current suite of analytic tools and describe how the findings of data characterization and the initial PCORnet studies have influenced the development roadmap of future tools, as well as plans to increase the throughput of query activities, such as allowing query fulfillment activities to occur outside of the PCORnet Coordinating Center.

Lesley Curtis is a Professor in the Department of Medicine and Director of the Center for Population Health Sciences in the Duke University School of Medicine. She is a co-lead of the DRN OC along with Dr. Brown. Dr. Curtis will serve as moderator for the panel, setting the stage for the presentations of the other panelists by providing a high-level overview PCORnet, DRN OC activities and a summary of queries issued to-date. She will also discuss the learning cycle that underpins the work of the DRN OC and how it ties together the different workstreams.

Importance of topic

DRNs provide an important platform for the conduct of large-scale observational and comparative effectiveness research. Understanding the relationship between the CDM, data characterization and analytic tool utilization/development is important, as it can have an impact on the reproducibility of the research results and the ability of the network to meet the needs of its stakeholders, which is crucial for long-term sustainability. In addition, the general principles articulated in this panel have applicability beyond distributed research networks. Any project that seeks to use EHR data that have been transformed into a CDM will face similar issues. Raising awareness is the first step towards minimizing error and variability, ultimately leading to more high-quality research.
Target audience
Informatics professionals who generate EHR or CDM datasets; researchers who analyze EHR or CDM datasets.

Discussion questions
• Given the inter-relatedness between the CDM, data characterization and the use/development of analytical tools, how can findings be best communicated to all stakeholders?
• As the quality of the underlying data and sophistication of the query tools increases, should efforts be made to repeat earlier studies / queries?
• Can a ‘scorecard’ be created that describes the state of network/data at the time of analysis?
• How can these processes be translated to run outside of a DRN, so that they can be employed at a single institution?

Statement of participation
All panelists have agreed to take part in the panel.

Getting Hooked on CDS: Toward an Open Standard Architecture for Clinical Decision Support in Leading Electronic Medical Records

Blackford Middleton, MD, MPH, MSc¹, Aziz Boxwala, MD, PhD², J. Marc Overhage, MD, PhD³, James Doyle⁴, Mary Sung⁵

¹Apervita, Inc., Chicago, IL; ²Meliorix, Inc., San Diego; ³Cerner Corp., Kansas City, MO; ⁴Epic Systems, Inc., Verona, WI; ⁵athenahealth, Inc., Watertown, MA

Abstract

This interactive panel will discuss the current state-of-the-art with respect to implementing clinical decision support in commercial EMRs, the state of standards used in clinical decision support, and newer approaches to externalizing knowledge management and clinical decision support as web services consumed by an EMR. The discussion is timely given the explosive growth of new knowledge creation and the need for enhanced decision support for clinicians, and their patients, in the areas of precision medicine, care coordination, chronic disease management, and in the setting of rapidly changing clinical practice or acute disease outbreaks (e.g. Zika). The goals of this panel are to facilitate a discussion with leading EMR vendors, application builders, and CDS platform vendors to describe about their approach to CDS and the challenges above.

Significance

Clinical decision support is has been demonstrated to impact the quality, and cost of care when appropriately implemented and effectively used. While most US healthcare delivery organizations (HDOs) have successfully adopted electronic health record technologies due to the ARRA/HITECH stimulus bill (“Meaningful Use”), it is clear that the value proposition predicted by many has yet to be achieved. This may in part be due to challenges HDOs have in optimizing their EHR implementations – the process wherein clinical workflows, care communications, user interactions, and clinical knowledge for decision support is fine tuned to make it most beneficial to the end-user clinician, and positively impact the outcomes of the clinical encounter. Part of this optimization process – the part relating to clinical decision support -- is stymied by the complexity involved for some EHR systems to readily access and use knowledge-based tools and services external to the EHR. These may be in the form of standard knowledge representation formats that should theoretically allow import and use within an EMR, or external knowledge services which interact with an EHR via a standards-based web service to provide clinical decision support. In this interactive panel, one panelist will present a summary of the state-of-the-art with respect to standards for externalized CDS services, and four different perspectives will be provided by members of the vendor community: those who must design and deliver EHRs that can functionally access externalized CDS tools and services, and those that design and deliver such externalized CDS tools and services that must work with all EHRs.

Description of the Panel

The panel will be organized as follows:

<table>
<thead>
<tr>
<th>Time</th>
<th>Speaker</th>
<th>Topic</th>
</tr>
</thead>
<tbody>
<tr>
<td>5 min</td>
<td>Middleton</td>
<td>Introductions, framing of the discussion</td>

<td>All</td>
<td>Discussion, Q&amp;A with Audience</td>
</tr>
</tbody>
</table>
Learning Objectives:

1. Understand current approaches among leading EMR vendors to accessing and/or incorporating external knowledge-based tools and services in their EMR.
2. Understand current standards relating to the delivery of externalized knowledge-based tools and services.
3. Understand practical approaches to delivery of externalized knowledge-based tools and services to an EMR.

Individual Speaker Contributions

- **Blackford Middleton**: Dr. Middleton will provide a brief introduction for the panel participants, and framing of the discussion.
- **Aziz Boxwala**: Dr. Boxwala will provide a summary of the state-of-the-art with respect to standards for externalized CDS services. A brief synopsis of recent work including HL7 efforts in the FHIR “Clinical Reasoning Module”, and the “CDS-Hooks” workstreams will be highlighted. Assessment of the opportunity for a unified approach harmonizing these workstreams will be discussed, including current state of the effort. Highlights of his company’s efforts in building CDS tools and services using these standards will also be described.
- **James Doyle**: Mr. Doyle will provide a perspective on access and use of externalized CDS tools and services from the vantage point of a commercially successful EHR – Epic. Particular attention will be drawn to what requirements the Epic EHR may have that are unique, or limit the ability of using current standards, or a harmonized standard as outlined by Dr. Boxwala.
- **Marc Overhage**: Dr. Overhage will provide a perspective on access and use of externalized CDS tools and services from the vantage point of a commercially successful EHR – Cerner. Particular attention will be drawn to what requirements the Cerner EHR may have that are unique, or limit the ability of using current standards, or a harmonized standard as outlined by Dr. Boxwala.
- **Mary Sung**: Ms. Sung will provide a perspective on access and use of externalized CDS tools and services from the vantage point of a commercially successful EHR – athenahealth. Particular attention will be drawn to what requirements the athena EHR may have that are unique, or limit the ability of using current standards, or a harmonized standard as outlined by Dr. Boxwala.
- **Blackford Middleton**: Dr. Middleton will provide a perspective on providing standards-based externalized CDS tools and services from the vantage point of a commercial entity providing CDS in a ‘platform as a service’, and a marketplace for the exchange of knowledge artifacts, to multiple disparate EHRs.

Expected Discussion

Given the growing interest in clinical decision support in the evolution of clinical practice toward precision medicine and value-based care, we anticipate this will be a lively discussion about the various standards being developed and deployed for clinical decision support in EMRs. We anticipate questions form the audience regarding the methods by which clinical decision support may be deployed – hosted in EMR, vs. delivered by an externalized knowledge-based service. The moderator will facilitate discussion with each presenter, and sufficient time will be reserved for general audience Q&A.

Intended Audience

- **C*IOs**: clinicians in the role of CMIO, CNIO, and other, with responsibility and/or oversight for clinical decision support
- **CIOs**: responsible for the success of EHR implementations
- **CMO/CQO/CNO**: responsible for achieving high quality care, reduced unwarranted clinical variation, reduced patient harm
- **Physicians, Nurses, all EHR end-users**
- **IT Developers**: development staff building EHR and clinical decision support tools and services
- **IT Implementers**: implementation staff responsible for implementation and effective use of EHR tools, and system optimization
- **Knowledge vendors** supplying content for CDS services
Attestation

The Panel Moderator has assurances from all participants that they will be available to participate in the panel at AMIA’17.
Panel: Clinical NLP in Languages Other Than English

Aurélie Névéol1, PhD, Noémie Elhadad2, PhD, Sumithra Velupillai3, PhD, Hua Xu4, PhD, Guergana Savova5, PhD

1 CNRS, LIMSI, Université Paris Saclay, F-91405 Orsay
2 Columbia University, New York, NY, USA

5 Children's Hospital Boston and Harvard Medical School, Boston, Massachusetts, USA

Abstract

Natural Language Processing (NLP) of clinical free-text has been an active area of research in the past decades. Clinical documents are routinely created across health care providing institutions and are generally written in the official language(s) of the country these institutions are located in. As a result, free-text clinical information is written in a large variety of languages. While many efforts for clinical NLP have focused on English, there is a steady interest to extend this work to other languages in order to gain medical information about patient cohorts in geographical areas where English is not an official language. Furthermore, adapting current NLP methods developed for English to other languages may provide useful insight on the generalizability of algorithms and lead to increased robustness. This panel aims to provide an overview of clinical NLP for a wide variety of languages including Germanic, Romance, Sino-Tibetan and Afro-Asiatic languages. We will also discuss initiatives to support clinical NLP research and sharing of clinical resources for NLP in multiple languages.

General Description of the Panel

The goal of this didactic panel is to engage the medical informatics and clinical Natural Language Processing community in a discussion about ways to advance research through languages other than English. We will report on the current state of clinical NLP in a wide variety of languages including Germanic, Romance, Sino-Tibetan and Afro-Asiatic languages. We seek to provide the audience with insight on how to develop a clinical NLP system for a language other than English. We identify strategies to leverage existing resources and tasks in English and other languages to address new challenges. Finally, we identify the best opportunities for a contribution to the field and propose that new resources be integrated in a state-of-the-art repository.

Clinical NLP in languages other than English.

Natural Language Processing (NLP) of clinical free-text has been an active area of research in the past decades, demonstrating its potential to analyze large quantities of documents rapidly and accurately (Demner-Fushman and Elhadad, 2016). The ability to analyze clinical text in languages other than English allows to unlock medical data concerning cohorts of patients who are treated in countries where English is not the official language. In this context, data extracted from clinical texts in languages other than English adds another dimension to data aggregation. Further, with international initiatives like OHDSI (Observational Health Data Sciences and Informatics) which brings together clinical repositories from more than 60 countries under the same data model (Hripcsak et al, 2016), there is an unprecedented opportunity to foster robust NLP research across the globe.

We follow-up on a panel addressing this topic at the AMIA Fall Symposium in 2014. We widen the scope of the languages covered in the panel to include non Indo-European languages such as Chinese and Hebrew. As the importance of clinical NLP gains recognition, clinical corpora become available to researchers in languages other than English, prompting work that sometimes builds on methods validated for English. Adapting systems that work well for English to another language is a difficult task that may be carried out with varying level of success depending on the task and language (Grouin et al., 2009; Velupillai et al. 2014; Täckström et al., 2012; Tourille et al. 2017). These experiments prompt a reflection on how to carry out clinical NLP in a more global context: should methods be developed for one language and then ported to other languages? Can the source language method benefit from the porting? Can algorithms be more robust if they are initially designed with a multi-language perspective?

North Germanic languages, although closely related to English, exhibit properties that require adaptation and specific solutions for accurate processing of clinical narratives. In recent years, approaches have been developed for
e.g. named entity recognition in Swedish (Skeppstedt et al. 2014, Weegar et al. 2016), dictionary construction for adverse drug event detection in Danish (Eriksson et al. 2013), within several large-scale national and cross-country research initiatives in north Europe.

**Romance languages** benefit from a large coverage in the UMLS. Automatic de-identification is becoming quite advanced for French (Grouin & Névéol, 2013), paving the way for targeted clinical information extraction tasks (Pham et al. 2014). Notable work on Spanish has addressed the analysis of social media and clinical records for pharmacovigilance (Oronoz et al. 2015). For Portuguese and Italian, approaches rely on rule-based or unsupervised methods to avert the greater lack of domain resources in these languages (Silva et al. 2013; Alicante et al. 2016).

In Israel, there is an emerging need for processing the clinical notes for point of care decision support, as well as for supporting biomedical discovery. There are no established Hebrew medical terminologies however. As such, a lot of the work in Hebrew medical NLP is on language adaptation for such resources through transliteration of medical concepts and linking to existing English terminologies (Cohen et al, 2011; Cohen and Elhadad, 2013). Further, effective word segmentation (a critical task for Hebrew) has been shown to improve information extraction from clinical notes (Cohen et al, 2010).

**Chinese clinical text** has been accumulated rapidly due to wide implementation of EHRs in China. Recently researchers have developed various approaches for diverse NLP tasks on Chinese clinical text, such as named entity recognition (Lei et al. 2014, Wu et al. 2015), speculation detection (Zhang et al, 2016), negation detection (Kang et al. 2017), and temporal information extraction (Zhou et al 2011).

**Panelists**

**Dr. Noémie Elhadad** (Associate Professor at Columbia University) will present work in schemas for NLP in the international initiative OHDSI as well as research directions in processing of medical texts in Hebrew. She led the OHDSI clinical NLP data modeling effort, and is co-founder of the hNLP Center with Profs. Palmer and Savova.

**Dr. Sumithra Velupillai** (Postdoctoral Research Fellow at KTH, Sweden) will present work on North Germanic languages including Danish, Norwegian and Swedish. Dr. Velupillai has worked on Swedish clinical narrative data and been involved in several past and ongoing Nordic research collaborations in this research area.

**Dr. Aurélie Névéol** (Staff Scientist at LIMSI-CNRS, France) will present work on Romance languages including French, Italian, Portuguese and Spanish. Dr. Névéol has been leading a project addressing the automatic understanding of French clinical narratives for translational research.

**Dr. Guergana Savova** (Associate Professor at Harvard Medical School) will act as a moderator and will present the hNLP center for health data sharing, which she co-founded. Dr. Savova has been leading the development of the core Clinical Text Analysis and Knowledge Extraction System (cTAKES; ctakes.apache.org).

**Dr. Hua Xu** (Professor at UTHealth) will present work on Chinese medical language processing. Dr. Xu has conducted several projects on named entity recognition from Chinese clinical text using supervised machine learning and deep learning approaches.

**List of Discussion Points**

After the introductory presentations, the moderator will ask questions as well as solicit questions from the audience, to prompt discussion among the panelists. Potential topics and questions include:

- What are your needs for clinical NLP methods, tools and resources in a language other than English?
- To fill existing gaps, are there alternatives to replicating what is currently done for English?
- How can we share data across languages for (1) methodological developments, (2) translational studies?

The first author affirms that all panel participants have agreed to participate and have contributed to the preparation of this document (as of March 9, 2017)
Panel Sponsored by Evaluation and People & Organizational Issues Working Groups

Innovation in Workflow Methods for Consumer Health Informatics

Mustafa Ozkaynak, PhD1 (organizer), Rupa Valdez, PhD2, George Demiris, PhD3, Laurie Novak, PhD4, Yong Choi, MPH3, Charlene Weir, RN, PhD5 (moderator)

1University of Colorado, Aurora, CO, USA; 2University of Virginia, Charlottesville, VA, USA; 3University of Washington, Seattle, WA, USA; 4Vanderbilt University Medical Center, Nashville, TN, USA; 5University of Utah, Salt Lake City, UT, USA

Abstract

Consumer health information technologies are becoming an essential part of wellness and management of chronic conditions. The literature on health informatics emphasizes that workflow studies are key to the design and implementation of health information technologies in clinical settings. Consumer health informatics interventions should also be informed by workflow in daily living settings, however, additional challenges exist such as, privacy, variability in living styles, preferences and daily routines. Workflow methods that have been utilized in clinical settings should be thoughtfully adapted to daily living settings. Compared to traditional approaches in institutional health care settings, novel methods may be needed in the home that account for the unstructured and personal nature of daily living settings. The success of workflow studies depend on the robustness of the methods used to capture, analyze and re-design workflows. This panel will begin with a discussion by each panelist of their experience in workflow research for consumer health informatics interventions and their use of innovative methods. This will be followed with an interactive session, where the audience and panelists will create a list of challenges. Finally, the audience and panelists will discuss effective strategies to address these challenges.

Intended Audience

The intended audience for this panel includes all AMIA attendees with various levels of experience, interested in designing, implementing and evaluating consumer health informatics interventions. Designers, implementers and researchers of these interventions can benefit from this session, by understanding the current state and challenges of workflow methods, and shaping the development of future methods.

Introduction of the Topic

Consumer health information technologies have become an essential part of wellness and management of chronic conditions. Design and implementation however, requires a fit between technology characteristics and the context of the patient’s environment, as well as their abilities and preferences regarding self-management practices. The importance of understanding workflow in clinical settings has been emphasized in the informatics literature. Workflow studies reveal established routines as well as variations that should be accommodated by informatics interventions. Understanding workflow in daily-living (home and community) settings is required to ensure that consumer health informatics technologies do not disrupt the day-to-day life of the individual in unintended ways or confuse patients, yet take full advantage of their potential in terms of supporting self-management. Workflow in daily-living settings represents temporal organization of health-related activities performed by patients and their proxies. There are at least three reasons for innovative workflow research in these settings: (1) Traditional methods are insufficient in capturing high levels of variability; (2) Daily living settings are private environments and intrusive methods may not be appropriate; (3) The context (e.g. physical, organizational, social and cultural) for each patient is unique, and should be studied concurrently with their health-related activities.

Aim of Discussion

The aim of the discussion is to present the state of workflow research in daily-living settings and identify major weaknesses for the purpose of producing insights for future directions. To gain the broadest insight, we will enlist the exchange of ideas and experiences with both the expert panel and audience.

Timeliness of the Topic

This panel is timely because daily-living settings are becoming critical environments to consider in health management. Increasing interest in consumer health informatics by the public, researchers and policy makers does
not necessarily translate into better health outcomes. The current state of workflow research and its associated, limitations in daily-living settings, can be one of the roadblocks. This panel aims to bring panelists and the audience from various disciplines, to address and mitigated this roadblock. Because of its interactive nature, this panel will serve as a forum in which members of the audience and panelists can collaboratively advance the dialogue at the intersection of workflow research and consumer health informatics. The audience will have the opportunity to learn from the panelists and vice versa about experiences and new developments at this intersection. The sharing of experiences stimulated by this panel will serve as a foundation for generating and prioritizing future design and research initiatives informed by effective workflow studies that utilize innovative methodologies.

**Contribution of Each Panelist**

**Mustafa Ozkaynak:** Traditional methods of capturing workflow, present challenges in our understanding of health-related activities in the daily living environment of individuals. To address this challenge, we designed a multi-method qualitative study to better understand self-management of chronic disease. Data were collected through patient interviews (pre & post journaling), the journals and provider interviews. Journaling was accomplished by tablet computers that included software that allowed for voice entry. The qualitative analysis allowed us to develop workflow diagrams for self-management, examine the impact of context, identify challenges and facilitators of self-management as well as gaps between clinical settings (where the therapy plan was developed) and daily living settings (where the therapy plan was implemented). Our analysis also provided insights on the design, implementation and evaluation of consumer health informatics interventions in terms of needed functional requirements. Dr. Ozkaynak will discuss the effectiveness and limitations of our design in terms of richness of data, how data were incorporated from different sources, and concurrent analysis of health-related activities and the embedded context. The discussion will also include strategies to establish validity and reliability in studying workflow in this setting.

**Rupa Valdez:** To help guide design consumer health, IT designers should be informed by an understanding of patient’s existing health information management workflows. Additionally, redesign efforts should be guided by an understanding of the challenges patients face using health IT solutions within the context of existing workflows. As a whole, health information management is comprised of multiple workflows related to information-seeking, information organization, and information communication. The latter of these, although recognized as burdensome for patients, has received little formal attention from consumer health IT designers. The purpose of this research was to explicate health information communication workflows, to serve as a foundation for consumer health IT design for one patient population – individuals with disabilities. This study focused on workflow for both design and redesign efforts. In the first part of the study, interviews were conducted with individuals living with physical, cognitive and sensory disabilities to understand current practices of communicating health information to members of their social network. Emphasis was placed on determining to whom, how, why, and what health information was communicated in addition to when and where this communication occurred. In the second part of the study, task analyses and journaling exercises were used to determine how this workflow was impacted when participants were asked to use three existing consumer health IT apps for health information communication (Microsoft HealthVault, Epic’s MyChart, and CaringBridge). Task analyses took place in a controlled setting, while journaling took place in participants’ daily living settings. In this talk Dr. Valdez will discuss how these methods were triangulated to understand workflow both with and without a specific consumer health IT intervention and the challenges and lessons learned when applying these methods with a range of individuals with disabilities.

**George Demiris:** The emergence of Internet of Things (IoT) technologies whereby everyday household objects become interconnected via the Internet and able to send and receive data, is starting to define new opportunities for home-based monitoring of patients who aim to maintain independence and safety at home. Family caregivers who are essential to the delivery of home health and rehabilitation services for loved ones, are called to carry out various caregiving tasks and often oversee complex medication administration regimens and other care tasks and processes. We demonstrate how the use of IoT technologies in the home enables family caregivers to better understand patterns of daily living for their loved one and accordingly adjust their caregiving workflow. IoT tools have the potential to unintentionally, disrupt and redesign the caregiving workflow. Dr. Demiris will discuss practical, methodological, ethical and other challenges and opportunities associated with the introduction of this emerging consumer informatics tool.

**Laurie Novak:** Adherence to recommended therapy and self-care practices improves clinical outcomes in diabetes, yet carrying out doctors’ recommendations remains a challenge for patients. An emerging science of “patient work”
complements existing adherence research by using established frameworks and methods for studying activities of workers (i.e. in business/industrial settings) to study the work of patients and caregivers, and how that work is organized and made reliable. Understanding patient workflow can produce opportunities for innovation in consumer health informatics design. In the study presented, the primary research questions were: 1) How are diabetes self-care routines aligned with other activities in everyday life?; and 2) What is the relationship between strongly aligned routines and diabetes self-care success?

To answer these questions, we documented from the perspective of 50 patients with diabetes and their caregivers, the actors, actions and structures for each of four primary routines: 1) diet and nutrition, 2) medication and insulin management, 3) physical activity, and 4) physiological monitoring. Examples of structures include artifacts, events, places, people, cultural norms, and other factors that facilitate or impede adherence. The study also involved the application of a novel method to score the routines’ level of embeddedness in other, everyday life routines. Findings will be presented, along with a discussion of the implications for consumer health informatics design.

Yong Choi: Residential settings with embedded technologies to facilitate passive monitoring of residents, also known as smart homes, have the potential to support aging in place and allow for detection of trends and delivery of early interventions for older adults who live alone and want to maximize the quality of their life. Such systems are based mostly on various sensors that capture data related to activities of daily living and also environmental parameters such as humidity and temperature. Mr. Choi will describe an ongoing smart home initiative that utilizes smart home sensors installed in the homes of adults over the age of 65 years who live alone. The vast data generated by this initiative needs to be summarized and presented effectively, in order to provide added value to the stakeholders (namely older adults, clinicians, and family). Mr. Choi will showcase various visualization approaches and present conceptual scenarios to demonstrate how the visualization of behavioral and environmental sensing data affect the decision making workflow for both clinicians and consumers.

Interactive Session

After the introductory presentations the panel and audience will engage in a discussion of (1) Challenges of studying workflow for consumer informatics interventions and (2) Strategies to overcome these challenges, facilitated by the moderator. The moderator will identify rules of discussion; establish a safe environment for participants, and summarize the exchange when appropriate. Prioritized lists of challenges and strategies will be developed for research and design domains. The moderator will engage the audience, stimulate discussion, and maintain a balance between audience and panelists. If time permits, the panel and audience will also engage in a discussion of workflow considerations for linking consumer informatics interventions to clinical informatics interventions.

All panelists have agreed to take part on this panel.

Abstract

With recent studies highlighting the pervasiveness and severity of preventable medical errors, renewed efforts have turned to health technologies to improve quality of care and patient safety. However, few efforts target patients and caregivers as primary users of quality and safety-oriented technologies. In this panel, we will describe four new efforts in developing health technologies to engage patients and their caregivers to improve quality of care and to reduce preventable harm. These efforts include co-designing with both a pediatric and adult population, using sensors to promote safe and healthy mobility, engaging hospitalized patients and caregivers in the safety plan, and using gamification techniques to engage patients in chronic illness management. Attendees will learn new approaches for engaging patients and their caregivers in ensuring they receive high-quality, safe care while they are in the hospital. The panel will provide insights that information technology designers, developers, and researchers can build upon to address caregivers’ and patients’ safety needs, while realistically fitting within the workflow of an organization.

Introduction

Although many efforts have called attention to the prevalence of medical errors, recent studies have shown the problem to be much more widespread than previously thought. James’ analysis estimated that 440,000 deaths a year in the U.S. alone are caused by preventable medical errors and 10-20 times that number receive serious harm.¹ In a more recent study, Makary and Daniel found medical errors to be the third leading cause of death.²

Many efforts have used technology to reduce this harm from these medical errors, but few inpatient efforts engage patients and their caregivers. Although patients having access to health information is positively associated with their ability and willingness to get involved with their own safety³, in a hospital setting, medical personnel and system processes receive most of the attention for preventing harm while patients receive little support. Patients and their caregivers offer a distinctive perspective and set of skills that could help reduce preventable harm if they are supported through appropriate technologies. Enhancing patients’ and caregivers’ access to and engagement with meaningful information can help address communication challenges that are often the root cause of many undesirable events. In this panel, we will present recent efforts to design and develop information technology to engage patients and caregivers to prevent harmful errors. Moreover, we will highlight integration of bio-behavioral and positive psychology approaches into technology using gamification⁴ to assist patients with activating their personal strengths as a means to enhance healthy behaviors, motivate positive change, and improve health outcomes.

Learning Objectives

• The attendee will be able to summarize the challenges related to development and use of consumer-facing technologies to engage patients in the quest for high quality and safe care.
• The attendee will describe challenges and opportunities associated with integration of innovative technologies into the clinical workflow of an organization.
• The attendee will describe strategies to improve patient engagement related to high quality and safe care using consumer facing health technologies.

Moderator: David Bates, M.D., M.Sc.

Professor of Medicine, Harvard Medical School, Professor of Health Policy and Management, Harvard School of Public Health, Boston, MA, USA. David Bates is a Professor of Medicine at Harvard Medical School, and a Professor of Health Policy and Management at the Harvard School of Public Health, where he co-directs the Program in Clinical Effectiveness. He directs the Center for Patient Safety Research and Practice at Brigham and
Women’s Hospital, and serves as external program lead for research in the World Health Organization’s Global Alliance for Patient Safety. He is the former board chair of AMIA, former North American representative to IMIA, and the immediate past president of the International Society for Quality in Healthcare (ISQua).

Dr. Bates will provide a brief overview and scope of the problem of preventable medical harm and the promise of health information technology to reduce the problem. He will introduce each panelist and moderate the question answer session.

**Panelist: Wanda Pratt, Ph.D.**

Dr. Wanda Pratt is a Professor in the Information School with an adjunct appointment in Biomedical & Health Informatics in the Medical School at the University of Washington. Dr. Pratt serves on the board of directors for AMIA, and chaired the 2016 AMIA Annual Symposium. Her work in consumer health informatics has received multiple best paper awards from AMIA, the ACM CHI Conference on Human Factors in Computing Systems, and the Journal of the American Society of Information Science & Technology. She is the principal investigator of the Patients as Safeguards Project—a project funded by the Agency for Healthcare Research and Quality (AHRQ) to understand the information needs of and design technology for hospitalized patients’ and their caregivers to prevent, detect, and recover from medical errors.

Dr. Pratt will describe results from co-design efforts with pediatric patients, adult patients, caregivers, and clinicians. She will present highlights from multiple co-design sessions and discuss technology functionalities that participants thought were necessary to support patients and caregivers in their important safeguarding role. Dr. Pratt will include design examples, and summarize how they are building upon those designs to develop in-hospital technologies for patients and caregivers.

**Panelist: Patricia Dykes, Ph.D., M.A., R.N.,**

Dr. Patricia Dykes is research program director in the Center for Patient Safety Research and Practice at Brigham and Women’s Hospital and associate professor at Harvard Medical School where she has a program of informatics and patient safety research. She is past Chair of the AMIA Nursing Informatics Working Group and on the Board of Governors for the Alliance for Nursing Informatics. Dr. Dykes’ program of research includes using health information technology to provide the tools, knowledge, and decision support for patient activation in their recovery plan during an acute hospitalization.

Dr. Dykes will review a suite of tools designed developed through an AHRQ-funded patient safety learning lab to engage hospitalized patients and family in their safety plan. She will review the benefits and challenges of providing bedside access to personal health and safety information through the use of mobile technology and clinical decision support to promote patient activation during an acute hospitalization. Dr. Dykes will review the patient engagement value of the technology and preliminary results evaluating its effectiveness.

**Panelist: Ryan Greysen, M.H.S., M.A., M.D.**

Dr. Ryan Greysen is Chief of Hospital Medicine in the Division of General Internal Medicine at University of Pennsylvania. Dr. Greysen’s quality, safety, and research efforts focus on improving hospital and transition care for vulnerable patients, particularly older adults with multiple morbidities. His program of research focuses on patient-centered stressors such as poor functional status, mobility, sleep, and engagement in care and the potential for personalized mobile technologies to help alleviate these stressors and increase patient and caregiver engagement in acute and recovery care.

In his panel presentation, Dr. Greysen will talk about his research using mobile sensors with goal of reducing falls and other complications including hospital acquired pressure ulcers and hospital acquired infections. He will describe on ongoing pilot program that “prescribes” mobility goals to patients in the hospital. In addition, Dr. Greysen will discuss the benefits and challenges of linking the sensor data with Epic MyChart interface.

**Panelist: Cornelia Ruland, R.N., Ph.D.**

Dr. Ruland is professor and past Department Head of the Center for Shared Decision Making and Collaborative Care Research at Oslo University Hospital in Oslo Norway where she initiated and directs an innovative, externally-funded program of research focusing on user-centered design and evaluation of informatics tools to improve shared decision making, illness management, self-management and patient-centered collaborative care. These tools have shown through randomized controlled trials to be highly effective in improving health outcomes. As a PI of
numerous international research studies, Dr. Ruland has widely disseminated her research and received substantial external recognition, including several best paper awards from AMIA.

Dr. Ruland will highlight her current project that uses gamification to support patients in chronic illness management. Dr. Ruland’s presentation will explore how information and communication technology can be used to help and engage patients in discovery of their personal strengths and provide support and guidance on how their strengths can be used in more efficient health management. She will explore how gamification mechanisms can enhance user engagement, motivation and positive health behavior, but also to foster reflection, self-discovery and capacity building as part of the self-management process. Including patients’ personal strengths into clinical consultations aligns patient care with people’s personal values and preferences and thus is an important factor for patient safety.

**Discussion Questions**

- What are some common and unique features from presented projects/participant projects that serve to engage patients and their care partners while hospitalized in improving the quality and safety of healthcare?
- What are key operational and implementation challenges that were encountered? From the patient/caregiver perspective? From the provider perspective? How are clinical, technical, and operational workflows reconciled?
- How does is technology used to enhance the experience of patients and family caregivers while engaging them in high quality and safe practices? How is information shared across patient and provider platforms to ensure efficiency?

**Summary**

In summary, this interactive panel will engage participants in a range of key topics to share lessons learned from their work related to the design, develop, and implement health technologies to engage patients and caregivers in improving the quality and safety of healthcare and to identify additional lesson learned from participants.

**Statement of the panel organizer**

All panelists have agreed to take part in this important panel.

Abstract

The goal of this panel is to provide an overview major initiatives in Latin America, provide an overview of the World Health Organization (WHO) national e-health strategic planning toolkit, challenges in implementation of e-health systems, overview of the PAHO e-health strategy for the Americas, and provide approaches for implementing programs using cooperative models.

Learning Objectives

1. Identify challenges for the development of e-health in the Latin American region
2. Describe the priority areas for e-health development and informatics training
3. Discuss challenges in deployment and support of informatics systems in clinical and public health sectors

Panel Description

This goal of this panel is to provide an overview major initiatives in Latin America, provide an overview of the Pan American Health Organization/World Health Organization (PAHO/WHO) national e-health strategic planning toolkit, challenges in implementation of e-health systems, overview of the PAHO e-health strategy for the Americas, and provide approaches for implementing programs using cooperative models.

Key Topics

1. Present examples of e-health Initiatives and strategies in Latin America
2. Provide overview of the PAHO/WHO National e-health strategic planning toolkit
3. Discuss models of public-private cooperation for global health challenges
4. Discuss strategies for managing non-communicable diseases
5. Discuss human-centric approaches to healthcare services
6. Discuss ways for managing the risks and impact of current and future epidemics

Speakers

- Session Moderator Yuri Quintana, PhD
- The PAHO/WHO National e-health strategic planning toolkit, WHO Third Global Survey on eHealth (Region of the Americas), and e-health Initiatives and strategies in Latin America, David Novillo, PhD
- E-Health Strategies in Brazil, Heimar Marin, RN, PhD
- Digital Strategy at Clinica Alemana, Santiago Chile, Marcelo Lopetegui, MD, MS
- Digital Strategies in Costa Rica and RACSEL Red Americana de Cooperación para el desarrollo de la Salud Electronica, Mario Ruiz Cubillo, MD
- Clinical Informatics Training Programs, Paula Otero, MD,

Why this topic is important

- Latin America has a growing e-health sector and academic informatics programs
- There synergies and common experiences that can be shared among these programs
- There is an opportunity for AMIA members to be more involved in Latin America via informal networks and formal collaborations
Questions

- What are the priorities in each country and institution?
- What process was used to define the priorities?
- What role can national and international informatics organizations can have in the training and development of informatics in the region?
- What opportunities are there for AMIA members to collaborate in Latin America?

All panelists have agreed to participate.
Design and Implementation of a Structured Sequencing Report Format: A Multi-Stakeholder Perspective from eMERGE

Luke V. Rasmussen, MS\textsuperscript{1}, Darren C. Ames, MS\textsuperscript{2}, Samuel J. Aronson, ALM, MA\textsuperscript{3}, Lawrence J. Babb\textsuperscript{4}, Casey L. Overby, PhD\textsuperscript{5,6}

Abstract

With continued interest in adopting genomic medicine practices, an ongoing barrier has been around enabling the transmission of genomic laboratory results in a structured manner that allows a receiving institution to perform local computations on those results, including those for clinical decision support. The electronic Medical Records and Genomics (eMERGE) network, now in its third phase, has implemented a structured representation of results for a custom sequencing panel of over 100 genes and 1500 SNPs. This panel will describe the selection of the structured report format, the experiences of two clinical sequencing centers in aligning their laboratory systems to the format, how the format is received by eMERGE institutions, and the lessons to date that have potential relevance to other institutions exploring the integration of structured genomic results.

Panel Overview

In recent years, several research consortia have been exploring the use of genomic results as part of routine clinical practice. These groups, including the NHGRI-sponsored electronic Medical Records and Genomics (eMERGE) network\textsuperscript{1,2}, Implementing GeNomics In pracTicE network\textsuperscript{3} and the Clinical Sequencing Exploratory Research Consortium (CSER)\textsuperscript{4}, have implemented and evaluated novel methods by which genomic results may be better incorporated into existing electronic health record (EHR) systems for pharmacogenomics and genomic medicine. Lessons learned have included considerations for implementing structured results to facilitate clinical decision support (CDS), storage and handling of the results, and strategies for reporting results to patients and healthcare providers.

While much has been learned, there are still many unanswered questions. The eMERGE network, for example, is now in its third phase (eMERGE 3) with nine institutions that will receive results from one of two central sequencing and genotyping centers (CSGs; Baylor College of Medicine and Partners HealthCare with Broad Institute). Results from each of the CSGs will include a customized sequencing panel (eMERGE-Seq) of over 100 genes and 1500 single nucleotide polymorphisms (SNPs) developed for this study. Samples and results are managed in accordance with the Clinical Laboratory Improvement Amendments (CLIA), and include formatted reports (represented as PDF documents) as well as structured representations of the information contained in the reports.

Given the unique infrastructure at each sequencing center, as well as the heterogeneity of EHRs at each of the nine participating institutions, a major consideration has been how to facilitate collaboration across network sites with respect to methodology and technology. A critical underpinning of this has been to achieve consensus on a format for the structured representation of sequencing results. While several candidate formats exist – including SMART on FHIR Genomics\textsuperscript{5} and HL7 Clinical Sequencing\textsuperscript{6} – the involvement of Partner HealthCare, which developed the GeneInsight platform\textsuperscript{7} prompted consideration of the underlying XML format used in GeneInsight as an alternative. The GeneInsight XML format was reviewed by the CSGs and eMERGE network sites, and was accepted with some additional constraints applied on elements. A computable definition of the format has been made available online at: https://github.com/emerge-ehri/results-schema.

While the selected XML format is not a ratified standard (although it has been shared with the HL7 Clinical Genomics Workgroup), and is currently used by GeneInsight users and now at eMERGE network institutions, we believe the experiences in implementing this format across the network will provide generalizable lessons of interest and importance to other institutions. This panel (as described in more detail in the Panelists section) includes a variety of stakeholders from the project, representing perspectives from project leadership, laboratory operations, technical implementation and end-users of the sequencing results. A broad range of AMIA attendees that identify with these groups should find interest in the panel, and will garner real-world experiences of two laboratories aligning to a common standard, considerations for the technical implementation and workflow of these labs when
delivering data for both discovery science and clinical care, as well as the experiences of institutions receiving and processing structured results for return to providers and patients, and for use in CDS. Although a particular structured format will be described, the discussion will focus on the importance of structured results regardless of underlying standard, allowing attendees to apply these lessons at their own institutions for whichever structured representation is available.

Panelists:
Casey Overby – Dr. Overby will act as the moderator for the panel, and as co-chair of the eMERGE EHR Integration workgroup will provide a brief overview of the current objectives of the eMERGE network with respect to EHR integration. This will frame the rest of the panelists as they describe their work within the context of these objectives.

Larry Babb – Mr. Babb will describe the rationale and design behind the original GeneInsight XML format, and the considerations that were made for extending it for the eMERGE project. Given his involvement in HL7, Mr. Babb will also discuss how the efforts within eMERGE align towards standards for clinical sequencing.

Daren Ames – Dr. Ames will discuss the role of DNAnexus® and Baylor College of Medicine (BCM) within eMERGE, and the work performed to align DNAnexus and BCM infrastructure with the selected XML format. Topics will include considerations for mapping existing results to the structured report template, and automation of delivery for both identified and de-identified results.

Sandy Aronson – Mr. Aronson will describe his work as co-chair of the eMERGE EHRI Working Group (with Dr. Overby) in aligning the sequencing labs and participating institutions in the design, review and implementation of the selected XML format. Mr. Aronson will describe considerations from his viewpoint as a project facilitator, IT Director of a laboratory producing results, as well as a consumer of the results at Partners HealthCare.

Luke Rasmussen – Mr. Rasmussen will provide the perspective of a consumer of the selected XML format, describing early experiences in review of the proposed format, through preliminary testing and current implementation work at Northwestern University. This will also include approaches taken across the network to share tools and methods for integrating results across disparate EHR systems.

Discussion Questions
The following discussion questions will be used to initiate further audience discussion following the panelist presentations:
1. Given that standards for clinical sequencing exist, but the reality that not all labs may not currently return results in that format, what seems to be the minimal set of information that should be transmitted?
2. What still needs to be addressed to make structured genomic results more accessible to institutions not involved with consortia such as eMERGE?
3. Given the heterogeneity of EHR systems and the complexities of sequencing results, are structured results worth the hassle to both generate and consume?
4. How do changes in the interpretation of a particular variant factor into the implementation decisions made within eMERGE, and what broader considerations are there for other institutions?

Disclosures
Mr. Aronson works for Partners HealthCare, which receives a royalty on sales of GeneInsight.
Mr. Babb is employed by GeneInsight, a Sunquest Information Systems company, which reports grants from eMERGE III in conjunction with Partners Healthcare as well as independently.

Confirmation of Agreement
The panel organizer (LVR) confirms that all listed participants have agreed to take part in this panel.

20 Years Of Digital Pathology-An Overview Of The Road Travelled And What Is On The Horizon

Joel Saltz, PhD, MD¹, Ashish Sharma, PhD², Alexis B. Carter, MD, FCAP, FASCP³, Liron Pantanowitz, MD⁴, Tahsin Kurc, PhD¹

¹Biomedical Informatics Department, Stony Brook University, Stony Brook, NY; ²Biomedical Informatics Department, Emory University, Atlanta, GA; ³Pathology and Laboratory Medicine, Children’s Healthcare of Atlanta, Atlanta, GA; ⁴Pathology and Bioinformatics, University of Pittsburgh Medical Center, Pittsburgh, PA

Abstract

Over the past 20 years, Digital Pathology has developed into a thriving field with both clinical and research applications. FDA approval is anticipated this year to allow use of digital whole slide imaging for primary Pathology diagnosis. Once this occurs, we expect digital Pathology to become as ubiquitous in clinical practice as digital Radiology. While the concept of the Virtual Microscope, a software tool that implements the operation of a whole slide microscope and enables viewing of large digitized tissue samples, is now two decades old, the adoption of Digital Pathology informatics tools in clinical practice is still a work in progress. This panel will describe the history, state of the art, promise and challenges in digital Pathology Informatics. Informatics related challenges include the need for interoperability and standards, integration of analytic pipelines and results into clinical decision support.

Introduction

The true promise of digital pathology lies in precision medicine – leveraging image-derived information to generate Pathology Imaging biomarkers that can be combined with Radiology information and molecular data to steer treatment. The creation of meaningful ways to validate, classify, display and explore these results, integrated into the entire clinical picture will be a crucial Pathology- and Informatics-based contribution to precision medicine. An approach that employs survival curves, patient demographics, genomic data is critical to allow this information to be used to craft individualized patient care plans and to evaluate response to treatment and is not trivial given the very big data sets involved.

Building upon successful work showing that Pathology imaging biomarkers predict survival in Glioblastoma and can be used to sub-classify tumor types, the NCI has funded the development of tools for lung cancer which discover reproducible pathology imaging biomarkers that have prognostic significance. By interrogating large data sets of multiple tumor types, it is expected that certain Pathology imaging biomarkers will be predictive within a tumor type and others across multiple tumor types.

This panel will discuss past and present efforts to develop infrastructure to scan, catalog and store large collections of whole slide images (WSI), both for clinical work and research. Methods and tools to carry out large-scale, integrated analysis with visualization, interrogation and mining of WSI will also be discussed. The panel participants will describe example of institutions and consortia that launched into large scale digital Pathology data acquisition efforts as well as efforts to integrate images and annotations into the Electronic Medical Record through Vendor-Neutral Archives. The panel will also speak on how challenges in digital pathology relate to challenges in other fields of biomedical informatics and how work in digital pathology can enhance and benefit from work in other biomedical informatics fields.

Panelist Presentations

Joel Saltz (Organizer and Participant) will give a lightning overview of the last 20 years of digital Pathology beginning with 1) early speculations about digital Pathology and its telepathology predecessors, 2) initial prototypes, 3) current enterprise level and open source digital software systems, and 4) recent advances in research and development of methods and tools presented in Pathology and imaging conferences and journals. He will address informatics issues around leveraging digital Pathology for clinical decision support, health care quality and precision medicine. He will then describe how digital Pathology will become a ubiquitous component of clinical workflow.
due to imminent FDA approval for primary diagnostic use of whole slide imaging and how Pathology Informatics will become a pivotal component in all areas of biomedical informatics.

Alexis Carter (Participant) will describe the advantages and barriers of Vendor Neutral Archives (VNAs) both within and outside Pathology for storage and retrieval of medically important Whole Slide Images. She will present the potential power of integrating VNA whole slide images with Genomic, Radiologic and other clinical data for research and discovery.

Liron Pantanowitz (Participant) will describe how digital pathology has evolved over time as a research and clinical tool. He will present the current regulatory trajectory in the US and the impact of changes in regulations and FDA approval on the broader applications of digital pathology in research and clinical settings.

Ashish Sharma (Participant) will present challenges and software systems for whole slide tissue image management, visualization and analysis. He will describe the challenges of whole slide tissue image (WSI) management, as the sizes of image datasets scale to federated archives of population-scale image collections. We will present the challenges of processing WSIs at large scales and integrating analysis results with other imaging, molecular, and clinical datasets. He will then go on to discuss the role of visual analytics in the development of robust pathology imaging biomarkers.

Tahsin Kurc will serve as the panel moderator.

**Timeliness and Significance of Panel**

FDA approval is anticipated this year to allow use of digital whole slide imaging for primary Pathology diagnosis. FDA approval and introduction of digital Pathology into the clinical workflow will mark the advent of digital Pathology as a sub-area of clinical informatics, and will allow the integration of analytics from the research arena to clinical practice.

The first Virtual Microscope cost about $300K to set up was one-of-a-kind, and took over 12 hours to scan a single slide. Today, 20 years later, WSI devices are important tools in supporting diagnosis, education and scientific discovery in Pathology. The next 20 years promises to see this tool at the center of Anatomic Pathology through its ability to collect and present objective, reproducible and accurate data derived from WSI, thus enhancing Pathologists’ analyses and patient care.

By developing tools to leverage digital pathology, beyond routine clinical applications, a deeper understanding of tumor pathophysiology will be possible. Integrating this information into the landscape of the entire spectrum of clinical information will drive both disease specific and patient specific information which can be used to drive high risk high reward cancer trials to better results faster. To bring this vision to reality it will be necessary to develop and deploy infrastructure to scan, catalog and store extremely large collections of WSI, both for clinical work and research. We will describe a number of examples of institutions and consortia that launched into very large scale digital Pathology data acquisition, storage and integration efforts. Integration is the key to correlate WSI data with clinical, radiologic and genomic information for clinical care and discovery.

Today and going forward WSI analytics will be powered by artificial intelligence, feature extraction and powerful algorithms to allow reproducible and quantifiable results, such as assessment of the percentage of tumor-infiltrating lymphocytes, important in assessing the body’s immune response to cancer, or to produce a virtual flow cytometry indexing and cataloging cell types present in a WSI. Beyond what is visible to the human eye, image analysis can produce powerful Pathology imaging biomarkers, which can be integrated with genomics, survival curves, patient demographics, public health data, environmental data and census data to drive personalized cancer diagnosis, prognosis, and therapy and also to better understand and predict response to treatment. This pool of personalized data, when scaled up, collected and linked with cancer registry data will provide a radically detailed view of cancer trends and has the potential of significantly impacting treatment regimens and the broader policy around the NCI Cancer Moonshot Program.

**Discussion Questions**

- How will the ubiquitous use of whole slide images impact clinical decision making?
- How can ubiquitous availability of whole slide imaging be employed to improve health care quality?
• In what way can whole slide image information complement information obtained from Pathology reports?
• Should patients have access to their Pathology images? If so, what kind of explanation/education should we provide for patients?
• How can whole slide images be used to better target therapy?
• Crucial decisions hinge on Pathology interpretations. Availability of images in electronic health records will allow non-Pathologists to easily examine the data that goes into Pathologist interpretations. Will this democratize decision-making?
• How can deep learning and artificial intelligence be used to create new Pathology classifications that may do a better job of targeting therapy?
• How should ontologies and controlled vocabularies be leveraged to describe Pathology image features?
• How will regulatory approval for deep learning (AI) with WSI proceed in the USA?
• Can collections of population-scale pathology archives affect our understanding of disease and treatment efficacy?

**Statement from Panel Organizer**

All participants have agreed to take part on the panel.
Evaluating Impacts of Patient-Facing eHealth Technologies: Connected Care in the Veterans Health Administration

Stephanie L. Shimada, PhD1,2,3, Timothy P. Hogan, PhD1,3, Thomas K. Houston, MD MPH1,3, D. Keith McInnes, ScD MSc1,2, Neil C. Evans, MD4,5
1Center for Healthcare Organization & Implementation Research, Department of Veterans Affairs, Bedford, Massachusetts, USA; 2Department of Health Law, Policy, and Management, Boston University School of Public Health, Boston, Massachusetts, USA; 3Division of Health Informatics and Implementation Science, University of Massachusetts Medical School, Worcester, Massachusetts, USA; 4Office of Connected Care, Department of Veterans Affairs, Washington, DC, USA; 5Washington DC VA Medical Center, Department of Veterans Affairs, Washington, DC, USA

Abstract
Patient-facing eHealth technologies such as patient portals, mHealth applications, home telehealth devices, and automated texting systems are increasingly common. Rigorously evaluating the impacts of these technologies is thus increasingly important. These ‘impacts’ can include both the intended positive effects on access, patient engagement, and health outcomes as well as other unintended adverse consequences. In this panel, we will present new data on the impacts of a range of patient-facing technologies being implemented across the Veterans Health Administration (VHA), including the My HealtheVet patient portal, Secure Messaging, and VHA’s automated, tailored text-messaging system. Attendees will learn about current and upcoming patient-facing technology implementation in the VHA, approaches for gauging different stakeholder experiences, and to select appropriate measures for positive and negative impacts of patient-facing technology. Implications for future evaluations will also be discussed.

The panel will be moderated by Dr. Neil Evans, Chief Officer for the Office of Connected Care for the Veterans Health Administration. We will present findings from a randomized trial of an intervention to encourage adoption of secure messaging, an evaluation of the implementation of an automated texting system to support patient self-management, and a multi-modal study to identify and categorize unintended consequences of multiple patient portal features.

Introduction
Engaging and supporting patients through technology has been a national priority for over a decade and is actively encouraged through policy initiatives, including meaningful use requirements focused on access to and use of patient portals and secure messaging. Systematic reviews in the area of Consumer Health Informatics have reported on patient and provider attitudes toward these technologies and on adoption and utilization. Many opinion papers also cite the potential of these technologies, but fewer rigorous studies have assessed impacts on specific outcomes, including patient access, disease outcomes, or costs. Further, most research to date has focused on the expected positive benefits of patient-facing eHealth technologies.

VHA’s Office of Connected Care is responsible for the implementation and evaluation of patient-facing virtual eHealth technologies across the VHA healthcare system. We consider eHealth as a model for the delivery and receipt of healthcare services that has great potential to improve a variety of outcomes, including patient access to healthcare services, care coordination, and the broader transition from episodic to continuous care. In the eHealth model, patients, their families, and clinical team members use patient-facing eHealth technologies that support functions (i.e., communication, behavior support, transactions) that are critical to disease prevention and health management, which, in turn, influence behaviors, processes, and outcomes. In an effort to successfully fulfill its mission, the Office of Connected Care has invested in the eHealth Partnered Evaluation Initiative, an evaluation center that draws upon the theories, strategies, and methods of implementation science, to support the further integration of patient-facing eHealth technologies into VHA care.

Our panel encompasses recent and ongoing work from investigators affiliated with the VA eHealth Partnered Evaluation Initiative and will offer a balanced perspective, demonstrating positive impacts but also presenting
important unintended consequences. The VHA Offices of Connected Care and Health Services Research & Development Service both support this research with the goal of enhancing healthcare quality and assuring patient safety. The results will guide future VHA implementation efforts, educate patients, guide providers, and ultimately enhance these technologies. Our panel is timely as adoption of patient-facing technologies is experiencing exponential growth. Much work remains to be done to fully understand the implementation of these technologies, and we anticipate that our presentations and the subsequent discussion will be of interest to researchers in Consumer Health Informatics and to those in leadership positions who are committed to the careful evaluation of patient-facing technologies in their respective healthcare organizations.

An Overview of Connected Care in the VA (Dr. Neil Evans)
We will describe the mission of the Office of Connected Care and proceed to review some of the key patient-facing technologies currently being rolled out by VHA. These include, but are not limited to, the My HealtheVet patient portal with integrated patient-to-clinical-team secure messaging, the Annie automated text messaging system, VHA’s expanding suite of mHealth applications, and telehealth programs that support real-time video-audio interactions among patients and members of their care team. Recognizing the speed with which eHealth technologies evolve and the implications of broader organizational changes for technology adoption, this review will emphasize key functions – education and information sharing, communication, behavior support, and transactions with the healthcare system – that VHA’s patient-facing eHealth technologies are intended to support. Our focus on technologies and the functions they support will serve as a framework for the subsequent research and evaluation project presentations.

Supported Adoption Intervention for Secure Messaging (Dr. Thomas K. Houston)
We will present findings from a randomized trial of a supported adoption intervention for Secure Messaging. Within the My HealtheVet patient portal, Secure Messaging is a way for Veterans to asynchronously communicate requests for information and requests for action to their healthcare teams. My HealtheVet users from three VA Medical Centers who had not previously sent Secure Messages to their clinical teams (N = 1,196) were randomized to be encouraged to use Secure Messaging, or to receive no intervention. For those randomized to intervention, we established a supported adoption intervention (SAI) curriculum that included motivational messages, reminders, and educational instruction about how to use Secure Messaging. Those in the SAI arm received the curriculum in a stepped approach, beginning with educational mailings and proactive Secure Messages from the facility informing patients of the ease and benefits of Secure Message use, the steps needed to send a Secure Message, and numbers to call for assistance. Next, those SAI patients not yet engaged in Secure Messaging after the educational mailings and Secure Messages received a motivational telephone call during which the Veteran was asked to think about how they could personally leverage Secure Messaging for their own healthcare, and during which research assistant trained in motivational interviewing techniques could troubleshoot any potential barriers with the patient.

Demographic characteristics, age, gender, socio-economic status, were balanced by randomization across the two groups. Among those randomized to the intervention, 14.3% began using Secure Messaging during the six-month follow-up, compared with only 4.6% of those Veterans randomized to control. Among those patients randomized to SAI who subsequently did send a Secure Message, 44% sent the first message prior to the motivational call, and 56% sent the first message after the motivational call. In an intent-to-treat analysis, Veterans randomized to the intervention were more likely to report that it was easy or very easy to communicate with their doctor when they needed to (65.6%), compared with the Veterans randomized to no intervention (58.5%, p = 0.052). This difference was driven by the subset of intervention Veterans who began using Secure Messaging, 79% of whom reported it was easy to communicate with their doctor. Intervention patients also reported higher scores on the Health Care Climate Questionnaire (p = 0.01 compared with control).

Veterans in the SAI group had near-triple the rate of adoption of Secure Messaging, and reported higher rates of perceived access and self-reported health care climate. Veterans reported that the SAI reminders and education about when to use Secure Messaging with their team influenced their use of the system.
Automated Patient Text Messaging System – Formative Evaluation to Assist with Wider Adoption
(Dr. Timothy P. Hogan and Dr. D. Keith McInnes)

The “Annie” text messaging system was developed in the VHA based on a similar system that was implemented in the United Kingdom’s National Health Service. Annie uses baseline patient profiles and expert-written rules, called “protocols”, to deliver targeted text messages and elicit responses from individual patients. We present results of a formative evaluation based on 48 qualitative interviews with stakeholders including patients, clinicians, and clinical staff from 4 VHA Medical Centers where the Annie system was being tested.

Patients reported feeling more accountable for their behaviors, and perceiving Annie as a kind of coach to assist them with chronic disease management. Providers appreciated the ability to help patients continue to be engaged with care between office visits, and utilized the customization features to have the appropriate kinds and volume of text messages sent to patients. Our interviews revealed various barriers to (e.g. challenges fitting into clinical workflow) and facilitators of (e.g. quality improvement culture in the adopting clinic or hospital) implementing the Annie text messaging system which in turn have implications for understanding both the intended and unintended consequences of the system for different stakeholder groups. We will present the results of this evaluation and extrapolate broader lessons learned that can inform the implementation of similar automated texting systems as well as other patient-facing eHealth technologies.

Unintended Consequences of eHealth Implementation (Dr. Stephanie Shimada)

Too often, health informatics studies are designed only to find differences in the hypothesized positive effects of that technology, ignoring the greater context and potential unintended adverse consequences which may have far-reaching impacts such as on patient-provider relationships, clinical workload and workflow, and even patient safety. This narrow window of evaluation has had important implementation consequences.

We sought to develop a taxonomy of unintended consequences of patient-facing technology use, by focusing on the unintended consequences of My Health eVet implementation in VA. We gathered data on actual and potential positive and negative consequences related to patient portal use from the literature, from prior studies of patient portal use in VA, and an in-depth qualitative evaluation with key VA stakeholders including My Health eVet operational staff, providers, and patients. We will present the results of this evaluation, including both negative and positive unintended consequences of patient portal use, discuss some of the factors involved in unintended adverse consequences of patient-facing eHealth implementation, and make recommendations for including consideration of unintended consequences in evaluations of other patient-facing technologies moving forward.

Discussion Questions to Enhance Audience Participation

Thinking of your role as a patient, clinician, or informatician, how do the presented results relate to your own experiences with patient-facing technologies?

If you are a clinician, how are you leveraging patient-facing technologies with your patients? If you are not, what are some of the barriers to doing so?

What are the best ways you have found to incorporate the patient voice into your research along with other stakeholder input?

What are other appropriate measures for evaluating patient-facing technologies? What data sources can or should we leverage to gather the data necessary for accurate and timely measurement of impacts?

What types of unintended consequences related to patient-facing technologies (portals, telehealth, mobile apps, etc.) have you encountered in your work or research?

The moderator and all presenters have agreed to take part in the panel.

This work is supported by the U.S. Department of Veterans Affairs, Grants # PPO 15-395, PEC 15-470, IIR 15-101. The views expressed are those of the authors and do not necessarily reflect the position or policy of the Department of Veterans Affairs or the United States government.
Interactive Panel: Participatory Health Informatics for Data-Driven Precision Medicine

Jaideep Srivastava\textsuperscript{a}, Luis Fernandez-Luque\textsuperscript{b}, Fernando Martin-Sanchez\textsuperscript{c}, Kenneth D. Mandl\textsuperscript{d}

\textsuperscript{d} Computational Health Informatics Program, Boston Children’s Hospital, Boston, Massachusetts

Abstract

Lifestyle plays a major role in the prevention and management of chronic conditions. Sleep, physical activity and nutrition behaviours are being found to play a major inter-related role in physical and mental wellness of all of us. Worldwide empowered citizens are using new technologies such as social media, mobile apps and wearables to track their health and also get support from digital health services and peers. In that process, big and heterogeneous data sources are being generated. This panel will explore how data generated by empowered patients can facilitate the development of precision medicine. The panelist will address, among others topics, a) the use of social media to monitor lifestyles, b) data analytics of health wearables, c) the linkage between Genotype/Phenotype/Expotype data, and d) integration with other biomedical data sources.. Using an interactive approach with the audience the panel will aim to identify key elements for the development of a roadmap for research and practice.

Keywords: Social media; wearables, participatory health; precision medicine

1. Introduction

Precision Medicine is foreseen as a drastical transformation of our healthcare systems. This transformation is based on the availability of new individual health data that can be used to personalize health prevention and management in an unforeseen manner. Particularly promising is the integration of personal health data, such as lifestyles, which is often necessary to understand the health context of the patients in their real life. This integration encompasses data sources ranging from environmental data, such as sleep or physical activity (expotypes), to genomics (genotypes) and clinical data (or derived phenotypes). Further, the data are highly heterogeneous and spread among many different stakeholders. How to “link” personal health data with more “traditional” biomedical data is one of the major challenges ahead to achieve the full potential of precision medicine\textsuperscript{1}, and some initiatives are emerging to reduce those data-gaps\textsuperscript{2}.

Health consumers are increasingly becoming more proactive (empowered) stakeholders, which is drastically transforming the personal health data ecosystem. Empowered patients and participatory medicine as a movement are catalyzing an explosion of person-generated health data, often as part of the quantified-self movement\textsuperscript{3}. Currently, wellness and fitness devices are becoming massively adopted. If we consider participatory technologies, such as smartphone apps, Direct-To-Consumer services and wearable devices as sources of individual health data for potential clinical use we have to acknowledge that person-generated data is still largely an under-utilized health resource.

The use of these type of data for precision medicine raises many technical, legal and practical questions (e.g. privacy, liability, ownership). Yet alone, the integration and linkage with clinical data open many other questions such as the creation of new data and patient-driven health information economical models. A machine learning and data-driven ecosystem also brings many ethical questions, and some opponents of machine learning are even suggesting that “Artificial Intelligence is the White Guy Problem” as “smart” models are built inherently biased due to the type of data used by the machine learning algorithms. This panel is aiming at discussing those aspects and starting collaborative work to draft a possible roadmap for research and practice in this area.

2. Learning and Discussion Objectives

After participating in this session, the audience should be better able: 1) to analyze and understand complex socio-ethical challenges arising in the use of patient-generated data for precision medicine, 2) to study technical challenges and potential precision medicine solutions for the integration of personal health data in precision medicine applications, 3) to define strategies for deploying data-driven solutions based on personal health data.

Further, this panel is aiming to create debate and promote discussion on controversial aspects, which are currently hot topics in both research and practice. The audience is expected to engage in this dialogue to provide their insights. Among others, a key element for the discussion will be the effect of data-driven precision medicine in participatory health (i.e. patient empowerment, doctor-patient communication) and vice versa.

3. Panel Description

This panel provides a ground for discussing how Participatory Medicine, and particularly patient empowerment, can play a role in the development of data-driven precision medicine. This panel brings together members of AMIA, the Society of Participatory Medicine and two IMIA Working Groups (Big Data Mining and Analytics and Social Media). The panelists have extensive experience in various facets of social media, wearable and mobile health, participatory health informatics, data mining, and the analysis of biomedical data for health research.

4. Panel Characteristics

**Intended audience:** Patient advocates, healthcare professionals, data scientist, and medical informatics community at large.

**Aim of the discussion:** To create an inclusive roadmap for the research and development agenda of precision medicine based on participatory health informatics.

**Interactivity:** the panel presentations will be shared in Slideshare (with license creative commons) prior to the conference and distributed among working groups mailing lists. We will seek comments with regards of questions for debate using a Google Form.

During the conference we will engage with the online and offline audience. The presentation will be shared using Facebook Live Video and Twitter using the hashtag of AMIA 2017. The debate questions raised in the panel will be put under vote using a real-time voting system (e.g. Poll everywhere). These polls will be also used for getting information on the background and experience of the participants. The polls will distinguish between online and in-situ participants.

After the panel the audience will be invited to continue the debate offline aiming at developing a white paper on the topic of the panel. This will follow the example of a previous experience. This paper will be circulated among related AMIA/IMIA Working Groups. Funds for Open Access of the paper will be seek from the Qatar Foundation Open Access Fund.

---

6 Pre-selected tool for polling https://www.polleverywhere.com/
5. Panel Organization and Participants

Moderator: Dr. Luis Fernandez-Luque is co-Chair of IMIA Social Media Working Group and Scientist at Qatar Computing Research Institute and member of the Society for Participatory Medicine. He is also co-founder of the digital health startup Salu media which develops mobile applications for empowering patients with cancer.

1) Introduction to the Panel and Topics (15 minutes)
by Luis Fernandez-Luque (Scientist at Qatar Computing Research Institute)

He will initially provide a brief 15-min overview of the panel’s aims, format, structure and tools for participation. This introduction will provide a background and help to frame each individual panel member’s presentation and examples. The following questions will be used as a guide for discussion:

- What advantages/benefits does participatory medicine offer to the development of precision medicine?
- What are the challenges and negatives aspects that may arise to achieve the full potential of precision medicine?
- Which are the socio-ethical challenges ahead?

He will then introduce each panel member and thereafter, each will provide a short presentation (10 minutes each) of a select topic relevant to the discussion.

2) Data Mining of Personal Health Data: Leading and Misleading? (10 minutes)
By Prof. Jaideep Srivastava – Computer Science Department, University of Minnesota

- Short bio: Jaideep Srivastava is Professor at the University of Minnesota with over 30 years of experience researching in data mining, both in academia and industry.
- Panel Focus: He will focus on the technical challenges ahead, in special the role of deep learning and wearable data as study case. He will also explain cases in which machine learning can lead to erroneous and dangerous results.

3) Breaking the Silos of Digital Health Data for Precision Medicine (10 minutes)
By Prof Kenneth Mandl MD, MPH FACMI– Department of Biomedical Informatics, Harvard Medical School, Harvard University

- Short bio: Prof. Kenneth D. Mandl directs the Computational Health Informatics Program at Boston Children’s Hospital.
- Panel focus: Prof. Mandl will focus on how new approaches to interoperability and innovation in healthcare, including of the SMART on FHIR apps ecosystem can facilitate the integration of personal health data from consumer health applications with other biomedical data sources.

4) Precision Medicine requires linking Genotype/Phenotype and Expotype Data (10 minutes)
By Fernando Martin PhD FACMI, Professor of Healthcare Policy and Research, Weill Cornell Medical College, Weill Cornell in NYC.

- Short bio: Prof Martin-Sanchez is Co-chair of the IMIA Big Data Working Group, member of the Society for Participatory Medicine and a researcher in the All of Us Research Program (US Precision Medicine Initiative). His current research focuses on the application of informatics methods in Participatory Health and Precision Medicine.
- Panel focus: He will cover aspects related to methods for linking Genotype/Phenotype/Expotype data. He will also open the discussion on socio ethical issues.

5) Debate and Roadmap Discussion (45 minutes)
In this part of the panel the moderator will unveil the different questions polled during the session. These will be addressed using the three major areas for discussion highlighted in the introduction.

The audience will be encourage to think on a timeframe of 5-10 years in the future for the discussion to identify major aspects with long term impact. Further, the audience will be encouraged to suggest additional topics for discussion.

5. Statement of the Panel Organizer

All panel members agree to take part in the panel.
Advancing electronic case reporting (eCR) to enable public health disease control and emergency response: getting into the technical weeds!

Catherine J Staes, BSN, MPH, PhD1, John W. Loonsk, MD FACMI2, Kathy Turner, PhD, MPH3, Noam Arzt, PhD, FHIMSS4, Patina Zarcone-Gagne, MPH5

1University of Utah, Salt Lake City, UT; 2CGI Federal, Fairfax, VA; 3Idaho Department of Health and Welfare, Boise, ID; 4HLN Consulting, Palm Springs, CA; 5Association of Public Health Laboratories, Silver Spring, MD

Abstract

Many healthcare institutions grapple with the legally required mandate to report information to public health authorities when patients present with conditions of public health importance, such as pertussis, salmonella, Zika virus infection. Existing reporting of communicable diseases by health care providers is incomplete, untimely and predominantly a manual, paper-based process. Electronic case reporting (eCR) is relevant for over 200 conditions reportable in over 3,000 public health jurisdictions in the US. As such, eCR requires an ecosystem (knowledge, decision support, infrastructure, and standards) that can meet unique jurisdictional and clinical needs. The panelists represent leaders in the public health and informatics community involved in building the platform that supports standards-based services and defining the eCR-specific HL7 standards for reporting and response. The panel objectives are to a) describe the need for a scalable, flexible strategy for eCR that meets both routine and emergency reporting needs; b) describe the decision support services, infrastructure, and HL7 document standards that support bi-directional communication for eCR; and c) explore the strengths and limitations of the current eCR strategy. The Zika infection case reporting scenario will be used to illustrate key findings, and experience from pilot testing during 2017 will be shared.

Background

Tracking and responding to common and emerging public health threats (e.g., gonorrhea, measles, Zika infection, lead poisoning) requires communication between clinical settings and public health authorities that conduct surveillance and control efforts. Currently in most US communities, case reporting by health care providers is dependent on manual processes (phone and fax) and as a result, reporting is incomplete and untimely1. Providers are often not aware of reporting requirements.2 Electronic laboratory reporting has significantly improved the completeness of case finding for those conditions for which a laboratory result is necessary, however, there are other conditions for which laboratory results are not timely enough for case detection or not appropriate or available, and laboratory information is only part of the information required for initiating public health investigations. Due to the complexities around case reporting, many healthcare institutions grapple with the legal mandate to report required information to public health.

Electronic Case Reporting (eCR) is enabled by the widespread adoption of electronic health records (EHRs),3,4 and the emerging technical and standards-based ecosystem that supports bi-directional communication between public health and healthcare systems. Such an ecosystem must support routine eCR and be able to scale up during public health emergencies. Establishing new communication channels in the midst of an outbreak can be difficult and disruptive. The AMIA informatics community has, and can, contribute significantly to the implementation of the nationwide scalable, and standards-based eCR solution.

Objectives

The objectives of the panel are to a) describe the need for a scalable, flexible strategy for eCR that meets both routine and emergency reporting needs; b) describe the infrastructure, decision support services, and HL7 document standards that support bi-directional communication for eCR; and c) explore strengths and limitations of the current eCR strategy.

Panel description

This didactic panel is organized so key leaders in the public health, informatics, and technical aspects of eCR can discuss the ecosystem (including knowledge, decision support, infrastructure, and standards) for bi-directional communication to support eCR. The Zika infection case reporting scenario will be used to illustrate key findings.
Several panelists are involved in the eCR Digital Bridge initiative (http://www.digitalbridge.us/about/) and will be able to share experiences based on pilots performed during 2017.

The panel will be moderated by Dr. Kathryn Turner, Chair of the Surveillance and Informatics Committee for the Council of State and Territorial Epidemiologists (CSTE), and member of the Governance Committee for the Digital Bridge initiative. CSTE represents state and local epidemiologists throughout the US engaged in public health surveillance and emergency response.

**Panel presentation 1: Framing the problem addressed by electronic case reporting (eCR)**

eCR is dependent upon public health laws and programmatic needs for disease surveillance and investigation that vary by jurisdiction. These needs may change in response to specific public health threats. In addition, eCR should support clinicians who desire bi-directional electronic communication with the public health community. During public health emergencies (e.g., Ebola and Zika outbreaks), the eCR solution must be scalable and flexible so it can be leveraged for newly identified conditions or be adapted for higher sensitivity to detect events during emerging outbreaks.

Implementation of eCR requires new automated processes for initiating and determining the reportability of clinical events. Determining reportability requires knowledge that is being systematically documented with input from epidemiologists across the US. To date, default logic has been defined for 69 of the over 200 conditions reportable in at least one jurisdiction. Some of the 69 conditions, upon preliminary review, include criteria that add complexity, such as epidemiologic criteria (41% of the conditions), symptoms (39%), preliminary lab results (30%), lab orders (20%), lab value comparisons (20%), and immunization data (5%). For 41% of the conditions, optional logic was requested to be available for use during emergencies or to accommodate reporting rules that sometimes vary by state. The standard codes required to automate the reporting logic informed the development of the event-based triggers that will be used by an EHR to initiate the case reporting workflow.

Dr. Catherine Staes, an informaticist and co-lead of the CSTE Reportable Condition Knowledge Management System (RCKMS) project, will provide background information to frame the problem addressed by eCR and briefly describe the knowledge developed to trigger the EHR to initiate the case reporting workflow and determine reportability. Trigger codes and reporting rules for Zika infection will be used to illustrate key concepts.

**Panel presentation 2: Defining a long-term public health clinical decision support (CDS) strategy**

As the knowledge required to support case reporting evolves from unstructured to more structured and standardized formats, it becomes suitable for electronic clinical decision support (CDS). CDS for case reporting confronts two challenges: a) While EHRs are moving toward local CDS capabilities, it will take several years for EHR systems to consistently support this capability; and b) public health-related CDS knowledge, such as Zika infection detection and reporting rules, may differ from jurisdiction to jurisdiction. Therefore, there is an ongoing need to manage reporting rules in a distributed manner. The Reportable Condition Knowledge Management System (RCKMS) is a component of the current eCR solution. RCKMS has the following capabilities that serve key the above requirements: a centralized CDS service that can be accessed by EHRs until they all have local CDS capabilities; and a knowledge authoring environment that allows ongoing distributed rule authoring (whether these rules are accessed through a central service or eventually exported for local EHR implementation).

Dr. Noam H. Arzt, president of HLN Consulting, LLC - the entity building the RCKMS service and authoring tool for CSTE and CDC - will describe how RCKMS supports the strategy for public health knowledge management, and how it will evolve over time to provide the systems and services to satisfy short-, mid-, and long-term public health CDS requirements. In addition, Dr. Arzt will reference emerging technical standards that support this work with which RCKMS is compliant. CDS concerning Zika infection will be used to illustrate the ideas presented.

**Panel presentation 3: Building the ecosystem on a scalable, flexible services platform**

Knowledge and CDS to enable automated case reporting must reside in an ecosystem that supports collaboration between clinical and public health partners and includes the necessary tools and services. Centralization of services is a focal theme to ease the implementation burden for both jurisdictions and reporters. Part of the eCR solution includes hosting key services on the Association of Public Health Laboratories (APHL) AIMS platform. AIMS provides a secure and flexible infrastructure for both messaging and public health decision support that determines the reportability of the condition, and to which jurisdiction the case report should be sent. AIMS is built on top of Amazon Web Services (AWS) which provides extreme scalability as demands and needs grow over time. The platform serves to connect clinical EHRs through trust networks to the RCKMS and finally to public health agencies.
Patina Zarcone-Gagne, Director of Informatics at APHL, is a member of the Digital Bridge Governance Group and chairs the Digital Bridge Sustainability Workgroup. Ms Zarcone-Gagne will discuss a) how the AIMS Platform is being used as part of the national ecosystem for routine public health surveillance, b) describe services and validation and transport functions supported by the platform, and c) briefly describe the process for clinical systems to on-board to AIMS and the status and timeline for the national eICR project.

**Panel presentation 4: Establishing standards for bi-directional exchange to support eCR**

Finally, the eCR ecosystem requires standards for bi-directional information exchange. Public health case reporting had been conspicuously absent from Meaningful Use criteria, and thus has not benefitted from the HITECH incentives that have met other public health needs (e.g., immunization registries and electronic laboratory reporting). The absence was partly because the standards for public health case reporting have been historically problematic even though standards are central to the application of incentives. In the past, standards development efforts suggested having individual standards for each of the more than 200 conditions reportable to a US public health agency. Another past effort suggested harmonizing the case reporting content for all programs and jurisdictions into one standard. Both approaches were problematic for policy and practical reasons, but laid the groundwork for the current approach.

The current approach for standards development supports a two-step automatically-initiated reporting process. To develop that standard for the first step, epidemiologists with CSTE identified a set of data (all of which should be available in certified base EHR products) that they expect will be sufficient to meet most, if not all, public health needs for initiating a case investigation. The HL7 Public Health and Emergency Response (PHER) working group used the data set to develop the electronic Initial Case Report (eICR) using the Consolidated Clinical Document Architecture (C-CDA) document. The second step of the eCR solution involves providing information from a public health agency back to clinical care. The information must be specific to the patient and the condition and indicate the reportability status of the information shared in the eICR. To develop the standard for this second step, the HL7 PHER workgroup is developing a Reportability Response (RR) using the HL7 CDA document structure.

John W. Loonsk, MD FACMI, Executive Sponsor and lead developer of the two HL7 eCR standards, will discuss the approach, challenges, and limitations of the eICR and RR standards, again using the Zika infection scenario to illustrate specific issues. In addition, Dr. Loonsk will share information about the experience from testing and prototyping in a number of settings, and convey plans for enhancing eCR standards.

**Audience Discussion**

At least 15 minutes will be reserved at the end for a discussion with and among the audience. Questions will be posed, such as: From the health care enterprise perspective, do the requirements and systems for implementing eCR leverage your existing infrastructure and make case reporting more efficient? Are there unintended consequences that the informatics and public health community should be thinking about?

**Conclusion**

This panel will allow the AMIA audience to get updated information about the knowledge, infrastructure, and standards supporting electronic case reporting (eCR) and experiences gleaned from pilot implementations supported by the Digital Bridge initiative. Reaching the goal of bi-directional communication between clinical and public health settings will require engagement from the AMIA community.

The State of Interoperability and Health Information Exchange in the U.S.: Advancing Steadily or Treading Water?

Walter Sujansky, M.D., Ph.D.¹, Julia Adler-Milstein, Ph.D.², Ross Martin, M.D., M.H.A.³

¹Sujansky & Associates, LLC, San Carlos, CA; ²Department of Medicine, University of California, San Francisco; ³Chesapeake Regional Information System for our Patients (CRISP), Baltimore, MD

Abstract
Prompt and efficient access to clinical data, regardless of its source, is one of the key promises of electronic health record technology as EHRs approach universal adoption in the United States. But in the nation’s complex and fragmented health care system, that goal requires interoperability and health information exchange across disparate information systems and business entities. In this panel, experts from academia and industry explore whether the U.S. healthcare system is now finally nearing the objective of broad-based technical and organizational interoperability for health data or still struggling against formidable barriers that have frustrated past interoperability initiatives. The panel presentations and discussion will assess the current state of interoperability and health information exchange (IHIE), as well as the potential contributions of contemporary IHIE initiatives, such as the FHIR standards and the Carequality and CommonWell industry consortia, to advance IHIE. The speakers will demystify these initiatives, highlight their novel attributes, and identify their remaining limitations in delivering on the promise of interoperability and health information exchange, including lessons learned from personal experience. The discussion will engage the audience and explore specific actions that informatics and health I.T. stakeholders can take to advance interoperability and HIE goals.

Learning Objectives
1. Review the goals of clinical data interoperability and health information exchange and characterize the current state of interoperability and exchange from an empirical and realistic perspective.
2. Analyze several contemporary technology efforts to advance IHIE, including the FHIR standards and the Carequality and CommonWell industry consortia, with a particular emphasis on what may be new and different in these efforts versus similar to past unsuccessful approaches.
3. Describe the primary remaining challenges to achieving true interoperability and health information exchange based on applied research and the experiences and lessons learned from a specific health information exchange organization.
4. Highlight the most important actions that can be taken by the medical informatics and health information technology communities to accelerate progress today.

General Description
This didactic panel will explore whether the U.S. healthcare system is advancing steadily toward the objective of broad-based technical and organizational interoperability for health data or still struggling against formidable barriers that have frustrated past interoperability initiatives. The panel presentations and discussion will assess the current state of interoperability and health information exchange (IHIE), including through the presentation of empirical research findings. The panel will also assess the potential contributions of contemporary IHIE initiatives, such as the FHIR standards¹ and the Carequality² and CommonWell³ industry consortia, to advance IHIE. The speakers will demystify these initiatives, highlight their novel attributes, and identify their remaining limitations in delivering on the promise of interoperability and health information exchange, including lessons learned from personal experience. The discussion will engage the audience and explore specific actions that informatics and health I.T. stakeholders can take to advance interoperability and HIE goals.

Panel Presentations
The panelists will each address the following aspects of this topic: 
Julia Adler-Milstein, PhD will present current data on the state of IHIE in the U.S. She will describe challenges to IHIE to date, including technical, regulatory, and market barriers. She will describe current policy efforts to advance IHIE.

Walter Sujansky, MD, PhD, will describe the potential for FHIR standards to address long-standing technical barriers to IHIE, the current state of FHIR, and remaining challenges in realizing the expected benefits of FHIR. He will also describe two large initiatives to advance IHIE among healthcare organizations – Carequality and CommonWell – including their current state and future challenges.

Ross Martin, MD, MHA, will describe the current and planned capabilities of CRISP – the state-designated health information exchange for Maryland, which also serves the District of Columbia and West Virginia. He will highlight how the current policy, standards and certification processes impact real-world efforts to bring relevant clinical information to the point of need in support of care coordination and clinical decision making and will discuss ways in which the medical informatics community can shape our path forward.

**Timeliness and Value of This Topic**

This topic is timely and of broad interest because achieving the vision of IHIE is a top policy priority and a goal for which both the public and private sector are devoting substantial attention and resources. Today, there is a flurry of touted IHIE initiatives, resources, organizations, and policies. Yet, it is difficult to understand where we stand with respect to IHIE progress, and whether we are now on a fast upward trajectory due to recent developments, or stalled out because we have not yet addressed the key obstacles. Such an understanding is critical to guide ongoing efforts. Our panel will bring empirical evidence and observations based on deep expertise, both theoretical and practical, to help audience members separate reality from hype and understand where we have made progress, where we expect to make progress, and where substantial barriers remain. We will explain key “hot topics” in the IHIE space – FHIR, Carequality, and CommonWell – and give a realistic assessment of how they advance IHIE and where stumbling blocks remain. The panel members are well-suited to address this topic, in that they are knowledgeable and directly involved, yet unencumbered by vested interests in any particular approach, resource, or commercial endeavor.

We expect that this panel will draw a wide array of attendees – from academic, practitioner, industry, and policymaker backgrounds – who understand the importance of IHIE but are not fully informed on the topic. Because we focus on the latest advances, we expect that we will draw a large number of participants who want to understand topics such as FHIR in an accessible and not overly-technical way.

**Potential Discussion Questions**

1. What is the level of IHIE that we’re trying to achieve? Is there a consensus?
2. Why do we not yet have IHIE today, as generally envisioned, despite widespread EHR adoption? What are the key barriers holding us back?
3. What is FHIR and how is it different from previous interoperability standards? Which challenges to IHIE could FHIR address? What work remains for FHIR to deliver on its potential?
4. What are the Carequality and CommonWell consortia and what specific resources do they provide to advance IHIE? What are their similarities and differences? What are their remaining challenges in supporting IHIE?
5. What real-world obstacles do provider organizations, state entities, and health information organizations face in achieving envisioned levels of IHIE? Are their expectations realistic? Are they knowledgeable about the nature of the barriers? What can the medical informatics community do to help them advance their IHIE knowledge and goals?
6. What specifically could the informatics research community do to advance IHIE? Policy makers? Medical informaticists working in industry? NIH/NLM?

**Statement of Participation**

All participants have agreed to take part on the panel.

Panel Proposal: Computational Phenotyping on Diverse Data Sources

Jimeng Sun, PhD¹, Bradley Malin, PhD², Abel Kho, MD³, Joydeep Ghosh, PhD⁴,
Mark Craven, PhD⁵

¹Georgia Institute of Technology, Atlanta, GA, USA, ²Vanderbilt University, Nashville,
TN, USA, ³Northwestern University, Chicago, IL, USA, ⁴University of Texas Austin, TX,
USA, ⁵University of Wisconsin Madison, WI, USA

Abstract

Phenotypes are the measurable biological, behavioral and clinical markers of a condition or disease. The process of deriving research-grade phenotypes from clinical data using computer-executable algorithms is called computational phenotyping (or phenotyping for short) [1]. Phenotyping includes a range of approaches, ranging from specifying existing phenotype using expert-derived rules and discovery of new phenotypes through novel computational methods that account for the interplay of many features conditions simultaneously. Traditionally, phenotyping has focused on algorithms for extracting clinical phenotypes from electronic health records (EHR). However, there is an increasing need to broaden the scope of, as well as standardize the principles underlying, computational phenotyping: 1) to capture and process more diverse health related data (e.g., *omic and mHealth); 2) to extract more sophisticated phenotypes based on temporal and spatial patterns; and 3) to speed up algorithm development, validation and deployment to support clinical and research applications. The learning objectives include various topics in phenotyping for diverse data sources, which include:

- Advanced machine learning methodologies for phenotyping
- Phenotyping development on national health networks
- Multi-scale phenotype development from multiple data sources
- Privacy considerations and knowledge sharing about phenotyping

Intended Audience: Medical informatics researchers and practitioners

Introduction

The national Precision Medicine Initiative aims to enroll one million members in a national cohort that will integrate data from biospecimens, sensor and mobile technologies, and healthcare, largely from electronic health record (EHR) data, to advance biomedical discovery and improve health. The realization of this vision will require efficient and effective methods to convert data from diverse data sources into specific and reliable phenotype characterizations that can be used to predict an individual’s risk of disease or response to drug therapy.

The quantity and quality of biomedical data that is growing. It is being collected across an increasing collection, and diversity, of technologies and mechanisms (e.g., EHR, mHealth, genomic data), which are distributed across institutions. Thus, it is critical for the medical informatics community to appraise the state of affairs in computational phenotyping methods, provide guidance on how best to translate such methods (and the phenotypes themselves) into practice, and define an agenda for the future of research to make phenotyping scalable and reusable. We believe such a panel is badly needed to provide necessary background and to inspire discussion of research in phenotyping for diverse data sources.

Topics for discussion:

Advanced machine learning methodology for phenotyping (by Prof. Ghosh) Raw EHR data collected across diverse populations and multiple care-givers tend to be extremely high dimensional, unstructured, heterogeneous, and noisy. Manually querying and interpreting such data is a formidable challenge for healthcare professionals. In the past few years, however, there has been much progress in obtaining high-throughput “silver standard” phenotypes via computational/machine-learning approaches that extract insights from clinical notes, procedures and diagnoses pertaining to large patient databases. Dr. Ghosh will highlight some of the key approaches and findings, and discuss how one may further such progress by incorporating even more diverse data sources, including multi-scale m-health sensors and ICUs, the additional challenges posed, and some new machine learning methods to deal with such challenges.

Phenotyping development on national health networks (Dr. Kho) We will describe national network phenotyping, and the effect of multi-institutional and external to EHR data on phenotypes. Several large national networks leverage
Electronic Health Record data across multiple institutions to define clinical phenotypes for research and quality improvement. Additional sources of data, for example provided directly by patients or inferred by geocoded data linked to home address, can add additional depth and breadth to EHR data. Dr. Kho will describe phenotyping efforts from national networks such as PCORnet, the NIH-sponsored Electronic Medical Records and Genomics (eMERGE) network), Next-D2, and EvidenceNOW and outline how multi-institutional data, and data captured outside of the EHR contribute to more fully informing computed phenotypes.

Multi-scale phenotype development from multiple data sources (Prof. Craven): We will talk about phenotyping from multiple rich data types, including EHR, imaging, 'omics, and mobile sensor data. Methods for risk assessment, disease subtype identification, and disease trajectory profiling can be potentially improved by employing approaches that characterize diseases in terms of their signatures in multiple data types. Moreover, there are technical challenges that are common across many of these data sources, such as high dimensionality and sparse longitudinal measurements. We will discuss applications of such approaches to Alzheimer's disease, breast cancer, and asthma.

Privacy consideration and knowledge sharing (Prof. Malin): As the diversity of data sources grow, it becomes increasingly challenging to define a priori hypotheses to test. As such, biomedical investigators benefit when they have access to resources either to validate what they see in their own data and to generate new ideas. In this respect, it is critical to ensure that data from diverse studies are made available on a wide scale. At the same time, there remain concerns that making such data available, even in a summarized form, can lead to the privacy compromises for the patients from which the data was collected. Over the past year, we have made substantial strides in demonstrating how summary data derived from genomic and phenomic resources (namely electronic medical records) can be made accessible while accounting for adversarial capabilities. In this section of the panel, Dr. Malin will report on the results of the iDASH Genome Privacy Competition, recent advances in sharing genomic data summary statistics for the Sequence and Phenotype Integration Exchange (SPHINX), which consists of data on over 8000 subjects in eMERGE [2]. He will further provide intuition into the privacy models that are being set in place in the All of Us Cohort program of the NIH Precision Medicine Initiative.

Discussion questions
- What are the challenges in phenotyping diverse biomedical data sources?
- What are the rational privacy consideration for phenotyping?
- How can advanced machine learning methods help improve phenotyping development?
- What are different phenotyping initiatives across the US?

Panel lineup:
- **Jimeng Sun (moderator),** Ph.D., is an Associate Professor of School of Computational Science and Engineering and a co-director of center of health analytics and informatics at College of Computing at Georgia Institute of Technology. His research focuses on health analytics and medical informatics, especially in applying large-scale predictive modeling and computational phenotyping on biomedical applications. He has published over 100 papers, filed over 20 patents (5 granted). He has received SDM/IBM Early Career Data Mining Research Award 2017, ICDM Best Research paper in 2008, SDM Best Research Paper in 2007, and KDD Dissertation Runner-up Award in 2008. Dr. Sun received his B.S. and M.Phil. in Computer Science from Hong Kong University of Science and Technology in 2002 and 2003, and PhD in Computer Science in Carnegie Mellon University in 2007. Prior to joining Georgia Tech, He was a research staff member at IBM TJ Watson Research Center.

- **Mark Craven,** Ph.D. is a professor in the Department of Biostatistics and Medical Informatics at the University of Wisconsin, and an affiliate faculty member in the Department of Computer Sciences. He is the Director of the Center for Predictive Computational Phenotyping, one of the NIH Centers of Excellence for Big Data Computing. He is also the Director of the NIH/NLM-funded Computation and Informatics in Biology and Medicine (CIBM) Training Program, and a member of the Institute for Clinical and Translational Research, the Carbone Cancer Center, and the Genome Center of Wisconsin. The focus of his research program is on developing and applying machine-learning methods to the problems of inferring models of, and reasoning about, networks of interactions among genes, proteins, clinical and environmental factors, and phenotypes of interest.

- **Abel Kho** MD, MS is Associate Professor of Medicine and Preventive Medicine in the Feinberg School of Medicine at Northwestern University and Director of the Center for Health Information Partnerships (CHiP www.healthinformationforall.org). He has been PI or Co-PI of over $50 million in funding to the Chicagoland
or surrounding region including the ONC funded Chicago Health IT Regional Extension Center (www.chitrec.org), the PCORI funded Chicago Area Patient Centered Outcomes Research Network (http://capricorn.cdrn.org/), and the AHRQ funded Health Hearts in the Heartland consortium (http://www.healthyheartsintheheartland.org/) within the EvidenceNOW initiative. His research focuses on developing regional Electronic Health Record (EHR) enabled data sharing platforms for a range of health applications including high throughput phenotyping, cohort discovery, estimating population level disease burden, and quality improvement.

- **Bradley Malin**, Ph.D., is Vice Chair and Professor of Biomedical Informatics at Vanderbilt University. He is also a Professor of Biostatistics, a Professor of Computer Science, and is Affiliated Faculty in the Center for Biomedical Ethics and Society. He co-directs the Health Data Science Center, the Center for Genetic Privacy and Identity in Community Settings (an NIH Center of Excellence in ELSI Research), and the Big Biomedical Data Science Ph.D. program. Since 2007, he has led a data privacy consultation service for the Electronic Medical Records and Genomics (eMERGE) network, an NIH consortium. He is also the co-chair of the Data Privacy and Security Working Group of the All of Us Research Program of the U.S. Precision Medicine Initiative. His investigations on the empirical risks to health information re-identification have been cited by the Federal Trade Commission in the Federal Register and certain privacy enhancing technologies he developed have been featured in popular media outlets and blogs, including Nature News, Scientific American, and Wired magazine. He is an elected fellow of the American College of Medical Informatics and was honored as a recipient of the Presidential Early Career Award for Scientists and Engineers (PECASE).

- **Joydeep Ghosh** is currently the Schlumberger Centennial Chair Professor of Electrical and Computer Engineering at the University of Texas, Austin. Dr. Ghosh’s research interests lie primarily in data mining and their applications to a wide variety of complex real-world problems. He has received 14 Best Paper Awards over the years, including the 2005 Best Research Paper Award across UT and the 1992 Darlington Award given by the IEEE Circuits and Systems Society for the overall Best Paper in the areas of CAS/CAD. Dr. Ghosh has been a plenary/keynote speaker on several occasions such as ICHI’15, ICDM’13, Health Informatics workshops at KDD14, ICML13 and ICHI13; and has widely lectured on intelligent analysis of large-scale data. He served as the Conference Co-Chair or Program Co-Chair for several top data mining oriented conferences, including SDM’13, SDM’12 and KDD 2011.

We affirm that all panel participants have agreed to participate and have contributed to the preparation of this document.

Social and Behavioral Determinants of Health: Fundamental Informatics Challenges for Enriching Health IT Systems

Panelists
Albert W. Taylor, MD, Daniel J. Vreeman, PT, DPT, MS, Matteo Verzola, MS, Jon Puro, MPA

Abstract
In 2015, the Institute of Medicine released Capturing Social and Behavioral Domains and Measures in Electronic Health Records: Phase 2. This document identified core domains that were recommended for inclusion in patients’ health histories, and endorsed specific measures for each of these core domains. This work reflected the substantial impact of these factors on patients, families and communities.

This panel is designed to share the experience of a diverse set of stakeholders who have been engaged in the recognition of social determinants of health (SDH) factors on health status and the current and future state of SDH domains and measures within electronic health records. The panel will present the current ONC (Office of the National Coordinator) perspective on the 2015 HIT (Health Information Technology) certification criteria that included many of the IOM endorsed domains and measures, highlight the critical work that a standards development organization (LOINC) plays both currently and in the future, implementation challenges identified and addressed within a health care system (Verzola), and the integration and use of SDH data within primary health care (Puro). The panel presentations will emphasize lessons learned as well as current and future barriers that can be addressed to foster more inclusion of SDH factors in clinical care.

This panel is sponsored by the AMIA Social Determinants of Health (SDH) discussion group.

Introduction and Background
Good health results from interactions with the healthcare system, and also from factors that include exposure to early childhood events, the environment, neighborhoods, and community and family cultural influences. Recognizing, understanding, and including these factors in health care delivery are an important part of helping individuals and communities improve their health status. Data on these ‘social determinants of health’ (SDH) can be used on their own or through predictive modeling to help identify barriers to care and prognosis for recovery, inform clinical decision-making and the tailoring of interventions, enable care coordination with appropriate services, and support development of tailored clinical decision support in electronic health records. SDH are also gaining recognition as factors that should be incorporated into new schemas for managing patients in the framework of value-based care and accountable care organizations. Data related to SDH are of great interest to large-scale, cooperative research projects like PCORnet (cf. PCORnet’s SDH research interest group). Currently, there is no accepted, comprehensive standard for capturing data related to SDH in the electronic health record (EHR).

Panel Description
In this panel, we will discuss the present opportunities and challenges in the current state of SDH information, including standard development for SDH information, ways to improve the identification and use of these data areas, and lessons learned from implementation pilots. The best approach for capturing the range of SDH that can be
meaningfully intervened upon by clinical providers and have substantive impact on patients’ health is still unclear, but this current work will inform the future pathway. Jon Puro will moderate the current and future role and impact of SDH from multiple perspectives, including the federal government, a major EHR vendor, and two clinical perspectives. The experiences and lessons learned from this early SDH work will help set the stage for ongoing work in this area as we move towards integration of these data sets in health care systems. Attendees will have an opportunity to understand the critical and difficult nature of including SDH information within the clinical care continuum and the urgent need for increasing attention to the inclusion of these factors in health care delivery models.

The panel will focus on issues including:

1. A review of various development and regulatory activities from the federal perspective (ONC)
2. Representing SDH in vocabulary standards
3. Implementing IOM (Institute of Medicine) recommendations within the EHR
4. Integrating SDH data sets into primary care and research: an IT perspective

Presenters

ONC: Current and Future (Taylor)

Dr. Taylor will discuss ONC’s perspective and approach to advancing the use of SDH in HIT. ONC recognizes and appreciates the work of Institute of Medicine (now National Academy of Medicine) and other organizations in the recognition of the direct health linkages of SDH and the degree of consensus and adoption of standardized representation of these domains and measures. This work was critical in the inclusion of a number of specific domains in ONC’s 2015 Edition HIT Certification Criteria and subsequent Interoperability Standards Advisories. Many of these measures, as well as those more directly representative of clinical domains, are trademarked or copyrighted property. These protections must be taken into consideration when negotiating the new use case using standardized terminology such as LOINC, including them in certification criteria and in commercial EHR products. Dr. Taylor will discuss ONC’s experience in navigating these issues so that measure developers and intellectual property owners can advance their own instruments in a HIT-enabled manner.

Representing SDH content in vocabulary standards (Vreeman)

Dr. Vreeman will discuss the fundamental need for representing individual- and community-level SDH variables in common vocabulary standards. He will discuss how enriching existing standards with representations of SDH measures can improve interoperable sharing, aggregation, and computation in clinical, population, and research applications. He will describe the growing momentum for incorporating SDH variables in LOINC (http://loinc.org), a freely available international standard for identifying health measurements, observations, and documents. As a widely adopted vocabulary standard in EHRs, LOINC codes enable interoperable data exchange and promotes reuse of this data through aggregation, analytics, and cross-study comparisons. Dr. Vreeman will provide an overview of LOINC’s current model [11], coverage for representing SDH content, and how implementers can use this content. He will also discuss the current efforts to catalyze addition of SDH content in LOINC and how users can propose new individual or community level variables for inclusion.

Implementing IOM Recommendations within the EMR (Matteo Verzola)

Mr. Verzola will discuss the approach to implementing the IOM recommendations around capturing social determinants of health within the Epic EMR, sharing valuable lessons learned for all HIT systems. He will cover approaches for ensuring data is captured as part of the already existing clinical workflows, as well as what tools physician, nurses, and care managers can use for reviewing a patient's individual domain risk and overall risk related
to SDH. The discussion will then move to how SDH information can be leveraged for other workflows, including research, analytics, and referral workflows to community resources to address SDH challenges.

Primary Care Experience from an IT perspective (Puro)

Mr. Jon Puro will discuss the technical methods used at OCHIN and the ADVANCE Clinical Data Research Network for importing and integrating geospatial data related to community level social determinants of health ("Community Vital Signs") into the ADVANCE Research Data Warehouse. ADVANCE and OCHIN regularly receive over 70 sets of geospatial metrics in partnership with the Robert Graham Center to use for patient care as well as community-focused research. Jon will describe these data sets, explain the technical extract, transform and load processes, and discuss current efforts and future plans for integrating these data into research and patient care. Jon serves as the PI of the ADVANCE Clinical Data Research Network.

Discussion Questions

1. What are the top three benefits and challenges for the inclusion of SDH domains and measures in EHRs?
2. How can the health informatics community leverage the lessons learned from prior EHR development efforts to help accelerate the development, deployment and integration of SDH standards?
3. What are appropriate ways to address IP issues that result from using SDH measures?
4. What can AMIA do to assist with the integration of SDH into clinical care?

Panel Organizer Statement: All participants have agreed to take part in the panel and discuss the topics as outlined above.

Abstract

With support from the U.S. Office of the National Coordinator for Health IT (ONC), the National Academy of Medicine (NAM) convened a collaborative effort with health care leaders to identify untapped opportunities and practical strategies for improving clinical decision support (CDS) practice and adoption. Through a series of NAM-facilitated working meetings and work groups focused on four key CDS areas (content authoring, platform integration, operations, and dissemination), expert authorities reviewed current and emerging CDS practices and identified collaborative opportunities to accelerate national progress in the real-time application and use of CDS to improve health and health care decision making. In this panel, leaders of this NAM effort will summarize the key findings identified by this multi-stakeholder collaboration of clinicians, academics/researchers, industry, patient advocates, and the government. The panelists will also present cross-cutting Priorities for Action developed at the conclusion of this work and engage the audience in an interactive discussion on how we can work together to pursue these priorities with the goal of optimizing health and health care at scale.

Description

The panel will be organized as follows:

Dr. Tcheng, who oversaw the NAM’s efforts as the Chair of the Planning Committee, will serve as the moderator and provide an overview of the motivation for the NAM effort and how the effort was carried out. Then, the leaders of each of the convened Work Groups will describe the current state, challenges, and opportunities identified in the areas of CDS content authoring (Kawamoto), platform integration (Weingarten), operations (Teich), and dissemination (Middleton). Dr. Tcheng will then present the cross-cutting Priorities for Action identified by the effort. Finally, Dr. Tcheng will moderate an interactive discussion with the audience on how the informatics community can work together with each other and their cross-disciplinary colleagues to pursue the action priorities and achieve the full promise of CDS-enabled care optimization.

Tcheng: Dr. Tcheng is a practicing interventional cardiologist and Professor of Medicine and Community and Family Medicine (Informatics) at the Duke University School of Medicine. He chairs the Informatics and Health IT
Task Force of the American College of Cardiology, in which role he seeks to advance evidence-based cardiac care at a national scale. He served as the Chair of the Planning Committee for this NAM initiative to advance CDS. In opening the panel discussion, Dr. Tcheng will provide brief overview of the motivation for the NAM CDS effort and how the effort was carried out.

Motivation for Effort: The foundational problem that motivated the NAM CDS effort is the large gap between the immense promise and current reality of CDS. In the last decade, electronic health record (EHR) adoption rates have skyrocketed; nearly every provider and hospital in the United States uses some form of an EHR, paving the way for increased use of CDS tools that leverage EHR data to provide decision support to clinicians and patients. These tools are directed toward reduction of errors and adverse events, promotion of best practices for quality and safety, cost profile improvement and more. Many government and payor programs, such as the Merit-Based Incentive Payment System (MIPS), the Protecting Access to Medicare Act (PAMA) and Accountable Care Organization (ACO) programs, include specific or implied requirements for the use of CDS.

At the same time, consumers are increasingly generating and collecting data via wearable devices and mobile health apps that supplement the information individuals provide about their preferences, lifestyle factors and goals of care. New models of care delivery and payment that aim to reward quality and value of care rather than volume of services cannot succeed without active engagement of patients and family caregivers. CDS interventions that leverage multiple data types, bring the most current and relevant evidence to bear on clinical decisions, produce actionable recommendations from the mounds of data, and account for conflicting influences and values affecting decision making are necessary to care for patients with multiple chronic illnesses or comorbidities.

For a variety of reasons, however, CDS implementation and actualization remain nascent. To realize the potential of these tools to improve the quality, safety and efficiency of healthcare we must identify key priorities for action needed to realize the full potential of CDS within real-world environments.

Approach Taken: With support from the ONC, the NAM (formerly the Institute of Medicine) convened a collaborative effort with health care leaders to better understand potential opportunities and practical strategies for improving CDS practices and adoption. Expert authorities first met in-person (March 16, 2016) to describe current and emerging CDS practices, identify collaborative opportunities to accelerate progress in the real-time application and use of CDS to inform health and health care decision making, and provide guidance on implementation challenges and strategies at a national scale. The second meeting in the series (October 27, 2016) provided an opportunity to review, discuss, and refine actionable next steps to address CDS content, technical implementation, operations, and distribution. In a final meeting (February 10, 2017), key public and private stakeholders were engaged to discuss implementation and next steps for continued collaboration. The project was guided by an external planning committee and was not a product of the ONC.

In addition to the meeting series, the NAM CDS Planning Committee initiated small work-groups to address: content (CDS authoring), platform integration (technical implementation), clinical functionality and measurement (operations), and dissemination and assessment (distribution). Each small work-group met virtually to help develop action plans on their designated topics, which were consolidated into cross-cutting Priorities for Action by the work group members and the larger community of stakeholders convened through this effort.

Kensaku Kawamoto: Dr. Kawamoto is Associate Chief Medical Information Officer, Assistant Professor of Biomedical Informatics, Director of Knowledge Management and Mobilization, and Chair of the CDS Committee at the University of Utah. Dr. Kawamoto is also co-chair of the HL7 CDS Work Group and co-Initiative Coordinator for the ONC/CMS-supported Clinical Quality Framework (CQF) initiative to develop and validate a harmonized set of interoperability standards for CDS and electronic clinical quality measurement. Dr. Kawamoto led the NAM CDS work group on CDS content authoring and will present on the current state, challenges, and opportunities associated with the creation, management, and curation of computable, effective CDS.

Scott Weingarten: Dr. Weingarten is senior vice president and chief clinical transformation officer at Cedars-Sinai. He is a professor of Medicine at Cedars-Sinai and a clinical professor of Medicine at the David Geffen School of Medicine at UCLA. Dr. Weingarten was the co-founder, president and chief executive officer of Zyox Health, which is the leader for order sets and care plans for EHRs, and he is the co-founder and Chairman of the Board at Stanson Health, a leading CDS solutions provider. Dr. Weingarten led the NAM CDS work group on CDS platform integration and will present on the current state, challenges, and opportunities associated with standards-based integration of CDS into EHR platforms.
Jonathan Teich: Dr. Teich is assistant professor of medicine and emergency medicine, and a board-certified attending physician at Harvard Medical School. He has served as Chief Medical Informatics Officer for Elsevier, a leading CDS content and solutions provider, and serves as Clinical Architecture Lead for Bahmani and for OpenMRS, which provides critical open-source health IT solutions to over 50 low- and middle-income countries. Dr. Teich was the founder and first director of the Clinical Informatics Research and Development department at Partners Healthcare System and has authored or co-authored over 100 papers, books, and other publications in the field of medical informatics and healthcare information systems, with a particular concentration in CDS. He co-directed the HHS Roadmap for National Action on CDS, and has served as the CDS subject matter expert for ONC. Dr. Teich led the NAM CDS work group on CDS operations and will present on the current state, challenges, and opportunities related to CDS functionality, usability, implementation, and impact evaluation.

Blackford Middleton: Dr. Middleton is Chief Informatics & Innovation Officer at Apervita, Inc., the provider of the largest marketplace for the creation, exchange, and use of data and analytics in healthcare. He is immediate Past-Chair of the Board of Directors of the American Medical Informatics Association (AMIA), and Instructor in the Harvard TH Chan School of Public Health in the Departments of Health Policy and Management, and Policy Translation and Leadership Development. Previously, he was a Professor of Biomedical Informatics, and/or of Medicine, at Stanford, Harvard, and Vanderbilt Universities, and he held executive leadership roles at MedicaLogic/Medscape, Partners Healthcare System, and at Vanderbilt. Dr. Middleton’s work is focused on clinical informatics – the applied science surrounding strategy, design, implementation, and evaluation of clinical information systems in complex environments. Dr. Middleton led the NAM CDS work group on CDS dissemination and assessment in the marketplace, and will present on the current state, challenges, and opportunities related to widely disseminating effective CDS, including discussions of the CDS marketplace, the role of public and private knowledge sources, business rules in ensuring a vibrant and successful marketplace, constructs for feedback loops to inform value, and the financial business case for CDS.

James Tcheng: Following the presentation on findings from the four NAM CDS work groups, Dr. Tcheng will share the 13 cross-cutting Priorities for Action defined across 3 key areas: (i) developing, testing, establishing, validating and applying standards; (ii) encouraging adoption, use, and assessment at the delivery system level; and (iii) establishing a national CDS infrastructure. Dr. Tcheng will then moderate an interactive discussion with the audience on how we as an informatics community can work together to move forward on these priorities and realize the full promise of CDS-enabled health care improvement.

Significance of panel topic and anticipated audience

The anticipated audience is biomedical informatics professionals from diverse backgrounds seeking to improve the quality, safety, and/or value of health care. This panel topic is important because CDS represents one of the most promising informatics-enabled strategies available for improving health and health care, and this panel provides a comprehensive analysis of the CDS landscape as well as a concrete guide for priority actions that the informatics community can take to finally realize the promise of CDS-enabled care optimization.

Discussion questions

How can you or your organization contribute to the Priorities for Action?

What can ONC, NAM, and others do to accelerate progress?

What barriers do you see, and how do you think we should overcome them?

Participation statement

All proposed panelists have agreed to participate in the panel if the proposal is accepted.
The Personal Journey – Informaticists Confront Their Own Health Issues

Jessie Tenenbaum, Ph.D. 1, Ed Hammond, Ph.D. 2, Ross Koppel, Ph.D. 3, Michael Kamerick, BSCS 4
1Duke University, Durham, NC; 2Duke University, Durham, NC; 3University of Pennsylvania, Philadelphia, PA, 4Sequoia Consulting, San Anselmo, CA

Abstract
As informaticists, we often create tools and manage data to assist patients in making difficult treatment decisions. What happens when one of us becomes a patient? How do we approach the dilemma of our own complex disease and possible response, especially when multiple treatment options are available? What is our decision-making modality? Do we engage in the same calm, rational process we espouse to others, or does our new-found sense of vulnerability overwhelm our analytic faculties? How has our own experience changed the way we approach the goals of our profession? A panel of informaticists discuss their personal encounters with disease, decision making, treatment, and outcomes.

Introduction
The concept of a patient-centric healthcare system has gained great currency in recent years, especially since the creation of PCORI. How has the informatics community responded to the idea of putting the patient at the center of the treatment process? In this panel discussion, we will see how several informaticists took the most direct path one can take to a patient centered worldview -- by becoming patients themselves.

Each of the panelists will present their personal experience of having become a patient confronted with a serious health condition, one that required a thoughtful and thorough approach to the decisions about which treatment path to follow and what outcomes to hope for. The panelists will discuss their own subjective responses to their diagnoses. They will also discuss the tools and resources they made use of to assist them in their decision-making processes, as well as suggested improvements to those tools. Individual presentations will be 15-20 minutes each, with sufficient time allowed for audience engagement after the presentations and during the last part of the session.

Presentations
1. Prostate Cancer – What I Knew Then and What I Know Now
   Michael Kamerick, BSCS

   In 2005, Mr. Kamerick was diagnosed with prostate cancer. At the time, he was employed at the UCSF Breast Care Center as the head of a team building various information systems to support cancer care and research. Some of those systems were built to help breast cancer patients understand their risk and possible treatments, and some were built to help physicians confer on the issues of specific patients. In that context, working alongside a team of oncologists, he had a wealth of information and support available to assist him. His presentation will discuss the steps and tests taken leading up to his final diagnosis, the tools he used to understand the nature and implications of his disease, the decision process he went through to determine a preferred course of treatment among those available at the time, and the outcomes of that treatment course.
2. Experiences in Aging
Ed Hammond, Ph.D.

My first serious experience with the healthcare system happened in 2012. Sitting at my computer terminal at home in the evening, I suddenly felt heat in the back on my head and suffered unbelievable pain. I live alone, so I will share what I did, and what happened to me over the next few days. The diagnosis was subarachnoid hemorrhage, and although my care was excellent, the experience was terrifying. I also want to share my experience with a diagnosis of Type 2 diabetes – what I did and am doing and the positive results. Finally, I will share my experiences with a wearable sensor and the reporting of that data into an Epic flowsheet as part of MyChart to my personal physician. Aging can be great...

3. I get to keep my hair, right? Therapeutic decision making for stage 0 cancer from the patient perspective
Jessie Tenenbaum, Ph.D.

In December 2016 Dr. Tenenbaum was diagnosed with ductal carcinoma in situ, or DCIS. Even for this non-life-threatening condition, a whole host of treatment decisions had to be made from medication to surgery to radiation. Tools and concepts that had previously been professional, including the patient portal, family health history, risk alleles, pharmacogenomics, and drug-drug interactions, were suddenly made personal. Dr. Tenenbaum will discuss the many decisions to be made throughout the treatment process, how informatics resources helped or fell short, and how the experience has informed her perspective on what we do as informaticists.

4. HIT and the patient experience – culture and workarounds in two nations
Ross Koppel, Ph.D.

Professor Koppel had the unfortunate and very recent advantage of experiencing both the NHS’ hospital service and a major American hospital’s service. In both cases he was able to observe the healthcare information technology as it affected clinical workflow and clinical functionality. While the systems were different in level of penetration, sophistication and what we shall charitably call interoperability, the interplay of clinical work with the HIT is both the subject of his observations and the focus of his talk at this panel.

Many of the themes are the obvious: usability, data accessibility, quality of data presentation, integration with workflow, responsiveness to clinical need and clinical efficiency, and IT staff’ responsiveness of the clinicians’ requests. Some of the themes, however, are perhaps not obvious: workarounds – both to the HIT and the rules, the effect of the technology on patients' understanding of their treatment and prognosis, the role of the technology in enhancing and reducing frustration by the medical staff, and the role of the HIT in expectations of improvements.

It may be of note that Koppel is a PhD sociologist and has been teaching research methods and ethnography, in addition to statistics and biomedical informatics.

Conclusion
The individual’s own experience of disease can bring abstract professional concepts into the personal realm. Such events present informaticists with an opportunity to employ their own tools, to validate their work, and to challenge themselves to improve and change what they have already built upon.
And Now for Something Completely Different: Successful Career Transformations in Biomedical and Health Informatics

Amy Y. Wang, MD1, Douglas B. Fridsma, MD, PhD, FACP, FACMI2, Judy Murphy, RN, BSN, FACMI, FHIMSS, FAAN3, Chintan O. Patel, PhD4, Hillary Ross, JD5

1Northwestern University Feinberg School of Medicine, Chicago IL; 2American Medical Informatics Association, Bethesda, MD; 3IBM, Washington, DC; 4Applied Informatics, Inc., New York, NY; 5Witt/Kieffer, Oak Brook, IL

Abstract

The health and biomedical career landscape continues to grow and evolve as new technological opportunities and challenges arise. As professionals pursue new opportunities, careers take winding paths across unknown terrain. In an interactive panel discussion, informatics leaders who have experienced or guided colleagues through dramatic career transformations will address this topic. Panelists have transitioned between academic, clinical, research, educational, government, nonprofit, and industry realms. The panel will discuss the development of “soft” skills, such as vision, strategy, perseverance, resilience, communication, mentorship, and emotional intelligence, which are valuable for all professionals. Panelists will also address skills that are relevant to specific domains and roles. The presentation will begin with defined questions and then discuss questions from the audience. The purpose of the panel is to help informatics professionals identify and develop skills to understand the full breadth of career opportunities and paths and prepare and plan for career transformations. The intended audience includes informatics students or professionals in all career stages who intend to transform their careers or mentor colleagues. This panel is jointly sponsored by the Education and Student Working Groups and supports AMIA’s core mission of professional growth and leadership development for our members.

Learning Objectives

• Recognize the diversity of paths, organizations, roles, and activities in health informatics careers
• Identify, develop, transfer, and apply essential skills for entering and succeeding in different roles and domains in health and biomedical informatics
• Prepare and plan for new career opportunities and transformations in health and biomedical informatics

Introduction

As the field of health and biomedical informatics continues to evolve, there is a growing need for competent informatics professionals to translate health information into improved outcomes. Professional growth and leadership are top priorities in AMIA’s vision and strategy1. Professional organizations have defined competencies for health informatics, and there are many educational programs and certification pathways for developing and demonstrating health informatics expertise2. As health informatics is an interdisciplinary, collaborative field, informatics professionals must develop multiple areas of interest and expertise3, 4 and plan to shift roles and areas of focus throughout their careers3, 4. Desired qualities include critical thinking skills and the ability to “think and learn” on the job. Specific areas of competency include health care, health terminology, clinical workflow, health information systems, information management, privacy, security, regulations, quality improvement, root cause analysis, computer science, databases, data analytics, software engineering, and mobile technologies3. Health information technology employers have also identified advanced and interpersonal skills, such as communication, negotiation, management, strategic thinking, leadership, and planning3. Organizations report significant needs and challenges in recruiting skilled informatics professionals4, especially those competent in clinical workflow, technology, politics, and interpersonal skills3. There are unique challenges for entry-level and mid-career professionals entering the field as well as for seasoned informatics professionals desiring career advancement.

Our speakers demonstrate diverse interests, experiences, and meandering paths across different domains and functions in health informatics. They represent the rich depth and breadth of the field of health and biomedical informatics. Panelists have served in academic, commercial, nonprofit, and governmental organizations in diverse endeavors such as product design and implementation, standards development, health system operations, public
Panelists will introduce themselves and share their career experiences, focusing on types of opportunities, how and where to start, challenges with transitions, and how to succeed before, during, and after transitions. Panelists will answer an initial set of questions and then engage in an interactive discussion with the audience. Topics will include:

- What are key success factors, such as education, competencies, experience, and mentorship?
- What is the role of educational programs, advanced certification, support groups, and other resources?
- How do roles and essential skills shift through different career stages and levels of leadership?

Panelists

Amy Y. Wang, MD (Panel Organizer and Moderator) is an assistant professor at Northwestern University Feinberg School of Medicine in Preventive Medicine and Family and Community Medicine. Her expertise is in standards and interoperability, health terminology, electronic health records, and informatics education. She was previously at Intelligent Medical Objects (IMO), where she developed and implemented terminologies for EHRs to help health care organizations transition to ICD-10-CM and meet Meaningful Use requirements. Prior to IMO, she worked for Greenway Medical and focused on EHR development, implementation, and clinician support. While at the College of American Pathologists (CAP), she served on the international team that developed SNOMED CT.

Douglas Fridsma, MD, PhD, FACP, FACMI (Panelist) is President and Chief Executive Officer of AMIA and an expert in interoperability, standards, and health IT. Dr. Fridsma was previously Chief Science Officer for the Office of the National Coordinator for Health Information Technology (ONC), responsible for the portfolio of technical resources for Meaningful Use and interoperability. At ONC, he developed the standards and interoperability framework for accelerating development of technical specifications for interoperability, and collaborated with the NIH and other agencies to establish priorities in the PCOR Trust fund. Prior to ONC, he held academic appointments at the University of Pittsburgh, Arizona State University, University of Arizona, and Mayo Clinic, and practiced medicine at the Mayo Clinic Scottsdale. As a former board member of HL7 and the Clinical Data Interchange Standards Consortium (CDISC), and current board member of SNOMED international, he has been instrumental in developing standards bridging clinical care and research. He is a Fellow of the American College of Medical Informatics (ACMI).

Judy Murphy, RN, BSN, FACMI, FHIMSS, FAAN (Panelist) is Chief Nursing Officer at IBM Global Healthcare, where she is responsible for building relationships and expanding business across the healthcare industry. She is a strategic advisor to clients and helps develop health IT solutions for providers to improve health and healthcare, and lower costs. Prior to IBM, she was CNO and Deputy National Coordinator for Programs and Policy at the ONC in Washington D.C. In these roles, she led federal efforts to assist health care providers in adopting health information technology to improve care and to promote consumers’ greater understanding and use of health information technology for their own health. She came to ONC with more than 25 years of health informatics experience at Aurora Health Care in Wisconsin, an integrated delivery network with 15 hospitals, 120 ambulatory centers, and over 30,000 employees. As Vice President-EHR Applications, she led their EHR program since 1995, when Aurora was an early adopter of health IT. She has served on the AMIA and HIMSS Boards of Directors and is a Fellow in the American Academy of Nursing, ACMI and HIMSS. She has received numerous awards, including the AMIA 2014 Don Eugene Detmer Award for Health Policy Contributions in Informatics, the HIMSS 2014 Federal Health IT Leadership Award, and the HIMSS 2006 Nursing Informatics Leadership Award.

Chintan Patel, PhD (Panelist) is Chief Technology Officer and cofounder of Applied Informatics and Trialx. Previously, he worked at IBM’s T.J. Watson Research, on ontology reasoning and information extraction that then became the infamous Jeopardy winning AI software “Watson”. He holds a PhD in biomedical informatics from Columbia University. His areas of expertise include software architecture, mobile technologies, semantic technologies, biomedical ontologies, machine learning and natural language processing.

Hillary Ross, JD (Panelist) is Managing Director and Leader of the Healthcare IT Practice with executive search firm Witt/Kieffer. She specializes in the recruitment of senior-level physicians and informaticians, including Chief Medical Information Officers and Chief Health Informatics Officers for academic medical centers, hospitals, health delivery systems, vendors, and consulting firms across the country. She is nationally recognized for her expertise in recruiting highly specialized and executive leadership positions, such as Chief Research Informatics Officer and Directors of Bioinformatics, Biomedical Informatics, Data Analytics, Personalized Medicine, Quality, and
Innovation. She is a frequent speaker and published author on informatics, IT, and executive recruiting and is based in Witt/Kieffer’s Oak Brook, Illinois office.

Panelist Contributions and Presentations

Amy Y. Wang, Moderator, will introduce the panel, drawing from her experience in clinical practice and health informatics, including major career transformations. She went from clinical practice into standards and terminology development at CAP, a nonprofit. She then implemented standards in EHRs through Greenway and then at IMO, which she helped grow from startup to mature company. She transitioned into full-time academia in 2016. Dr. Wang will touch on universal skills and those that apply to specific areas and roles in health informatics.

Douglas Fridsma, Panelist, has represented the voice of health informatics professionals at the highest levels of leadership as President and CEO of AMIA and Chief Science Officer at ONC. His scientific understanding, practical experience, and policymaking in informatics give him a depth of knowledge well suited to the critical challenge of transforming health and health care. Dr. Fridsma will discuss how to navigate budgetary, regulatory, technological, and political challenges in informatics. He will also discuss AMIA’s vision on professional development and leadership and how members can embrace new opportunities for advancement.

Judy Murphy, Panelist, will share her experiences as she transitioned from clinical practice to information technology and nursing informatics, including major shifts in career venues. She went from leading the EHR implementation at a large, non-profit healthcare organization to administering the Meaningful Use Program at the Federal Government to supporting healthcare clients at a large for-profit, publicly-traded IT company. In each venue, she drew from a core set of leadership and management skills which she will share with the audience. Ms. Murphy will also describe the importance of her involvement in organizational work at AMIA and HIMSS and how that contributed to her career advancement.

Chintan Patel, Panelist, will bring his many years of computer science, applied informatics, and industry experience to the panel. He cofounded and led a successful health information solution company, which spun off another successful technology company. He has also developed innovations with a large, multinational technology company. He will discuss the necessary skills and essentials on starting new companies and solutions, delivering value, and leading a business. He will share his insights on fostering innovation, creativity, and entrepreneurship in health information technology amid a rapidly evolving and competitive marketplace.

Hillary Ross, Panelist, with her leadership role in Witt/Kieffer’s Healthcare IT Practice and dedicated focus on informatics, counsels healthcare professionals with a passion for informatics and technology on diverse career paths. She will share a top-level recruiting perspective on informatics careers. There has been an explosion of interest and an expansion of leadership roles in a variety of areas. Informatics professionals may enter their positions from many paths and backgrounds. Ross will describe current expectations among healthcare organizations for various positions, how the roles have evolved, and what types of career paths leaders take. She will explore career advancement, leadership positions, and other issues critical to understanding and thriving in today’s new roles.

Participation Statement

I, Amy Wang, hereby confirm that all panelists listed in this proposal have agreed to participate in this panel. Panelists are aware that there are no travel funds available. Panelists are also aware that the Working Groups are unable to reimburse registration costs.

Abstract
One EHR activity that significantly affects patient safety is medication ordering and administration, where the interaction and communication among physicians, pharmacists and nurses is crucial. The different information requirements and priorities of these clinical team members and EHR users creates design challenges in the development of a pharmacy interface in both the inpatient and ambulatory environments. Failure to achieve these goals creates a system that, while functional, is neither fully optimized nor conducive to medication safety.

This interactive panel will bring together stakeholders from the physician, usability/workflow analysis, nursing, and pharmacy communities to foster dialog across the groups. Participants will discuss their respective priorities and pain points in terms of addressing information needs, communication, workflow, and data recording requirements when ordering, processing and administering medications. Improved understanding of the other stakeholders’ needs should provide valuable insight into what information is needed at various points in the process, and the engagement of human factors expertise on the panel will help bridge the gap between existing medication ordering and administration interface design. The ideas and findings of this panel will help inform the design of a better pharmacy interface.

Learning Objectives:
1. To increase awareness of the broad nature of real-world errors in medication orders and administration
2. To understand different stakeholder perspectives and priorities related to medication ordering, processing and administration
3. To develop a workflow for medication ordering, processing and administration that better encompasses all stakeholder perspectives
4. To explore informatics solutions that optimize medication ordering, processing and administration

The increasing adoption and utility of Electronic Health Records (EHR) has enabled better patient care through enhanced availability of clinical information, improved decision support, and communication between care team members. However, despite these successes, human factors and usability issues continue to hamper the optimal use of these systems, resulting in well-publicized complaints about electronic information technology and pandemic workarounds. One of the focal points of EHR activity with significant impact on patient safety is medication ordering and administration, where the interaction and communication among physicians, pharmacists and nurses is particularly critical. The different information requirements and priorities of these clinical team members and EHR users creates design challenges in the development of an ideal pharmacy interface in both the inpatient and ambulatory environments. The net result is a system that is functional, but still not fully optimized and continues to impact patient safety and be a source of medication errors.

This interactive panel will bring together stakeholders from the physician, nursing, usability, and pharmacy communities to foster dialog across the groups about their respective priorities and pain points in workflow, information needs, and data recording requirements when ordering, dispensing, and administering medications. The improved understanding of the other stakeholders’ needs should provide valuable insight into what information is needed at various points in the process, and the engagement of human factors expertise on the panel will help bridge the gap between existing order entry and administration interface design and a more optimized design suggested by the ideas raised through the panel.

While common issues such as alert fatigue and wrong patient/wrong drug orders continue to be problematic, this panel is particularly timely as many institutions are facing additional practical issues in EHR interface design that
transcend these traditional topics. Among the vignettes of medication ordering/administration issues with difficult informatics/workflow solutions that we will offer for discussion are as follows:

Errors at Transitions:
- Admission orders are written by the floor team while the patient is in the ED. The patient’s transfer to the med/surg floor is delayed. Should pharmacy deliver the medications to the med/surg floor or to the ED? If meds are delivered to the ED, but the patient is transferred before the meds are delivered to the ED, how do the medications follow the patient?
- A patient is transferred to the med/surg floor from the ED before admit orders are written. Some scheduled medications had been written while the patient is in the ED. How does the nurse know which medications from the ED should be continued on the floor?

Errors in medication timing/dose/discontinuation:
- A physician writes for multiple intravenous medications that are reasonable to order at the same time, but are not compatible for simultaneous administration. Is there a foolproof way for the nurse to know which medications can be given at the same time and, presuming she knows this, how does she know what order to administer the medications?
- An intravenous medication is supposed to be delivered over 2 hours, with a peak blood level drawn after the infusion to help assess the appropriate dose. Because of recurring occlusions, the medicine is delivered over 4 hours, and the peak level is drawn an hour late. How are these common, but often invisible variations addressed in the calculations to determine the correct dose?
- A patient is transitioned from a medication patch for pain control to a PCA. The order for the patch is discontinued after 24 hours of therapy but the initial frequency duration was 72 hours which is when the task reminder for the nurse appears. Patient receives two narcotics for pain control as the nurse forgets to remove the patch and the task does not appear to remind the nurse till 48 hours later.

Errors in visibility of special instructions:
- An epidural catheter is planned to be removed the second post-op day in the morning. Patient is scheduled to receive a dose of subcutaneous heparin at 6am. Instead of placing a medication order to hold the medication the prescriber writes a nurse communication order that is not seen by the nurse. The morning dose of heparin is administered and a six hour delay results before the epidural is discontinued.
- In order for a bladder irrigation to be ready for administration during an OR procedure, the resident writes the order the evening before. In the order the resident types in a note to the pharmacist that the irrigation is for OR the next morning – this note is not visible to the nurse and the nurse hangs the irrigation solution.
- A patient requires intubation due to respiratory failure. The patient is due for an antihypertensive medication – since the patient has an nasogastric tube the nurse crushes the medication and administers the medication via the NGT. The medication is an extended release tablet and the patient experiences hypotension requiring vassopressors. Usual practice on the unit is to not require the prescribers to re-write medications for the correct route (oral verses NGT) so the pharmacy is able to dispense the correct formulation of the medication.

Errors at the interface between IT systems and policy issues:
- Hospital policy requires that certain meds be given for only a few doses before a mandatory automatic discontinuation. How should IT be configured to avoid overuse of medication without leading to unintended gaps in medication administration?
- Automated dispensing machine (ADM) issues. A nurse removes a medication from an ADM as an “override” to handle an urgent situation. How does that override transmit back to the EHR to be processed as a verbal order, and how is appropriate “waste” of unused medication documented?

Interactive Component
The panel will consist of four brief presentations by the panel organizers, each representing physician, nursing, and pharmacy perspectives on the medication ordering, dispensing and administration process as well as insights from a usability/workflow expert on the priorities that have influenced the current state of information technology related to pharmacy processes. After the presentations, the audience will be divided into small groups each with representation from the different stakeholders. The groups will then engage in discussions, facilitated by the panel leads, who help define pitfalls in the medication ordering and administration process, and interface solutions that
could help to address the pitfalls. We expect the participants to continue the dialog outside of the meeting, and work to develop manuscripts based on the work initiated in the panel.

Panelists

Mark Weiner, MD, FACMI - Lewis Katz School of Medicine at Temple University
Dr. Weiner is a practicing general internist who will represent the physician perspective on the panel. His interests relate to medication reconciliation across the transitions of care at the boundaries between inpatient and ambulatory care as well as transitions across inpatient care settings. He is also concerned how issues like the frequency and timing of medications affect patient care, especially for medications where peak and trough values are critical in determining the correct dose.

Jennifer Boehne, PharmD, MHI, MPH -- CHPSO
Dr. Boehne will represent the pharmacy perspective on the panel. She brings insight into the information requirements needed to create a safe and reliable medication use process. Her research focuses on the unintended consequences of various forms of health information technology. She just completed an analysis of incidents involving opiates, benzodiazepines and their reversal agents.

Terese Kornet, MSN, RN -- University of Pennsylvania Health System
Ms. Kornet is the Director of Clinical Nursing Systems at the Hospital of the University of Pennsylvania. She has provided strategic and operation nursing leadership in the development, deployment, re-engineering and integration of clinical information systems to support clinician practices and patient care services. Her special interest related to medication prescribing and administration is BCMA, medication label font/content and weight management in the EHR

Ross Koppel, PhD, FACMI -- University of Pennsylvania
Dr. Koppel is a Senior Fellow at Wharton’s LDI and a Professor of Sociology at the University of Pennsylvania. His work focuses on healthcare IT, and of the interactions of people, computers and workplaces. At Harvard, Dr. Koppel is co-PI on the FDA-funded study of prescribing errors related to patient data displays. In addition, he served as an Internal Evaluator of their project that created the new HIT architecture (SMART) at Harvard. His work combines ethnographic research, extensive statistical analysis, surveys, and usability studies. His work in medical informatics reflects his 46-year career as researcher and sociologist of work and organizations, statistics, ethnographic research, survey research, and medical sociology. He will discuss several issues of visualization of the medication ordering screens--based in part on his recent work with the FDA-funded study of 5 hospital systems and 4 EHRs that focused on ordering screens associated with medication prescribing errors. Koppel will also discuss the interaction of workflow and the several UXs involved in the medication process.

Who Should Attend?

Physicians, nurses, pharmacists, and human factors experts with an interest in interface design, use and workflow related to medication ordering, dispensing, and administration.

All participants have agreed to take part on the panel.
Abstract

As the amount of health-related information being generated and collected by medical organizations continues to increase, the amount of data available to healthcare providers within the electronic health records (EHRs) continues to grow at an unprecedented rate. This vast amount of health-related data poses cognitive and comprehension challenges for medical professionals to understand patients' medical histories and conditions at the point of care and for researchers studying individual- and population-level exposure and outcome data. Information visualization and visual analytics have recently received a significant amount of attention as potential techniques to support the cognitive processes, understanding, and decision-making for anyone gathering and using vast amounts of digital health data.

In this didactic panel, we will review the current state-of-the-art visualization techniques that have been incorporated within EHRs, discuss the areas of healthcare in which better tools and visualization techniques are needed, and examine the need for user evaluations to better understand the effectiveness of different visualization techniques and dashboards in clinical settings. The panelists will also summarize some of the work of the AMIA VIS working group in increasing the awareness of the importance of effective visualization techniques when analyzing large collection of clinical data.

Introduction

Data visualization and visual analytics is an emerging discipline that combines elements of visualization, data mining, human-computer interaction, data analytics, and human cognition to facilitate the exploration, reasoning, and interpretation of complex multi-modal data. The mission of the AMIA Visual Analytics Working Group is to promote the development and validation of new data visualization techniques that can be used to address some of the fundamental data and informatics challenges evident in the healthcare domain. The purpose of supporting and motivating more research and development on new visual analytical methods in healthcare is to make information more insightful, accessible, and actionable to a wide range of participants in the healthcare ecosystem including clinicians, administrators, policy makers, researchers, patients, families, and caregivers. This didactic panel will help by fostering an active, interdisciplinary research community; highlighting impactful applications of the data visualization techniques; developing best practices for development and evaluation.

The didactic panel will consist of three 15-minute presentations focusing on these three
areas/topics:

1. EHR Visualization – Clinical Perspective: V. West and D. Dowding will briefly present a review of existing visualization techniques in healthcare [1] as well as recent studies exploring how to provide visualized data at the point of care to home care nurses to support their decision making for heart failure patients. Panelist will discuss key issues that have arisen from the study including the ability of nurses to comprehend data in a visualized format, how to prioritize what data to visualize, and how to provide it in a format and point in the EHR where it will be of most clinical value.

2. Visualization of EHR data for population health: H. Kharrazi will present a review of existing visualization techniques to support population health management and analysis. As the research director of the Johns Hopkins Center for Population Health IT (CPHIT), Dr. Kharrazi provides direct population-based applications to providers, patients, and payers. Some of his work includes how to provide visualization applications to more effectively illustrate data.

3. EHR Visualization and the AMIA VIS working group: J. Caban as the chair of the AMIA VIS WG will present some of the work been done by the AMIA VIS working group in increasing the awareness of visual analytics in healthcare by organizing tutorials, workshops, design challenges, and meet-ups [2].

Discussion Questions

1. What’s the current state of data visualization within EHR?
2. What are areas of healthcare in which better tools and visualization techniques are needed?
3. How can we better connect clinicians, engineers, developers, and patient in designing effective ways to visualize clinical data?

Conclusion

We proposed a didactic panel to share the current state of EHR visualization with AMIA audiences. All the four panelists (VW, HK, DD, JC) and the moderator (DW) have agreed on participating in this didactic panel.

PCMEDICS: Peace Corps’ Home-Grown EMR

Thomas M. Wilkinson MD (moderator), Shannon Behr DeNoble BA PMP, Kimberley Skrtic RN BSN MHA/INF, Monica D. Charles BA MPH(c), Lyndsey Knauf BA CORII; all from United States Peace Corps, Health Informatics Unit, Washington DC.

Abstract:
In 2016 Peace Corps deployed a cloud-based electronic medical record system to support the healthcare of Volunteers deployed throughout the world. The solution was designed, built, deployed, and supported by the Peace Corps’ Health Informatics Unit (HIU) in Washington, DC. Developers were embedded directly into medical operations at Peace Corps, and the resulting EMR has enjoyed significant support (even admiration) from its many end-users. This panel is a presentation of the HIU’s experience. It highlights some of the unique strengths of the EMR itself, explores issues around security in modern Federal IT systems, and describes the particular emphasis which the HIU has placed on a quality training and support program during go-live and in the year since.

Panel:

Wilkinson: Introduction and overview
[Introduction of panel members]
Peace Corps is mandated by the 1961 Peace Corps Act to provide all necessary healthcare to its active Volunteers. The Peace Corps healthcare system is basically a global primary care network, with an average of 2 Peace Corps Medical Officers (PCMOs) in each country where Peace Corps serves, providing direct care to our 7000 Volunteers in the field. In 2016, Peace Corps launched an EMR named PCMEDICS in 63 countries. It was built in-house, using a modified open source platform, and it came in on time and on budget. This panel is a brief presentation of the Health Informatics Unit’s (HIU) experience designing, building, deploying, and supporting a home-grown EMR.

Some of the fundamental requirements of the EMR were unique. It needed to coordinate frequent communications and care between posts, regional hubs, and Washington; it needed tools for mass immunization; it needed to support the collection of epidemiological data; and it had to meet some very specific legal requirements around sexual assault and medical inventory. We built in SNOMED encoding from the ground up to achieve deep indexing within the charts, to facilitate an information retrieval system. But fundamental to it all, PCMEDICS had to be a robust system able to operate on frail infrastructures, for which we built a distributed, partially redundant data model, redundant access points, and asynchronous synchronizations.

Behr DeNoble: Security
Federal information security requirements are governed by a number of laws, including HIPAA and FISMA, and securing electronic personal health information raises important ethical and professional implications as well. Additionally, Peace Corps is unique in that it tracks comprehensive information about our Volunteers, including financial, safety, and personal data. Implementing sound security practices throughout the development lifecycle of PCMEDICS required that project sponsors, project managers, and security leadership coordinate budgets, security resources, and plans, as well as balance multiple competing needs.

IT security boils down to identifying risk, planning its remediation and mitigation, documenting those plans, and then following through on them. Part of the approach involves putting a reliable perimeter around the system. Controls such as password protection and dual authentication, in addition to data
encryption during communications and at rest, help secure that perimeter. Furthermore, managing security in the cloud requires the cloud host’s active participation in implementing and documenting their security controls. Data integrity, which is related to the accuracy and completeness of data within the system, is supported with e-signatures and user audit trails. Finally, physical security includes failover systems and automatic backups.

At Peace Corps, we baked security into our culture. IT security resources from the Office of the Chief Information Officer were paired with PCMEDICS project teams from the beginning, so that security was considered at each new stage of EMR development. Our strategy also included engaging both stakeholders and team members in security awareness and planning. Every member of the HIU is seen as responsible for information security.

**Skrtic: Rollout education**

The HIU developed and facilitated global PCMEDICS training support to the users of the EMR before, during and after deployment. A series of web-based user scripts that provide detailed, step-by-step instructions with screen shots of clinical processes typical of the Peace Corps health system were released electronically on a weekly basis for two months prior to official PCMEDICS user training. This provided the opportunity for self-paced practice using a PCMEDICS web-based training environment. Immediately prior to go-live, Peace Corps required the attendance of all global providers and health unit ancillary staff at a unique, intensive 7–day EMR training program that taught the providers how to use PCMEDICS safely and effectively across the entire life cycle of the Volunteer, blending clinical care with day-to-day business processes and Peace Corps policies. Each Health Unit trained together as integrated teams, so that providers and assistants could learn and practice the handoff between roles in the new electronic system. Learners were required to show competency in PCMEDICS prior to returning to their posts by passing a standardized, role-based competency assessment. Remediation was immediately offered to individuals faltered in their skills or confidence, prior to their return to country. Within one week of returning to their health units, PCMEDICS went live at that post.

**Charles: Post-deployment education**

For post-deployment support, the providers in the field receive as-needed one-on-one support from the HIU, that is, from the same familiar staff that developed and deployed the EMR and facilitated their initial training. HIU staff provide ongoing education to the field using a Helpdesk ticket tracking system, Skype interactions, and frequent email communications regarding new changes to the EMR system and tips on how to use the system more efficiently. Web-based user scripts and policies related to EMR use are updated and housed on a SharePoint site for all users to access. Post implementation refreshers and new feature training are provided through periodic global Webinars and through live training at annual Peace Corps conferences.

At one-year post deployment we conducted a survey of providers using the system to elicit their ongoing educational needs. The vast majority (89%) of end users surveyed reported that they were feeling either pleased or ecstatic with the EMR overall. The open-ended responses provided further insight. In a qualitative analysis, three themes emerged: (A) requests for advice on how to best manage time and workflow during the day, while using the EMR; (B) a desire to leverage the EMR to improve patient care; (C) a desire to better understand charting standards and quality reviews in the context of an EMR system. Our conclusion was that medical professionals’ education needs evolve over time, starting with the basics (e.g. where to click, when to use certain features), then, after they navigate that learning curve, they want to understand more how to use the tool’s features to improve the quality of their work. Our post-implementation education likewise evolved to focus more on using PCMEDICS in the clinical environment – to help manage time, to improve patient care, and to meet charting standards.
Knauf: Tiered support

The HIU’s decision to build an in-house EMR resulted in the HIU owning its own internal IT support system. We built a three-tiered system. Tier 1 is online self-help, including step-by-step written materials accompanied by screen shots and narrated videos. Some Peace Corps countries have limited bandwidth connections to the internet, so we pay close attention to file sizes and accessibility issues. The advantage of online material is that Peace Corps countries have 24 hour access to help. Tier 2 is the public facing personable support described in more detail below; it is where the Helpdesk ticketing system is routed to, and it kicks in when self-help was not sufficient. Tier 3 is managed by the HIU developers, who respond to needs that rise beyond what Tier 2 support can resolve.

Our Tier 2 support has been pivotal in the ultimate success of PCMEDICS. An internal system for Tier 2 (and, to a lesser extent, Tier 3) humanizes IT support, since familiar staff become the “face” of support for the EMR, rather than anonymous technicians from a vendor. One of the most important benefits that the HIU has garnered from an internal support system is the ability for end users and IT support to forge a working relationship. When end users know that their questions and concerns are being managed by staff who also have a stake in seeing the EMR succeed, those end users tend to come forward with more observations and recommendations that improve the application. In-house support allows HIU to not only answer questions about the EMR, but also to observe our end users’ work flow patterns and sticking points. Those observations then provide us with a tight feedback loop, so support staff not only provide more context-sensitive EMR support, but can also steer enhancement recommendations and guide targeted educational efforts that have a big impact on end users.

Discussion Points:
1. Buy vs Build: a perennial question regarding IT systems. Our experience of building was quite positive.
2. What makes a system operationally robust, even while the underlying infrastructure is unreliable?
3. Data integrity is the high-water mark for FIPS 199 security classification of electronic medical record systems, not data confidentiality.
4. Training and support often occur as afterthoughts, relegated to negotiable line items in a contract; when done poorly, this mindset introduces risk to the patient and to the project, and it impedes adoption, integration, and socio-technical evolution.
Quality Assurance of NCI Thesaurus by Mining Structural-Lexical Patterns

Abstract

Quality assurance of biomedical terminologies such as the National Cancer Institute (NCI) Thesaurus is an essential part of the terminology management lifecycle. We investigate a structural-lexical approach based on non-lattice subgraphs to automatically identify missing hierarchical relations and missing concepts in the NCI Thesaurus. We mine six structural-lexical patterns exhibiting in non-lattice subgraphs: containment, union, intersection, union-intersection, inference-contradiction, and inference union. Each pattern indicates a potential specific type of error and suggests a potential type of remediation. We found 809 non-lattice subgraphs with these patterns in the NCI Thesaurus (version 16.12d). Domain experts evaluated a random sample of 50 small non-lattice subgraphs, of which 33 were confirmed to contain errors and make correct suggestions (33/50 = 66%). Of the 25 evaluated subgraphs revealing multiple patterns, 22 were verified correct (22/25 = 88%). This shows the effectiveness of our structural-lexical-pattern-based approach in detecting errors and suggesting remediations in the NCI Thesaurus.

Introduction

Biomedical terminologies and ontologies serve as a knowledge source for many biomedical applications, including natural language processing applications and decision support systems¹. Quality issues in terminologies, if not addressed, can affect the quality of all downstream information systems relying on them as a knowledge source². Terminology Quality Assurance (TQA) strives to estimate and enhance the quality of terminologies by improving consistency, coverage and completeness, non-redundancy and clarity³. However, it is labor-intensive and time-consuming to discover errors or inconsistencies by manual review of large biomedical terminologies. Therefore, automating TQA has been an active area of research⁴.

Developed and maintained by the National Cancer Institute (NCI), the NCI Thesaurus (NCIt) is a reference terminology used in an increasing number of NCI and other systems⁵, ⁶. It contains over 100,000 concepts related to cancer research, including cancer-related diseases, findings and abnormalities; anatomy; agents, drugs and chemicals; genes and so on⁷. Given the sheer size of the NCIt, it is unavoidable that errors may be introduced in its development, update, and maintenance phases. Moreover, it is impractical for human experts to manually review the terminology to discover quality issues such as missing concepts, concept redundancies, and missing hierarchical relations. Automatic approaches to quality assurance of the NCIt are highly desirable to provide human experts with error candidates for review and verification.

In this paper, we develop an automatic approach to detecting missing hierarchical IS-A relations and missing concepts in the NCIt based on non-lattice subgraphs, which were initially introduced for auditing SNOMED CT⁸. We investigate six structural-lexical patterns exhibiting in non-lattice subgraphs in the NCIt, with each pattern indicating a certain type of potential error and suggesting a potential correction. Human experts reviewed a random subset of non-lattice subgraphs automatically detected using this approach to confirm the uncovered errors and suggested corrections.

1 Background

1.1 NCI Thesaurus (NCIt)

The NCIt is a biomedical terminology for cancer research, covering vocabulary for clinical care, translational and basic research, and public information and administrative activities⁵, ⁶. It was first published in 2000 with the intention to facilitate data sharing and interoperability by different NCI components. Concepts in NCIt are hierarchically organized in 19 domains, including Abnormal Cell; Anatomic Structure, System, or Substance; Biological Process; Disease,
Disorder or Finding; Drug, Food, Chemical or Biomedical Material, Gene, Gene Product, Molecular Abnormality, and Organism. The version 16.12d of NCIt contains over 118,000 concepts.

The NCIt was built using Ontylog, a description logic explicitly for building large complex terminologies. It is published in several formats including Ontylog XML, Web Ontology Language (OWL), and flat files. The NCIt also has defined and inferred versions. The defined version contains the assertions about each concept by the terminology editors. The inferred version includes additional assertions and classifications inferred by DL classifiers. In this paper, we used the inferred version of the NCIt to perform our pattern-based error detection and correction.

1.2 Quality Assurance of Biomedical Terminologies

Researchers have proposed various approaches to auditing biomedical terminologies, such as the NCIt and SNOMED CT. Min et al. proposed the abstraction networks (AbNs) approach to audit NCIt based on area taxonomies and partial-area taxonomies, where area taxonomies are groups of concepts that have exactly same roles, and partial-area taxonomies are further divisions of areas so that they are structurally uniform and singly-rooted. Ochs et al. introduced subject-based AbN methods that summarize a subhierarchy rooted at a subject concept within a large hierarchy, and tribal-based AbN methods that are based on a subhierarchy rooted at a child of a hierarchy root to audit SNOMED CT. Verspoor et al. introduced an automated method for identifying univocality violations in Gene Ontology. Zhang et al. proposed a lattice-based structural auditing method to exhaustively detect non-lattice pairs in SNOMED CT. Cui et al. presented a big data approach to perform lattice-based terminology quality assurance on SNOMED CT. Agrawal et al. used a combination of positional similarity sets and structural indicators to identify modeling inconsistencies in SNOMED CT. Bodenreider introduced a method to identify missing hierarchical relations in SNOMED CT from logical definitions based on the lexical features of concept names. Ceusters et al. assessed the conformity of NCIt to widely accepted principles in terminology construction and ontology building. Mougin et al. presented a semantic web technology method for quality assurance of NCIt. Zhang et al. proposed a lattice-based structural auditing method to exhaustively detect non-lattice pairs in SNOMED CT. Cui et al. presented a big data approach to perform lattice-based terminology quality assurance on SNOMED CT. Agrawal et al. used a combination of positional similarity sets and structural indicators to identify modeling inconsistencies in SNOMED CT. Bodenreider introduced a method to identify missing hierarchical relations in SNOMED CT from logical definitions based on the lexical features of concept names. Ceusters et al. assessed the conformity of NCIt to widely accepted principles in terminology construction and ontology building. Mougin et al. presented a semantic web technology method for quality assurance of NCIt. Zhang et al. introduced a topological pattern-based method to recommend new concepts to include to NCIt.

More recently, Cui et al. have introduced a hybrid structural-lexical method based on non-lattice subgraphs for scalable and systematic discovery of missing hierarchical relations and concepts in SNOMED CT. Four lexical patterns in non-lattice subgraphs were proposed for error detection and correction in SNOMED CT. In this paper, we apply these four patterns to NCIt and introduce two new patterns to identify errors and suggest corrections. To provide better readability, we review the definitions of the four patterns proposed for SNOMED CT in the Methods section and illustrate the patterns with examples in the NCIt.

2 Methods

Our approach leverages both structural and lexical information in the NCIt to systematically detect potential errors and automatically suggest remediations. Firstly, we identify all non-lattice subgraphs in NCIt. Secondly, we mine structural and lexical patterns in the non-lattice subgraphs, where each pattern indicates a potential missing hierarchical relation or missing concept in the NCIt. Finally, human domain experts evaluate a randomly selected sample of the potential errors detected, as well as the proposed remediation. We used the 16.12d version of the NCIt in this work.

2.1 Detecting Non-lattice Subgraphs

Non-lattice pairs. From a structural point of view, lattice is a desirable property for a well-formed terminology. A terminology is a lattice if any two concepts in the terminology have a unique maximal shared descendant, as well as a unique minimal shared ancestor. A pair of concepts is known as a non-lattice pair, if the two concepts have more than one maximal shared descendant (alternatively minimal shared ancestor). A non-lattice pair generates a graph fragment with the nodes (or concepts) between the concept pair and the maximal shared descendants. There could be multiple non-lattice pairs which possess the same maximal shared descendants. In this case, it is not economical to examine each of these separately. If non-lattice pairs possessing the same maximal shared descendants are added together, this is also not economical since there might be concepts with ancestor-descendant relationship, which cause redundant analysis. Therefore the notion of non-lattice subgraphs has been introduced to facilitate effective analysis.
Non-lattice subgraphs. A non-lattice subgraph \( p = (c_1, c_2) \) can be obtained by first reversely computing the minimal common ancestors of the maximal common descendants, \( mcd(p) \); then accumulating the concepts and the edges between (including) any concept in \( mca(mcd(p)) \) and any concept in \( mcd(p) \). The reverse computation obtains the minimal concepts sharing the same maximal common descendants to avoid redundant analysis. The minimal concepts \( mca(mcd(p)) \) are called the upper bounds of the non-lattice subgraph, and \( mcd(p) \) are called the lower bounds. The size of a non-lattice subgraph is the number of concepts it contains. For instance, Figure 1A shows a non-lattice subgraph of size 6 in the NCIt, where Stage III Pharyngeal Cancer and Nasopharyngeal Carcinoma are the concepts in the upper bounds, and Stage III Nasopharyngeal Carcinoma AJCC v6 and Stage III Nasopharyngeal Carcinoma are the concepts in the lower bounds.

In this work, we first parse the NCIt distribution file “ThesaurusInferred.owl” to extract all the concepts and their labels, as well as hierarchical IS-A relations (i.e., Child-Parent relations). Then we leverage the computational pipeline implemented in previous work \( ^8 \) to exhaustively detect non-lattice subgraphs in the NCIt. Each resulting non-lattice subgraph consists of five components: concepts in the lower bounds, concepts in the upper bounds, concepts in the non-lattice subgraph, IS-A relationships in the non-lattice subgraph, and the size of the non-lattice subgraph.

2.2 Mining Structural and Lexical patterns in Non-lattice Subgraphs

Since manual review of non-lattice subgraphs to discover potential errors is labor-intensive and time-consuming, we further take into account of the lexical information (concept labels) to automatically identify structural and lexical patterns in non-lattice subgraphs. Each pattern indicates certain type of errors and suggests a potential remediation.

For lexical information, we consider the label of a concept as a set of words in lower case. For example, the concept label Stage III Pharyngeal Cancer is considered as a set of words \{stage, iii, pharyngeal, cancer\}. For structural information, given a non-lattice subgraph, we use \( U_i \) to denote the set of words for a certain concept in the upper bounds, and \( L_j \) to denote the set of words for a certain concept in the lower bounds.

We define six patterns taking into account of such lexical and structural information in the NCIt: Containment, Union, Intersection, Union-Intersection, Inference-Contradiction, and Inference-Union. The Containment, Union, Intersection, and Union-Intersection patterns were initially proposed in previous work \( ^8 \) for SNOMED CT. The Inference-Contradiction and Inference-Union patterns are newly proposed in this work, incorporating inference into the structural and lexical information.

2.2.1 Containment

A non-lattice subgraph is defined as exhibiting a containment pattern \( ^8 \), if the set of words for one concept \( U_i \) in the upper bounds is contained in the set of words for another concept \( U_j \) in the upper bounds, or the set of words for one concept \( L_i \) in the lower bounds is contained in the set of words for another concept \( L_j \) in the lower bounds. That
is, $U_i \subset U_j$, or $L_i \subset L_j$. This pattern may suggest a missing IS-A relation between the two concepts in the upper bounds (or lower bounds), that is, $U_i$ IS-A $U_j$ (or $L_j$ IS-A $L_i$). Consider the example in Figure 1A, $L_1 = \{\text{stage, iii, nasopharyngeal, carcinoma}\}$ in the lower bounds is contained in $L_2 = \{\text{stage, iii, nasopharyngeal, carcinoma, ajcc, v6}\}$ in the lower bounds. This indicates a potential missing hierarchical relation: $L_2$ IS-A $L_1$, with $L_2$ more specific than $L_1$. The suggested correction is to add the relation Stage III Nasopharyngeal Carcinoma AJCC v6 is a subclass of Stage III Nasopharyngeal Carcinoma (highlighted as a red edge in Figure 1B).

For the containment pattern, we do not consider non-lattice subgraphs with concepts involving negation words such as no, not, without, absence, since that would incorrectly suggest a missing hierarchical relation between a concept with negation and a concept without negation.

### 2.2.2 Union

A non-lattice subgraph is defined as exhibiting a union pattern, if the union of the sets of words for two concepts $U_i$ and $U_j$ in the upper bounds is equal to the set of words for some concept $L_k$ in the lower bounds, that is, $U_i \cup U_j = L_k$. This pattern may suggest a missing IS-A relation between other concepts in the lower bounds and $L_k$. For instance, in Figure 2A, the union of $U_1 = \{\text{testicular, non-seminomatous, germ, cell, tumor}\}$ and $U_2 = \{\text{malignant, testicular, germ, cell, tumor}\}$ in the upper bounds is equal to $L_1 = \{\text{malignant, testicular, non-seminomatous, germ, cell, tumor}\}$ in the lower bound. This indicates a potential missing IS-A relation between the other concept Childhood Testicular Yolk Sac Tumor in the lower bounds and $L_1$. That is, Childhood Testicular Yolk Sac Tumor IS-A Malignant Testicular Non-Seminomatous Germ Cell Tumor (highlighted as a red edge in Figure 2B).

**Figure 2:** (A) A non-lattice subgraph exhibiting the Union pattern. (B) The suggested remediation of the non-lattice subgraph in (A): Childhood Testicular Yolk Sac Tumor IS-A Malignant Testicular Non-Seminomatous Germ Cell Tumor.

### 2.2.3 Intersection

A non-lattice subgraph is defined as exhibiting an intersection pattern, if the intersection of the set of words for two concepts $L_i$ and $L_j$ in the lower bounds is equal to the set of words for some concept $U_k$ in the upper bound, that is, $L_i \cap L_j = U_k$. This pattern may suggest a missing IS-A relation between $U_k$ and other concepts in the upper bounds. For instance, in Figure 3A, the intersection of $L_1 = \{\text{splenic, t, lymphoblastic, lymphoma}\}$ and $L_2 = \{\text{splenic, b, lymphoblastic, lymphoma}\}$ in the lower bounds is equal to $U_1 = \{\text{splenic, lymphoblastic, lymphoma}\}$ in the upper bound. This indicates a potential missing IS-A relation between $U_1$ and the other concept Aggressive Non-Hodgkin Lymphoma in the upper bound. That is, Splenic Lymphoblastic Lymphoma IS-A Aggressive Non-Hodgkin Lymphoma (the red edge in Figure 3B).
2.2.4 Union-Intersection

A non-lattice subgraph is defined as exhibiting an union-intersection pattern, if the union of the set of words for two concepts $U_i$ and $U_j$ in the upper bounds is equal to the intersection of the set of words for two concepts $L_s$ and $L_t$ in the lower bounds, that is, $U_i \cup U_j = L_s \cap L_t$. This pattern may suggest a missing intermediary concept between the two concepts ($U_i$ and $U_j$) in upper bounds and the two concepts ($L_s$ and $L_t$) in the lower bounds. For example, in Figure 4A, the union of $U_1 = \{\text{localized, carcinoma}\}$ and $U_2 = \{\text{adult, liver, carcinoma}\}$ is equal to the intersection of $L_1 = \{\text{localized, non-resectable, adult, liver, carcinoma}\}$ and $L_2 = \{\text{localized, resectable, adult, liver, carcinoma}\}$, that is, $U_1 \cup U_2 = L_s \cap L_t = \{\text{localized, adult, liver, carcinoma}\}$. This indicates a potential missing concept Localized Adult Liver Carcinoma (green node in Figure 4B), which represents the features that are common to $L_s$ and $L_t$ in the lower bounds and inherited from $U_i$ and $U_j$ in the upper bounds.

It is worth noting that if $U_i \cup U_j = L_s \cap L_t$ happens to be equal to $L_s$ or $L_t$, then the non-lattice subgraph falls into the union pattern as well; if it happens to be equal to $U_i$ or $U_j$, then the non-lattice subgraph falls into the intersection pattern as well. In such cases, the suggestion for union pattern or intersection pattern is adopted, since no intermediary concept is needed.

2.2.5 Inference-Contradiction

Given a non-lattice subgraph $G$, we define two types of concept pairs appearing in $G$: related and unrelated. A pair of concepts $(C_i, C_j)$ in $G$ is called related if $C_i$ is a subclass or descendant of $C_j$; otherwise, $(C_i, C_j)$ is called unrelated. For instance, in Figure 5A, the concept pair (Anaplastic Cell, Neoplastic Large Cell) is related; while the concept pair (Anaplastic T-Lymphocyte, Neoplastic Large T-Lymphocyte) is unrelated.

Suppose $R$ is the set of all related concept pairs in $G$, and $\overline{R}$ is the set of all unrelated concept pairs in $G$. We perform a set-difference-based inference to derive contradiction in the following way. For each related concept pair $(B_d, B_a)$ in...
If $B_d - (B_d \cap B_a) \neq \emptyset$ and $B_a - (B_d \cap B_a) \neq \emptyset$, an inferred term pair \( (B_d - (B_d \cap B_a), B_a - (B_d \cap B_a)) \) can be derived. Similarly, for each unrelated concept pair \( (N_i, N_j) \) in $\mathcal{R}$, if $N_i - (N_i \cap N_j) \neq \emptyset$ and $N_j - (N_i \cap N_j) \neq \emptyset$, an inferred term pair \( (N_i - (N_i \cap N_j), N_j - (N_i \cap N_j)) \) can be derived. If there exists some common term pair that can be derived from both a related pair in $\mathcal{R}$ and an unrelated pair in $\mathcal{R}$, we say that the non-lattice subgraph is exhibiting an inference-contradiction pattern. For instance, in Figure 5A, the related concept pair \( \text{Anaplastic Cell, Neoplastic Large Cell} \) derives a term pair \( \text{Anaplastic, Neoplastic Large} \); while the unrelated concept pair \( \text{Anaplastic T-Lymphocyte, Neoplastic Large T-Lymphocyte} \) derives the same term pair \( \text{Anaplastic, Neoplastic Large} \). This pattern may suggest a potential missing IS-A relation between the unrelated concept pair: \( \text{Anaplastic T-Lymphocyte IS-A Neoplastic Large T-Lymphocyte} \) (the red edge in Figure 5B).

**Figure 5:** (A) A non-lattice subgraph exhibiting the Inference-Contradiction pattern. (B) The suggested remediation of the non-lattice subgraph in (A): \( \text{Anaplastic T-Lymphocyte IS-A Neoplastic Large T-Lymphocyte} \).

If $U_s \cup (L_i \cap L_j) = L_k$, this may suggest a missing IS-A relation between other concepts in the lower bounds and $L_k$. For instance, in Figure 6A, the intersection of $L_1 = \{\text{lungs, mucinous, adenocarcinoma}\}$ and $L_2 = \{\text{mucinous, bronchioloalveolar, carcinoma}\}$ in the lower bounds is $\{\text{mucinous}\}$, whose union with $U_1 = \{\text{lungs, adenocarcinoma}\}$ is equal to $L_1 = \{\text{lungs, mucinous, adenocarcinoma}\}$. This indicates a potential missing IS-A relation between the other concept $L_2$ in the lower bounds and $L_1$. That is, \( \text{Mucinous Bronchioloalveolar Carcinoma IS-A Lung Mucinous Adenocarcinoma} \) (the red edge in Figure 6B).

**Figure 6:** (A) A non-lattice subgraph exhibiting the Union, Inference-Contradiction, and Inference-Union patterns. (B) The suggested remediation of (A): \( \text{Mucinous Bronchioloalveolar Carcinoma IS-A Lung Mucinous Adenocarcinoma} \).

### 2.2.6 Inference-Union

A non-lattice subgraph is defined as exhibiting an inference-union pattern, if the union of the set of words for some concept $U_s$ in the upper bounds and the intersection of the set of words for two concepts $L_i$ and $L_j$ in the lower bounds is equal to the set of words for some concept $L_k$ in the lower bounds, that is, $U_s \cup (L_i \cap L_j) = L_k$. This may suggest a missing IS-A relation between other concepts in the lower bounds and $L_k$. For instance, in Figure 6A, the intersection of $L_1 = \{\text{lungs, mucinous, adenocarcinoma}\}$ and $L_2 = \{\text{mucinous, bronchioloalveolar, carcinoma}\}$ in the lower bounds is $\{\text{mucinous}\}$, whose union with $U_1 = \{\text{lungs, adenocarcinoma}\}$ is equal to $L_1 = \{\text{lungs, mucinous, adenocarcinoma}\}$. This indicates a potential missing IS-A relation between the other concept $L_2$ in the lower bounds and $L_1$. That is, \( \text{Mucinous Bronchioloalveolar Carcinoma IS-A Lung Mucinous Adenocarcinoma} \) (the red edge in Figure 6B).
2.2.7 Non-lattice Subgraphs with Multiple Patterns

We also investigate non-lattice subgraphs exhibiting multiple patterns among the above-mentioned six patterns. For instance, the non-lattice subgraph in Figure 1A exhibits both containment and inference-union patterns, and both patterns suggest a missing IS-A relation: *Stage III Nasopharyngeal Carcinoma AJCC v6 IS-A Stage III Nasopharyngeal Carcinoma*. The non-lattice subgraph in Figure 6A is following three patterns: union, inference-contradiction, and inference-union, and all these patterns suggest a missing relation between *Mucinous Bronchioloalveolar Carcinoma* and *Lung Mucinous Adenocarcinoma*.

2.3 Evaluation

For evaluation, we focus on small non-lattice subgraphs (size of 4, 5, and 6) due to two reasons. One is that small ones are relatively easy to visually inspect by domain experts. The other reason is that small non-lattice subgraphs may be contained in larger ones, and fixing errors in small ones will automatically eliminate the same errors propagated in the larger ones (although there might be other errors in the larger ones).

To evaluate the performance of applying different patterns in small non-lattice subgraphs to automatically detect real errors in NCIt and suggest corrections, we randomly selected 25 non-lattice subgraphs with a single pattern, and 25 ones with multiple patterns, respectively. These 50 sample non-lattice subgraphs as well as their suggested remediations were rendered in scalable vector graphics and provided to experts (authors MAB and JT) for evaluation. MAB evaluated cancer-related samples, and JT evaluated drug-related samples.

3 Results

3.1 Non-lattice Subgraphs Exhibiting Structural and Lexical Patterns

A total of 8,143 non-lattice subgraphs were identified in the NCIt (version 16.12d), among which 809 exhibits a single pattern or multiple patterns. Of these 809 non-lattice subgraphs, 678 were found exhibiting a single lexical pattern, 131 exhibiting multiple patterns. Of the 809 non-lattice subgraphs, 337 were small ones (size of 4, 5, and 6), among which 270 exhibited a single pattern, 67 exhibited multiple patterns. Table 1 shows the numbers of both non-lattice
subgraphs and small non-lattice subgraphs exhibiting different combinations of patterns (six single pattern, eighteen multiple patterns). For instance, there were 159 non-lattice subgraphs exhibiting a single containment pattern (the first row in Table 1), and 5 non-lattice subgraphs exhibiting multiple patterns: union, union-intersection, inference-union, inference-contradiction, and containment (the last row in Table 1). Figure 7 shows an example of non-lattice subgraph with these five patterns. For the 678 non-lattice subgraphs with a single pattern, the intersection pattern accounted for the largest proportion (430 non-lattice subgraphs). For the 131 non-lattice subgraphs with multiple patterns, the intersection and inference-contradiction patterns accounted for the largest proportion (33 non-lattice subgraphs).

Figure 7: (A) A non-lattice subgraph exhibiting five patterns: Union, Union-Intersection, Inference-Union, Inference-Contradiction, and Containment. (B) The suggested remediation of the non-lattice subgraph in (A): Sustained Release Buccal Tablet Dosage Form IS-A Sustained Release Tablet Dosage Form.

3.2 Evaluation

Of the 50 sample non-lattice subgraphs evaluated by domain experts, 33 were verified to contain errors and make correct suggestions (33/50 = 66%). Among these 33 correct cases, 32 were missing hierarchical relations and one was a missing intermediary concept. Table 2 presents the numbers of evaluated non-lattice subgraphs exhibiting each combination of patterns, and the numbers of correct suggestions confirmed by domain experts. Of the 25 evaluated non-lattice subgraphs with a single pattern, 11 were verified correct (11/25 = 44%). Of the 25 evaluated non-lattice
subgraphs with multiple patterns, 22 were verified correct \((22/25 = 88\%)\). This illustrates that non-lattice subgraphs with multiple patterns achieved a better performance than those with a single pattern in terms of the correction rate.

4 Discussion

In this paper, we investigated non-lattice subgraphs in NCIt based on six structural and lexical patterns, with each pattern automatically suggesting a potential missing hierarchical relation or missing concept. Our pattern-based approach leveraging both structural and lexical information is scalable and applicable to other terminologies for quality assurance work, since it generally takes concepts (as well as concept labels) and hierarchical relations of a terminology as the input, and generates erroneous non-lattice subgraphs and potential corrections as the output.

Analysis of failure cases. For the single-pattern non-lattice subgraphs evaluated in Table 2, the suggestions made by the intersection pattern turned out to have a low correction rate \((2/14 = 14.3\%)\). Figure 8A shows a non-lattice subgraph exhibiting the intersection pattern: \(\{\text{gestational, choriocarcinoma}\} \cap \{\text{ovarian, choriocarcinoma}\} = \{\text{choriocarcinoma}\}\). However, its automatic suggestion in Figure 8B is not correct. That is, \textit{Choriocarcinoma} is NOT a subclass of \textit{Malignant Female Reproductive System Neoplasm}, since \textit{Choriocarcinoma} can be a malignant female reproductive system neoplasm, but it can also arise in the male testis. Another example of wrongly suggested case by the containment pattern is: \(\{\text{osteoma}\} \subset \{\text{osteoid, osteoma}\}\). However, despite the similarity in names, \textit{Osteoid Osteoma} and \textit{Osteoma} are two completely different types of tumor, and \textit{Osteoid Osteoma} is thus NOT a subclass of \textit{Osteoma}.

![Diagram](image)

**Figure 8:** (A) A non-lattice subgraph exhibiting an Intersection pattern. (B) The wrongly suggested remediation of (A).

Comparison with previous work. The hybrid approach to mining structural-lexical patterns in non-lattice subgraphs was initially proposed in previous work\(^8\) for quality assurance of SNOMED CT, where four patterns were studied: containment, union, intersection, and union-intersection. In this paper, we applied these four patterns to NCIt, and further proposed two new patterns with implicit inference: inference-contradiction and inference-union. In addition, only single-pattern non-lattice subgraphs were investigated in previous work\(^8\), while in this paper, we not only studied non-lattice subgraphs with a single pattern, but also those with multiple patterns. Non-lattice subgraphs in NCIt with multiple patterns turned out to have a higher error detection and correction rate than those with a single pattern (see Table 2). For SNOMED CT\(^8\), the overall correction rate of the four patterns (by single pattern) was 59\%. For the NCIt in this paper, the overall correction rate of the six patterns (by both single pattern and mixed patterns) is 66\%.

Limitations and future work. A limitation of this work is that we only evaluated small non-lattice subgraphs (size of 4, 5, 6) for experts’ ease to review and validate. It would be interesting to further examine larger-size non-lattice subgraphs for evaluation. In addition, our evaluation was limited on the number of samples and only one domain expert was involved. We plan to evaluate more samples by multiple experts in the future. Another limitation of this work is that the list of negation words used in detecting the containment pattern was manually constructed based on our observation and previous experience. In the future, we expect to use a resource like NegEx for this purpose. The followings are a couple of directions for additional future work. When defining different patterns, we only used the concept labels for lexical information. We plan to take into account of the concept synonyms to complement concept labels, which may obtain more non-lattice subgraphs with patterns. Note that there are non-lattice subgraphs that may be erroneous but are not exhibiting any of the six patterns studied in this paper. New patterns or approaches are needed to uncover potential errors in such non-lattice subgraphs.
5 Conclusions

In this paper, we investigated a hybrid approach to identifying potential errors in the NCI Thesaurus and automatically suggesting remediations, by mining structural and lexical patterns in non-lattice subgraphs. This approach proved an effective way for error detection and correction in the NCI Thesaurus, and is applicable to other biomedical terminologies for quality assurance purposes.

Abstract

Patient safety and quality of care are at risk if the informed consent process does not emphasize patient comprehension. In this paper, we describe how we designed, developed, and evaluated an mHealth tool for advancing the informed consent process. Our tool enables the informed consent process to be performed on tablets (e.g., iPads) utilizing virtual coaching with text-to-speech automated translation as well as an interactive multimedia elements (e.g., graphics, video clips, animations, presentations, etc.). We designed our tool to enhance patient comprehension and quality of care, while improving the efficiency of obtaining patient consent. We present the User-Centered Design approach we adopted to develop the tool and the results of the different methods we used during the development of the tool. Also, we describe the results of the usability study which we conducted to evaluate the effectiveness, efficiency, and user satisfaction with our mHealth App to enhance the informed consent process. Using the UCD approach we were able to design, develop, and evaluate a highly interactive mHealth App to deliver the informed consent process.

Keywords— informed consent; mHealth; user-centered design;

Introduction

Objective: Informed consent (IC) is essential for the ethical conduct of research and medical treatment. The overarching goal of the IC process is to guarantee that the patient acquires a sound understanding of the purpose, risks, and methodology of a clinical trial and/or medical procedure¹,². For patients to fully understand the content of the IC process, the informed consent document should clearly explain the purpose, process, risks, benefits and alternatives to medical procedures or clinical research, while stressing the patient’s rights and responsibilities³. If the IC process achieves patient comprehension, then healthcare costs and patient safety risk can likely be deterred⁴. In regards to the expert consensus on IC tools, the Joint Commission (2007) reported that, “among patients who sign an IC form, 44% do not understand the nature of the procedure to be performed, and 60-70% did not read or understand the information contained in the form.” Thus, the Joint Commission urges reform given the poor potential of the IC process in achieving patient understanding.

Background: Studies have shown that the lack of sufficient comprehension of information included in the IC document negatively impacts patient safety and quality of care¹,². Patients want to be involved in making decisions about their own care. Currently, the standard consent process (paper and/or electronic) does not always guarantee patient comprehension or improve the quality of care. The real challenge is that many patients lack the means to truly comprehend existing IC documents⁵. As a result, many patients are consenting without fully comprehending the content and purpose of the consent form.

To minimize costs and risks, many providers have used electronic IC, but these systems are usually digital versions of standard paper-based systems⁶. Traditional consent forms, both paper and electronic, contain limited and/or inadequate descriptions – this inaccessibility is exacerbated with a high-level scientific vocabulary and a lack of a patient-centered approach. Therefore, the paper/electronic IC forms often require the medical provider or researcher to provide a simplified verbal laymen translation. This may also pose strain for patients, given the provider may not be the most adept at explaining the IC form contents. Many patient-centered outcomes research (PCOR) studies have advocated for providing more efficient, informative, and useful patient-centered informed consent processes²,⁷.
**Related works:** Research findings suggest Health Information Technology (HIT) interventions are successful tools for improving patient safety and quality of care. Virtual coaching, using mobile apps, shows great promise in encouraging general motivation to achieve healthy outcomes. Such interventions enabled through mobile health (mHealth) are completed by patients using apps on tablets (e.g., iPad), while maintaining the patient’s anonymity. mHealth architecture can be adopted as an IC medium in emphasizing patient-centered IC processes. mHealth achieves the planned aspect in that it allows patients to collect and report their own exposure history in real time on an app, rather than having to recall it after time has passed. Furthermore, in advocating for open and shared mHealth architectures, patients will not have to needlessly switch between apps to check exposure history or medical records. With an open architecture, the coherence and integration of mHealth benefits are emphasized. In addition to consolidating data interface in the mHealth tool, multimedia may also assist patients’ understanding and satisfaction with a research clinical trial or medical treatment process. Multimedia can also be used to tailor the mHealth tool to be more patient-centered, which is the primary goal of undertaken by this study.

**Study Development:** Given that the standard consent process does not always guarantee patient comprehension or improve the quality of care, many patients are consenting without the necessary knowledge of IC form contents. To improve the traditional IC process, we developed the Patient Centered Virtual Multimedia Interactive Informed Consent tool (VIC) (See Figure 1). Our approach uses virtual coaching to conduct a brief and virtual interview with patients using tablet computers (e.g., iPads) with a comprehensive multimedia library (e.g., video clips, animations, presentations, etc.) to explain the risks, benefits, and alternatives of the proposed treatment or clinical study, to enhance patient awareness. Our tool presents the IC materials to patients with the option of additional review to increase information grasp. The VIC tool has an option to assess patient comprehension with automated quizzes, which can help patients assess their own comprehension of the information presented. VIC provides many features and functions including Internet access to the consent, a retrievable electronic record of IC, electronic signature, and potential for seamless integration with the electronic health record (EHR). Moreover, VIC includes extensive security strategies that will guarantee the confidentiality and privacy of the patient and the clinical information. It also provides access to the IC content via the Internet before, during and after the study or procedure, allowing patients to benefit from supplemental resources as well.

In this paper, we present how we developed the VIC mHealth App based on prior work and evidence in IC research to support the patient-centered IC as well as enhance patient comprehension. We describe in detail the state-of-the-art software standards and the User-Centered Design approach (UCD) that we used to design, develop, refine, and test the VIC mHealth App. Moreover, we present the usability evaluation approach that we took to ensure that VIC satisfies the highest standard for usability and acceptability along while maintaining effectiveness, efficiency and patient satisfaction. The following sections list key factors that influenced design and development of VIC (Figure 2).

**Methods**

We used several methods to design, build, and evaluate VIC. The Our methods were based on the User-Centered Design (UCD) approach including requirement gathering and analysis, conceptual design, focus groups, design and development of mockups screen and prototype, usability evaluation of the prototype, development of the VIC system, and usability evaluation of VIC App. In this section, we describe these methods with an emphasis on the patient oriented design. The Institutional Review Board (IRB) of Yale University reviewed and approved the study protocol.
User-Centered Design Methodology (UCD).
We adapted UCD to build VIC, that is, an iterative multi-stage design approach that involves the user’s input throughout the development process\(^{18,19}\). UCD gives extensive attention to the user’s needs, wants and limitations at each stage of the design process and allows User Experience (UX) evaluations to be incorporated into the design. We used the data collected throughout various design phases to enhance the overall design iteratively. Specifically, we incorporated UCD techniques and UX evaluations to produce usable and acceptable software that delivers a more satisfying user experience. The result was a VIC system that is built and optimized around how patients can, want, or need to use it\(^{20}\). The following subsections list key factors that influenced design and development of the VIC system.

Conceptual Design.
The VIC system initial concept was developed based on prior work, and literature findings in IC research, patient input, and subject matter expert interviews. Our theoretical framework is based on Mayer’s Cognitive Theory of Multimedia Learning and the principle that the use of multimedia in the presentation of the IC process will improve patient comprehension\(^{15,16,21,22}\). In a recent study on patient-centered IC, Braithwaite et al. concluded that the type of IC that would be most suitable for patient-centered care is the type that is clinically oriented (e.g. decision aids) rather than legally oriented\(^{23}\).

Our goal was to develop a conceptual model with the patient in mind for a more efficient, informative, and effective patient-centered IC processes. We wanted to develop a model where a virtual coach could substitute for a human for most parts of the IC. The virtual coach would explain the IC in a way similar to how the study coordinator or a provider would explain the IC process to a study participant or patient. Therefore, the IC content could be presented in a style that is patient-friendly and easy to understand. The IC content should be brief and designed to quantify participant understanding, offering the participant a customized level of information. In addition, the model should include...
features to assess patient comprehension. Moreover, it should enhance the workflow and provide better access to the IC materials. Finally, it should also maintain the confidentiality and privacy of the patient and the clinical information.

**Front-End Focus Group.**

The goal of this focus group is to aid the initial design of VIC. We conducted a front-end focus group with patients and researchers from the Yale Center for Asthma and Airway Disease Mechanisms (YCAAD) clinic, and one IRB members from the Yale IRB office, as a part of the user requirements analysis. Patients were recruited by a research coordinator at the YCAAD clinic and were screened by the PI over the phone. Letters were then mailed containing directions and a reminder of the date and time of the focus group session. The focus group was held in a closed conference room at Yale University in July 2015 and lasted 80 minutes. All participants were told that their participation was voluntary and their information was confidential/anonymouse. An introductory script was read to explain the purpose and guidelines of the focus group and followed a dialogue of open-ended questions along with follow-up questions (Table 1). A member of the research team moderated the focus group and two observers took notes of the sessions, which was also audio-recorded. Patients in the focus groups were compensated with an incentive payment of $45 for their participation. The two research participants were recruited by several members of the research team and were not compensated. The audio recording was later transcribed for purposes of analyzing themes and comments.

The focus group contained 5 participants: 2 patients, 2 researchers, and 1 IRB member. Because patient input is vital to understanding the IC and how it is perceived from a patient prospective, we have identified two patients from the community to work directly on the project as co-investigators. We engaged the co-investigators in all aspects of the project including design, development, implementation and evaluation. The information gathered from the Front-End Focus Group was used to formulate the Initial User Requirements. Then, the research team then held several design sessions to carefully define and list all accepted technical and functional requirements of VIC.

</tbody>
</table>

In general, all participants were open to the use of the iPad to present the informed consent. When asked about the level of comfort with the paper IC, participants expressed lack of comfort with the paper IC process. They felt that the IC was hard to read and understand, and full of many large words. They said that even though they read it, they did not really understand the content most of the time. Some said it is always the same thing and it is being repeated over
and over. Participants stressed the importance of having the IC read out aloud to them. Some even said, “If no one reads it for me, I will just sign it and roll the dice”. Most participants felt the process was too long and should be made simpler. When asked about what is missing from the paper IC process, they said: “it should include a summary, some videos to let me know what to expect.” There were also comments regarding the need for patients to be informed. In summary, although participants were concerned about the safety and security of their private health information, they were very excited about the HIT approach to deliver the IC process.

We conducted a summative analysis of participant phrasing and word use. We used information gathered from this focus group to create user cases and personas.

User Requirements Collection and Analysis.
Because patient input is vital to understanding the IC and how it is perceived from a patient prospective, we have identified two patients from the community to work directly on the project as co-investigators. We engaged the co-investigators in all aspects of the project including design, development, implementation and evaluation. The information gathered from the Front-End Focus Group was used to formulate the Initial User Requirements. Then, the research team then held several design sessions to carefully define and list all accepted technical and functional requirements of VIC.

Conceptual Model of the VIC mHealth App.
Based on the outcome of the Front-End Focus Group and the development of the conceptual model, our focus was mainly on developing VIC as a web-based App that would run on iPads to present IC content in a style that is patient-friendly and easy to understand. The initial model revolved around using a virtual coach or provider (see Figure 2), which guides the patient through the IC process. In VIC, the information and messages are displayed on the iPad screen and spoken through headphones for patient privacy. One of the innovative features of VIC is the ability to deliver health information through the use of multimedia and virtually guided interviews by a virtual provider (i.e. VIC), which explains the risks, benefits, and alternatives of the clinical procedure. Patients can view demos and presentations, and listen to comments and explanations. Animations and presentations will illustrate complicated content. The desired readability level for the text in VIC will be the 8th-grade level. This will enable us to safeguard patients with limited literacy. VIC is modeled around the idea that the content IC session should be brief and designed to quantify participant understanding, offering the participant a customized level of information. Additionally, the model included automated quizzes to assess patient comprehension. It also required providing Internet access to the consent, a retrievable electronic record of IC, electronic signature, and integration with the electronic health record (EHR). Moreover, it required adopting comprehensive security strategies that would guarantee the confidentiality and privacy of the patient and the clinical information.

App Wireframe and Screens Prototypes.
We used Balsamiq Mockups to design the wireframe and screen mockups. Balsamiq Mockups is a drag-and drop mockup and a rapid wire framing tool that helped us work more efficiently. It reproduces the experience of sketching on a whiteboard, using a computer for the prototyping purposes. The quick prototyping helped us simulate and test different versions of the tool’s User Interface. We continued to modify the mockups until we reached consensus on the final design. We used the content of the conceptual model and the system requirement to design the VIC mockups using the Balsamiq Mockups for the UI of the tablet (See Figure 4). Multiple sets and versions of VIC screens mockups were developed and tested and the modified and refined. During this process, we modified many features and properties of the end user interface. This included for example the process for testing user ability to use audio and the placement of navigation control and video control. The mockups provided us with means to test the flow of the screens and information and the amount of text that can be placed on single iPad screen. It also helped us decide on the most appropriate font size and color. We were able to evenly order and space the important sections and the main procedures. The Mockups expedited the development process and gave each research team member to visualize the software application and to be able to contribute to the design process in the joint design sessions. Using Balsamiq allowed us to produce a PDF prototype with full navigation capability comparable to the one of the final App.
System Architecture.
In this subsection, we include detailed descriptions of the VIC system architecture, methods, technologies, tools, and the support services that were used in the implementation of the mobile App. We designed VIC to be a Web-based mobile application that runs using traditional Internet browser interface, or on Apple iPads and other mobile devices. We developed it using Microsoft C# .NET and it runs on Microsoft Windows Server, Microsoft Internet Information Server (IIS), and Microsoft SQL Server 2012. Figure 3 demonstrates VIC’s three-tiered architecture. In addition to tier separation and firewall protection, the separate tiers provide a model for creating secure, flexible, and reusable mobile application components.

**Tier 1 – Presentation Logic Tier (i-DMZ1):** The Presentation Logic Tier is the IIS Web Application Server, and it consists of standard ASPX files and HTML pages. The function of this tier is to gather the requests from the presentation graphical user interface (GUI) and then forward the requests to the Business Tier once a user makes a request from a web browser. The Presentation Logic Tier will support different end-user devices (e.g. iPad, desktop, laptop, etc.). In return, the Presentation Logic Tier receives the results/output from the Business Tier, and transforms the results into readable formats and forwards data back to the Presentation GUI.

**Tier 2 – Business Tier (i-DMZ2):** The Business Tier is the brain of the VIC system. It contains the business logic, business rules, user security, validation rules and processing rules of the functions provided by the application. For example, once information is received from the Presentation Logic Tier, the information is validated against the predefined business and validation rules and business logic. If the information meets all the criteria, the information is forwarded to the Data Tier. The Business Tier also generates confirmation codes and forwards it back to the Presentation Logic Tier. The Business Tier will reside on the Business Server.

**Tier 3 – Data Tier (i-DMZ3 (SQL Server 2012):** The Data Tier handles the storage and retrieval of the information in the database. It can save and retrieve information from the database. *Microsoft SQL Server 2012 Enterprise Edition* will be the Database Management System (DBMS) for the proposed application.

Text-to-Speech.
We wanted to create a patient-centered easy-to-use IC tool that is acceptable by all users. A tablet with text-to-speech interfaces addresses literacy issues and makes the IC process an option for inexperienced computer users. Text-to-
speech translation is a key feature of VIC and is achieved by online and automated text-to-speech translation. One way to add the audio functionality to VIC is to record the audio associated with textual content of every screen in waveform and then play it back when the screen is displayed. However, this approach needed significant time and effort to record and edit the audio. In addition, we will require fresh recording every time the text on this screen is edited or changed. This would have slowed down the development and reduced the quality of the App. Our challenge was to find a low-cost, efficient solution to translate text in English into speech in high quality audio without compromising App performance. A more effective method was to use Text-To-Speech (TTS), a means of converting text to synthetic speech using a computer. In VIC, we used an online TTS solution (www.ispeech.org) to handle text to speech translation. For each text segment in the App that will be displayed on the screen, VIC requests (in real-time) an audio file translation associated with that text from ispeech.org through an API call. The API will then return the equivalent MP3 file VIC and VIC plays to the user.

**VIC App Usability Evaluation.**

After the VIC App was developed and tested, we wanted to ensure that the tool followed user interface standards-compliant coding practices for usability and acceptability. We performed a usability evaluation on VIC using a structured walk-through process with recognized usability principles. **Usability** refers to the ease in which the users can interact with tools. For the final design, we conducted the usability evaluation with nine representative asthma patients recruited from the YCAAD clinic. Patients were approached by the study coordinator and informed of this pilot study and offered the choice to participate voluntarily. If they chose to participate in the study, then they were scheduled for a study visit at a later convenient date and time in our Medical Simulation Center. Usability evaluation sessions were conducted in one-on-one settings to gather performance and satisfaction data. We evaluated the extent to which the application’s user interface is functioning according to the user requirements in the design specification to ensure that user needs are met. On the study visit, participants were reminded of the study protocol, study purpose, and patient’s role.

At the beginning of the session, a description of the study and the order of activities were read to participants. Each participant was asked to sign the consent form before participating in the study. In addition, they were asked to fill a demographic survey and a Computer Efficacy Scale (CES). Participants were told that the session will be audio and video recorded and the iPad must remain within the view of the above recording camera, for future analysis of potential on-screen inefficiencies. Participants were provided with a headphone in keeping with the intended future use of the VIC in the clinical setting. The participants were asked to review the VIC tool on the iPad in the presence of a researcher, while being videotaped, and share their perceptions of the application by speaking out loud. Participants were asked to complete a demographic questionnaire, CES, before they use VIC. For CES, participants were asked to rate their confidence about using the new technology on the scale of 1–10 (1= not at all confident and 10= completely confident) for each of the listed condition.

Additionally, they completed a system usability scale (SUS) and supplemental quantitative/qualitative data gathering, after using VIC. The SUS, created by John Brooke, is an industry standard, quick and reliable tool for measuring usability that can be used for small sample sizes. The validated SUS is a ten item Likert Scale that measured user attitude, effectiveness, efficiency, and satisfaction with the application. A short post-use interview was conducted to allow for additional qualitative feedback from the participants. In this phase, participants were asked open-ended questions and probed for recommendations to enhance VIC usability. At the end, participants were rewarded with a gift card for $15 as appreciation for participation. Our study was reviewed and approved by the Yale University Human Investigation Committee (IRB).

Quantitative data was analyzed as numerical indicators and summarized using common descriptive statistics appropriate for discrete and continuous data. Non-numerical indicators were analyzed using qualitative methods. Key results were used to 1. Modify the VIC system to make it more usable and acceptable in terms of system’s design; and 2. Normalize VIC by reducing process and structural problems. We conducted data analysis by using audio and video recording, user screen capture, note-taking, and participant survey. Key usability measures included both qualitative and quantitative outcome measures. These include effectiveness, efficiency, and satisfaction.

**Usability Evaluation Results.**

In this section, we will list our main results of the usability evaluation based on using UCD approach for the development and evaluation of the VIC mHealth App. We found that the UCD approach was appropriate for VIC development. It provided hybrid techniques for requirement gathering and analysis and to create the initial and conceptual design of the VIC App with the patient in mind. Moreover, UCD approach was instrumental in guiding us
through various stages of the development including conducting focus groups, design and development of mockup screens and prototypes, development of the VIC system, and usability evaluation of VIC App.

All 9 participants (4 males and 5 females) completed the VIC usability study. All participants reported having at least a high school education (Table 3). All had access to both a desktop or laptop computer and reported having above 50% confidence in adapting to a new technology. Income brackets were largely similar with most sample participants identifying themselves as middle-class and most were Caucasian with only 1 African American and 1 Asian American.
The average CAS normalized score was nearly 78, indicating that the sample was relatively not anxious about using computers and adequately self-sufficient when it came to technology use (Table 2). The average SUS normalized score for all participants was 90th percentile, which is above the industry benchmark of 68th percentile (Table 4). All users reported that the user interface of the VIC mhealth tool was appropriate and easy to use, given that all subjects gave either a 4 or 5 when it came to ease of use and future implementation.

Overall, the users were successful in completing the tasks with a favorable impression of the VIC system. They had little difficulty understanding how to perform navigating the screens, playing and pausing videos and illustrations, showing and hiding the close caption text, playing or muting audio, answering the quiz questions, agreeing or disagreeing to participate, and signing the consent with their fingers on the iPad screen. However, they had some difficulty reading the text and suggested increasing the font size to make it more readable and to add audio to the quiz answer screen.

The most frequently suggested change to the mhealth tool was to change the Play button and make it indicate sound control. Also, to alter the interface such that hovering over the icon would show the icon’s meaning. All participants preferred the use of headphones with VIC, felt they had ample time to complete the program, and would strongly recommend its use in future clinical practice. Recommendations from the usability evaluation for improving the user experience included using larger font and control on-screen messaging to let users know how to proceed in the system; providing audio to the quiz screen and to read out load the quiz question and answer.

Conclusion

The use of mHealth can be successful in delivering health communications. More specifically, in developing a usable, acceptable, and efficient tool to deliver the IC process. Care must be taken to address the challenges that come with designing a new IC tool. One such challenge is ensuring that the new IC tool improves patient comprehension. This study focused on testing the feasibility of developing and evaluating such a tool.

Using the UCD approach we were able to design, develop, and evaluate a highly interactive mHealth App to deliver the IC process. The UCD approach facilitates working with multiple stakeholders and helped us plan and execute many tasks including requirement gathering and analysis, conceptual design, focus groups, design and development of mockups screen and prototype, usability evaluation of the prototype, development of the VIC system, rapid prototyping, and usability evaluation of VIC App.

Our Web-based mobile VIC App with virtual coaching and text-to-speech audio translation and iPad® interface offers some compelling ways to surmount existing implementation barriers. Our App architecture intentionally and readily addresses literacy issues and patients’ needs in the informed consent process. This has important implications for facilitating more meaningful and broader implementation of an IC tool, enhancing patient comprehension, and reducing provider burden engaging patients in an interactive IC process. Our user-focused development approach resulted in a product that is usable, acceptable, and efficient. Overall, the VIC mHealth tool had high usability as rated by the representative asthma patients. Successful research increasingly requires multi-disciplinary and inter-disciplinary teams. Our team has unique and complementary backgrounds encompassing HIT, human computer interaction, mHealth, UCD, UX evaluation, system design and architecture, human subjects protection, and clinical, and translational research. This study presents how our team is a success story of interdisciplinary collaboration between several entities.

Possible future directions include assessing the VIC tool capabilities for different chronic. Potential modifications include improving the reusable infrastructure of the VIC App by using a larger and more diverse sample size to create a more patient-centered mHealth tool. In the longer term, we are also interested in assessing whether the VIC predicts more positive health outcomes for patients.

Acknowledgements

Project described was made possible by grant from AHRQ R21 HS23987. We would like to acknowledge the two asthma patients who in the research team as co-researchers included Sheinea Doram (a finance associate with moderately severe asthma), and Judy Kaya (a former nurse with severe asthma). This publication was made possible by the Yale CTSA grant UL1TR000142 from the National Center for Advancing Translational Sci. (NCATS), NIH.

Abstract

Recent advances in data collection during routine health care in the form of Electronic Health Records (EHR), medical device data (e.g., infusion pump informatics, physiological monitoring data, and insurance claims data, among others, as well as biological and experimental data, have created tremendous opportunities for biological discoveries for clinical application. However, even with all the advancement in technologies and their promises for discoveries, very few research findings have been translated to clinical knowledge, or more importantly, to clinical practice. In this paper, we identify and present the initial work addressing the relevant challenges in three broad categories: data, accessibility, and translation. These issues are discussed in the context of a widely used detailed database from an intensive care unit, Medical Information Mart for Intensive Care (MIMIC III) database.

1 Introduction

The promise of big data has brought great hope in health care research for drug discovery, treatment innovation, personalized medicine, and optimal patient care that can reduce cost and improve patient outcomes. Billions of dollars have been invested to capture large amounts of data outlined in big initiatives that are often isolated. The National Institutes of Health (NIH) recently announced the All of Us initiative, previously known as the Precision Medicine Cohort Program, which aims to collect one million or more patients’ data such as EHR, genomic, imaging, socio-behavioral, and environmental data over the next few years¹. The Continuously Learning Healthcare System is also being advocated by the Institute of Medicine to close the gap between scientific discovery, patient and clinician engagement, and clinical practice². However, the big data promise has not yet been realized to its potential as the mere availability of the data does not translate into knowledge or clinical practice. Moreover, due to the variation in data complexity and structures, unavailability of computational technologies, and concerns of sharing private patient data, few projects of large clinical data sets are made available to researchers in general. We have identified several key issues in facilitating and accelerating data driven translational clinical research and clinical practice. We will discuss in-depth in the domains of data quality, accessibility, and translation. Several use cases will be used to demonstrate the issues with the “Medical Information Mart for Intensive Care (MIMIC III)” database, one of the very few databases with granular and continuously monitored data of thousands of patients³.

2 Promises

In the era of genomics, the volume of data being captured from biological experiments and routine health care procedures is growing at an unprecedented pace⁴. This data trove has brought new promises for discovery in health care research and breakthrough treatments as well as new challenges in technology, management, and dissemination of knowledge. Multiple initiatives were taken to build specific systems in addressing the need for analysis of different types of data, e.g., integrated electronic health record (EHR)⁵, genomics-EHR⁶, genomics-connectomes⁷, insurance claims data, etc. These big data systems have shown potential for making fundamental changes in care delivery and discovery of treatments such as reducing health care costs, reducing number of hospital re-admissions, targeted interventions for reducing emergency department (ED) visits, triage of patients in ED, preventing adverse drug effects, and many more⁸. However, to realize these promises, the health care community must overcome some core technological and organizational challenges.
3 Challenges

3.1 Data

**Big data is not as big as it seems**

In the previous decade, federal funding agencies and private enterprises have taken initiatives for large scale data collection during routine health care and experimental research\(^5,9\). One prominent example of data collection during routine health care is the Medical Information Mart for Intensive Care (MIMIC III) which has collected data for more than fifty thousand patients from Beth Israel Deaconess Hospital dating back to 2001\(^3\). This is the largest publicly available patient care data set of an intensive care unit (ICU) and an important resource for clinical research. However, when it comes to identifying a cohort in the MIMIC data for answering a specific clinical question, it often results in a very small set of cases (small cohort) that makes it almost impossible to answer the question with a strong statistical confidence. For example, when studying the adverse effects of a drug-drug interaction, a researcher might be interested in looking at the vital signs and other patient characteristics during the time two different drugs were administered simultaneously, including a few days before the combination and a few days after the combination. Often this selection criteria results in a very small cohort of patients limiting the interpretation of the finding and with statistically inconclusive results. As an example, a researcher may want to investigate if any adverse effect exists when anti-depressants and anti-histamines are administered simultaneously. A query of simultaneous prescriptions of Amitriptyline HCl (anti-depressant) and Diphenhydramine HCl (anti-histamines) returned only 44 subjects in the MIMIC database (Figure 1). Furthermore, by filtering the data with another selection criterion (e.g., to identify the subjects for which at least one day’s worth of data exist during, before and after the overlap) the query returned a much smaller cohort with only four records.

**Data do not fully capture temporal and process information**

In most cases, clinical data are captured in various systems, even within an organization, each with a somewhat different intent and often not well integrated. For example, an EHR is primarily used for documenting patient care and was designed to facilitate insurance company billing\(^10\), and pharmacy records were designed for inventory management. These systems were not developed to capture the temporal and process information which is indispensable for understanding disease progression, therapeutic effectiveness and patient outcomes. In an attempt to study clinical process of vancomycin therapeutic drug monitoring based on ICU patient records in the MIMIC database, it was discovered that such process is not easy to reconstruct. Ideally, a complete therapeutic process with a particular drug contains the history of the drug’s prescription, each of its exact administration times, amount and rate, and the timing and measurements of the drug in the blood throughout the therapy. From the MIMIC III database we were able to find prescription

![Diagram](image-url)
information but it lacks the detailed dosing amount and prescription’s length of validity. The “inputevents” table contains drug administration information but does not include the exact time-stamp and drug amount which is critical for studying intravenous infused vancomycin in the ICU. It is also difficult to match drug prescription and administration records because their recording times in the clinical systems often are not the precise event times, and prescribed drugs are not always administered.

Figure 2: An example of vancomycin therapeutic process reconstruction of one unique ICU stay using data from three different tables in the MIMIC III database.

Moreover, since the MIMIC III database does not contain detailed infusion event records which may be available from infusion pump software, one cannot know the precise drug infusion amount (and over what time) for any particular administration. The sparse and insufficient information on drug administration makes it almost impossible to associate available laboratory records and to reconstruct a therapeutic process for outcomes studies. Figure 2 is such an attempt of process reconstruction using data from the MIMIC III database including prescriptions, input events, and lab events for one patient during a unique ICU stay. The record only shows one valid prescription of vancomycin for this patient with start and end dates but does not indicate the administration frequency (e.g., every 12 hours) or method (e.g., continuous or bolus). The input events data (the second main column) came from the nursing records but it only shows one dose of vancomycin administration on each of the three-day ICU stay: one in the morning and two in the evening. Even though, as shown in the third main column, the “lab event” data contain the patient’s vancomycin concentration levels measured during this period, without the exact amount and duration of each vancomycin infusion, it is difficult to reconstruct this particular therapeutic process for the purposes of understanding its real effectiveness.

The problem of missing data remains relevant, even when the nursing workflow was designed to capture the data in the EHR. For example, as part of the nursing workflow, the information of drug administration should be documented in the medication administration records each time vancomycin was administered, and the MIMIC system was designed to capture all. But this was often not the case from our review of the database. Additionally, often times a patient’s diagnoses, co-morbidities, and complications are not fully captured nor available for reconstructing the complete clinical encounter. Those pieces of information are usually documented as free text not discrete data that can easily be extracted. Moreover, precise timings of the onset of an event and its resolution are rarely present. In the previous example of analyzing the effect of simultaneously administering Amitriptyline HCl and Diphenhydramine HCl, based on our selection criteria, we were able to find only one or two cases where such data were recorded (Figure 3). In the figure, each color represents one subject, and only one color (green, ID:13852) is consistently present in the time window for the selection criteria indicating missing systolic blood pressure measurements for the other subjects. This example is not an exception for cohort selection from data captured during care delivery, but a common occurrence due to the complex nature of the care delivery process and technological barriers in the various clinical systems developed in the past decade or so.

3.2 Access

Accessibility to patient data for scientific research and sharing of the scientific work as digital objects for validation and reproducibility is another challenging domain due to patient privacy concerns, technological issues such as interoperability, and data ownership confusion. This has been a widely discussed issue in recent years of the so-called patient or health data conundrum as individuals do not have easy access to their own data. We are discussing these challenges in the context of privacy, share-ability, and proprietary rights as follows.
Figure 3: Example of a cohort with missing systolic blood pressure data for three out of the four subjects meeting our clinical selection criteria. Day 0 (zero) is when drug overlap begins. This start of the overlap is aligned with multiple subjects and is denoted by the thick red line. Each data point represents one measurement from the “chartevents” table and each color indicates one subject and the black line indicates the average of the selected cohort.

Privacy
Access to health care data is plagued by vulnerability due to patient privacy considerations which are protected by federal and local laws of protected health information such as Health Insurance Portability and Accountability Act of 1996 (HIPAA)\textsuperscript{13}. The fear of litigation and breach of privacy discourages providers from sharing patient health data, even when they are de-identified. One reason is that current approaches to protect private information is limited to de-identification of an individual subject with an ID, which is vulnerable to twenty questions-like problems. For example, a query to find any patient who is of Indian origin and has some specific cancer diagnosis with a residential zip code 3-digit prefix ‘479’ may result in only one subject; thus exposing the identity of the individual.

Share-ability
Even after de-identification of patient data, the sharing of such data and research works based on the data is a complicated process. As an example, “Informatics for Integrating Biology and the Bedside (i2b2)\textsuperscript{5} is a system designed to capture data for scientific research during routine health care. i2b2 is a large initiative undertaken by Partners Healthcare System as an NIH-funded National Center for Biomedical Computing (NCBC). It contains a collection of data systems with over 100 hospitals that are using this software system on top of their clinical database. As a member of this project, each participating hospital system needed to transform their data into a SQL based star schema after de-identification. It required much effort for each institution to make the data available for scientific research as well as to develop the software in the first place. Although i2b2 was used exhaustively for research, sharing of data and research work as digital objects (i.e., the coding and the flow of the analysis) is not easily achieved. We argue that current EHR and other clinical systems do not empower the patients to take control of their data and engage in citizen science. The crowd sourcing approach might be one way to make a paradigm shift in this area which, unfortunately, is not yet possible with the current systems such as i2b2. A good example is the success in open source software technologies in other disciplines and applications (such as Linux, Git-hub, etc.) which rely on the engagement of many talented and passionate scientists and engineers all over the world to contribute their working products as digital objects\textsuperscript{14}.  

387
Figure 4: Sensitivity for the machine learning algorithms for different training sizes for prediction of Medical Emergency Team (MET) activation from the MIMIC database. The X-axis represents training size for different trials. For each training set, the results of a 10 fold cross validation are reported as box plots (the central red line is the median, the edges of the box are the 25\textsuperscript{th} and 75\textsuperscript{th} percentiles, the whiskers extend to the extreme data points the algorithm considers to be not outliers, and the red + sign denotes outliers). The blue asterisks represent the performance on the validation set of the algorithm that performs best on the test set. The blue dashed lines represent the performance of the National Early Warning Score (NEWS).

Proprietary rights
A relevant issue is the ongoing debate about the ownership of patient data among various stakeholders in the healthcare system including providers, patients, insurance companies and software vendors. In general, the current model is such that the patient owns his/her data, and the provider stores the data with proprietary software systems. The business models of most traditional EHR companies, such as Epic and Cerner, are based on building proprietary software systems to manage the data for insurance reimbursement and care delivery purposes. Such approach does not encourage or makes it difficult for individual patients to share data for scientific research, nor does it encourage patients to obtain their own health records that may help better manage their care and improve patient engagement.

3.3 Translation
Historically, a change in clinical practice is hard to achieve because of the sensitivity and risk aversion of care delivery. As an example, the use of beta blockers to prevent heart failure took 25 years to reach a widespread clinical adoption after the first research results were published. This problem is much bigger for big data driven research findings to be translated into clinical practice because of the poor understanding of the risks and benefits of data driven decision support systems. Many machine learning algorithms work as a "black box" with no provision of good interpretations and clinical context of the outcomes, even though they often perform with reasonable accuracy. Without proper understanding and translatable mechanisms, it is difficult to estimate the risk and benefit of such algorithms in the clinical setting and thus discourages the new methods and treatments from being adopted by clinicians or approved by the regulatory bodies such as the FDA.
For example, if a machine learning algorithm can predict circulatory shock from patient arterial blood pressure data, what would be the risk if the algorithm fails in a particular setting based on patient demographics or clinical history? What should be the sample size to achieve high confidence in the results generated by the algorithm? These are some critical questions that cannot be answered by those traditional “black box” algorithms, nor have they been well accepted by the medical community, which relies heavily upon rule based approaches.

As an example, a decision tree algorithm might perform very differently for prediction of Medical Emergency Team (MET) activation based on the training set or sample size from the MIMIC data. Furthermore, the prediction result can be very different when another machine learning algorithm, the support vector machine (SVM), was used (Figure 4).

3.4 Incentive

Yet another barrier in using big data for better health is the lack of incentive for organizations to take initiative to address the technological challenges. As mentioned earlier, EHRs are developed for purposes other than knowledge advancement or care quality improvement, and that has led to unorganized, missing, and inadequate data for clinical research. An individual health system does not usually have the incentive to make these data organized and available for research, unless they are big academic institutions. It would be easier for each individual health system to share data if they were organized and captured using standard nomenclature and with meaningful and useful detailed information with significant detail. A key question any health organization faces is: what is the return on investment for my hospital to organize all the clinical data it gathers? One model is the Health Information Technology for Economic and Clinical Health Act (HITECH) which promotes the adoption and meaningful use of health information technology. The act authorized incentive payments be made through Medicare and Medicaid to clinicians and hospitals that adopted and demonstrated meaningful use of EHRs, and the US government has committed payments up to $27 billion dollars over a ten year period. This incentive has paved the way for widespread adoption of EHRs since HITECH was enacted as part of the American Recovery and Reinvestment Act in 2009. However, for the purpose of using clinical data for scientific innovation and improving care delivery process, no apparent financial incentives currently exist for any organization to do so.

4 Opportunities

4.1 Data

For data driven research in health care, we propose to record the most granular data during any care delivery process so as to capture the temporal and process information for treatment and outcomes. For example, in an intensive care unit, the exact time of medication administrations need to be captured. This can be achieved in a number of ways. As a nurse bar code scans an oral medication into the electronic medication administration record (eMAR) the system also timestamps the action in the EHR. Detailed intravenous drug infusions can be linked to the patient clinical records by integrating the smart infusion pumps with the EHR systems. The Regenstrief National Center for Medical Device Informatics (REMEDI), formerly known as the Infusion Pump Informatics, has been capturing for capturing process and temporal infusion information. The planned expansion of such data set will allow linked patient outcomes and drug admin data forming a more complete treatment process for answering research and treatment effectiveness questions related to the administration of drugs such as drug-drug interaction, safe and effective dosage of drugs, etc., among others.

In order to achieve a statistically significant sample size after cohort selection, we promote breaking the silos of individual clinical data systems and making them interoperable across vendors, types and institutional boundaries with minimal effort. For the next generation of EHRs, these capabilities need to be considered.

4.2 Access

Patient/citizen powered research

To replicate the success in open source technologies in other disciplines by enabling citizen science, data and research analysis must be accessible to everyone. At the same time, patient privacy needs to be protected complying with the
privacy law and proprietary rights of the vendors, and researchers need to be protected. As an example, we have demonstrated such a system with the MIMIC database where interoperable and extensible database technologies have been used on de-identified patient data in a high performance computing environment19.

**Shareable digital objects**

For the next generation of EHRs and other big data systems such as REMEDi18 and i2b25, data must be findable, accessible, interoperable and reproducible (FAIR)20. For big data systems, a software-hardware ecosystem could work as a distribution platform with characteristics analogous to an Apple or Android “app store” where any qualified individual can access the de-identified data with proper authentication without the need for a high throughput infrastructure and the rigorous work, including pre-processing of the data needed to reproduce previous works. The proposed architecture is shown in Figure 519.

**4.3 Translation**

**Causal understanding**

Historically, clinical problems and treatment are studied and understood as “cause and effect”. For example, genetic disposition and lifestyle could lead to frequent urination, fatigue and hunger, and can be associated with diabetes. Based on this, the patient may be treated for this disease. However, most machine learning algorithms do not provide such a rule based approach; rather they predict the outcome of a given set of inputs, which may or may not be associated with known clinical understanding. Unlike other disciplines, clinical applications require a causal understanding of data driven research. Hence, most clinical studies start with some hypothesis, that ‘A’ causes ‘B’. The gold standard to identify this causation is randomized controlled trials (RCTs), which have also been the gold standard for regulatory approval of new drugs. Unfortunately, EHRs and the like data captured during routine healthcare has sampling selection bias and confounding variables and hence it is important to understand the limitation of such data sets. To answer the causal questions, a new generation of methods are necessary to understand the causal flow of treatment, outcome, and molecular properties of drugs by integrating big data systems for analysis and validation of hypothesis for transportability across studies with observational data21, 22. These methods would enable the regulators to understand the risk and benefit of data driven systems in clinical settings for new guidelines enabling the translation. Once those guidelines are established, technological solution must also be enabled at the point of care such that clinicians
can access for data driven queries as part of their clinical workflow.

5 Conclusion

“Big data” started with many believable promises in health care, but unfortunately, clinical science is different from other disciplines with additional constraints of data quality, privacy, and regulatory policies. We discussed these concepts in pursuit of a holistic solution that enables data driven findings to be translated in health care, from bench to bedside. We argue that the existing big data systems are still in their infancy, and without addressing these fundamental issues the health care big data may not achieve its full potential. We conclude that to make it to the next level, we need a larger cohort of institutions to share more complete, precise, and time stamped data as well as with greater willingness to invest in technologies for de-identifying private patient data for it to be shared broadly for scientific research. At the same time, as more and more “big data” systems are developed, the scientific and regulatory communities need to figure out new ways of understanding causal relationship from data captured during routine health care, that would complement current gold standard methods such as RCTs as well as identify the relationship between clinical practice and outcomes, as there is a wide disparity in the quality of care across the country².

¹Claremont Graduate University, Claremont, California, USA; ²Loma Linda University, Loma Linda, California, USA

Abstract
Diet-related chronic diseases are on the rise. Current dietary management approaches are mostly calorie-counter tools that draw our attention away from the nutritional quality of our food choices. To improve consumers’ dietary behavior, we need a simple technique to educate them about nutrition and increase their understanding of the nutritional quality of their food. This study aims to design a dietary tool to promote a nutrient-dense diet. To this end, we applied the concept of Nutrient Profiling to classify food recipes based on their nutritional quality, by developing the Intelligent Nutrition Engine. This engine undergirds our mobile-based application, Easy Nutrition, which was designed to enable users to find food recipes and understand their nutritional quality. To evaluate the usability and understandability of our approach, we piloted the prototype of Easy Nutrition on 24 consumers. The results indicate that our approach provides a sustainable avenue to help consumers manage their diets.

Introduction
Diet-related chronic health conditions, such as diabetes, obesity, hypertension, and cardiovascular disease, present a major public health concern. As of 2014, more than one-third (36.5%) of U.S. adults are obese, according to the National Center for Health Statistics (2011-2014)¹. Two-thirds are overweight². These trends are spreading worldwide. According to a global WHO report from 2016, an estimated 422 million adults worldwide were living with diabetes, compared to 108 million in 1980. The global prevalence of diabetes has nearly doubled since 1980, as it had raised from 4.7% to 8.5%³. Furthermore, the American Diabetes Association reports that 29.1 million Americans (9.3% of the population) had been diagnosed with diabetes in 2012⁴. Another WHO report from 2004 on food and health in Europe states that diseases with major nutritional determinants account for 41% of disability-adjusted life years among all diagnosed diseases in Europe⁵. The root of the problem of all these conditions is a poor diet. Tackling this problem is by no mean easy and requires complex lifestyle changes. However, a healthy diet is a key component of a healthy lifestyle that can prevent the onset of these chronic diseases or mitigate their severity⁶.

Technology-tailored interventions to facilitate dietary management have been introduced in different formats, mainly through mobile-based applications (mHealth). Although evidence for the efficacy of mHealth is generally sparse⁷, research has shown that the use of the hand-held devices can improve the dietary intake of healthy food groups, such as whole grains and vegetables⁸. Also, the use of mHealth has the potential to reduce health costs, and to improve well-being in various ways, for instance, through the promotion of a healthy lifestyle by constant monitoring and self-management⁹,¹⁰. In their systematic review, Kroeze et al. conclude that there is sufficient evidence in favor of computer-tailored interventions for improving dietary behavior¹¹. These findings have also been supported by Long and colleagues in their review on the technology employed for dietary assessment¹². This suggests that mHealth may have a significant effect on individuals sustaining a healthy lifestyle.

Most of the current technology-tailored dietary tools deploy diet recalls and food records as the main dietary management approaches¹³,¹⁵. These approaches focus on the quantity of the food. That is, users are prompted to quantify the portion of the food that they consumed. One of the critical issues in this context is time. It is very tedious and time-consuming to track food intake. Another problem in addition to the time it takes to track food intake is the issue of recall⁶. Users have to sit down at least once a day, remember what they had eaten during the day in correct portions, and type in their food intake. Despite their effectiveness, these tools require performing some tasks that are unpractical to apply on a daily basis. Research suggests that too much detailed information on mobile-Phone may result in user being discouraged from using these tools¹⁶. The focus on food quantity with relation to the issues of time and recall has undermined the effectiveness of technology-tailored dietary tools.

The notion of nutrition profiling can alleviate these issues because it presents how healthy a food item is in a single holistic measure that is easy to follow and intuitive to understand. Nutrient profiling is defined as the science of
ranking foods according to their nutritional composition for reasons related to preventing disease and promoting health (WHO). By focusing on the food quality instead of the quantity, nutrient-profiling based systems aim to educate users about the overall nutritional quality that constitute a good or bad food choice. In light of this notion, systems such as Nuval (Nutritional Value) and ANDI (Aggregate Nutrition Density Index) have been developed to rank foods according to their nutritional quality. These systems have been tested, and widely accepted in the market landscape to rank food products based on their nutritional content.

This study aims to apply the concept of nutrient profiling in a mobile-based dietary application called Easy Nutrition. Easy Nutrition aims to increase consumers’ understanding about nutrition and raise their awareness about the nutritional value of the food recipes they choose. To rank different food recipes, we developed the Intelligent Nutrition Engine. This algorithm takes into account the three major macronutrients, two micronutrients and the number of calories the consumer needs daily. To present the nutritional quality of a particular food recipe in a simple, easy to understand manner, we adopted the notion of the traffic-light diet. The nutritional information is not given as a strict tri-color output. Rather, it is by analogy a color-coding food rating scale of eight values that rates the food recipe based on its nutrition from red (for less nutritious choices) to green (for nutritious choices).

While the goal of this study is to increase individuals’ understanding about nutrition and ultimately improve their dietary behavior by avoiding poor nutrition diets, the goal of this paper is to presents consumers’ feedback regarding our approach in presenting nutritional information. The rest of the paper is organized as follows. The literature will be reviewed from two perspectives. First we will investigate the state of dietary management and nutrition education to prevent the onset of chronic diseases. Second we will investigate the role of technology to facilitate this process. The method section will elaborate on the design science research, the approach we followed to develop the Intelligent Nutrition Engine and Easy Nutrition. This section will additionally outline the three-stage evaluation plan for my research, of which this paper represents the first stage. In the fourth section, the results of this stage (pilot study) will be illustrated and discussed in terms of the usability of Easy Nutrition and the understandability of its interfaces. Finally, we will conclude by arguing that our study contributes equally to both science and society. Our approach provides a new methodology (the Intelligent Nutrition Engine) to rank food and a dietary tool (Easy Nutrition) to help consumers better manage their diet by focusing the nutritional quality of their food choices.

Literature Review

Dietary Management

Managing diets is essential when it comes to treating diet-related chronic diseases. Furthermore, for healthy individuals, it is a preventative measure to maintain a healthy weight and overall wellbeing. Essentially, there are four different approaches to manage diets. These approaches encompass: dietary recall, food records, self-management and menu planning. In the first approach, the patient is asked over the phone about the amount of food, drinks consumed typically in a 24-hour period along with the method of preparation and the brand of the food items. Using food records, patients will have the chance do the same by writing this information down. In the self-management approach, personal digital assistant software is used. The patient will set some pre-defined goals on what quantities of food to consume. In this case, patients are in charge of how to keep their diets under control no matter what kind of food is consumed. The last approach is menu planning where patients get to have their meals planned based on previously identified food preferences. As the first three approaches are prone to the tediousness of counting and recording food intake multiple times a day, the focus in this study is to utilize the last approach, which is menu planning where users get to plan their meals after learning about their nutritional value.

Many studies have been conducted to develop and evaluate computerized dietary tools that are based on diet recall and food record. These two methods are designed as diet trackers and calories counter to assist individuals better manage their diet. However, the notion of calorie counting is very tedious and entails many issues from the patient’s perspective. First, the underlying method can suffer from recall issues, where users have to log their daily food intake. Examples of these food and calorie tracker apps include “MyFitnessPal”, “Lose It!”, or “Calorie Count” among many others. These apps allow users to log their food on a daily basis, define personal weight loss goals and review and analyze the gathered data against these goals. In this context, the second issue stems from a realistic limitation, which is the food database where users get to pick from. The quality of the food tracking/dairy app is tightly dependent on this underlying database. However, even the largest current food databases are still far from being complete and often contain only country-specific products. The notion of nutrition education or nutrition
profiling help mitigate these issues as it aims to educate patients about the underlying nutrients that constitute a good or a bad food choice.

**Nutrition Education**

To better manage diets and sustain a healthy lifestyle, one has to be aware and knowledgeable about the nutritional content in the food consumed. Being educated and aware of the macro nutrition and micro nutrition contributes to one’s overall health by minimizing poor nutrition diet. This leads to a healthy behavior that holds the promise of preventing the onset of chronic diseases and sustaining a healthy lifestyle. Diet education is effective to both understand diet requirements and control body weight and blood sugar levels. This is especially true when such educational material is delivered in an easy to follow, and convenient to understand manner. Indeed, knowledge-based nutrition education alone does not change dietary behavior. Behavioral nutrition education does a better job to change dietary behavior. The effectiveness of the behavioral nutrition approaches are investigated by Bader and her colleagues in. These approaches range from gaining familiarity with general nutrition principles, acquiring general planning frameworks, and finally planning tools to use meal replacements or prepared meals.

Bader and colleagues in their attempt to evaluate the effectiveness of nutritional education conducted a pilot study where they investigated one of the most preferred dietary management approaches: menu planning. The study targets type-2 diabetics. Authors conducted a single-arm clinical trial to evaluate one of the commercial internet-based menu planning tools. They examined pre- to post intervention changes in body weight, blood pressure, and glycaemia among overweight patients with T2DM (n=33). Nutritional recommendations were operationalized into weekly Internet-delivered menu plans. The findings indicate that there was 5% weight reeducation in 18% of the participants. The study highlights the effectiveness of the behavioral nutrition approaches that are less structured. These approaches range from gaining familiarity with general nutrition principles, acquiring general planning frameworks (eg, carbohydrate exchanges, “points”) and finally planning tools to use meal replacements or prepared meals.

**Nutrient Profiling**

Nutrient profiling is one of these behavioral nutrition approaches that do not dictate people what to eat or what not to eat. Rather, it aims at educating users about the overall nutritional quality of the food and leaving the choice of the meal to them. Nutritional profiling aims to rank food based on their nutritional content, as it is driven by the focus on food quality instead of food quantity. Individuals who follow high-scored food would most likely improve their dietary behavior. Simplicity is a key when it comes to presenting nutritional information. It has been suggested that nutritional information on mobile phones should be easy to read and understand. Approximate information is better than accurate facts that are harder to access but more precise. It was further suggested that the food information on phones should not be too fine-grained, as too much detailed information may result in user discouragement and little user friendliness. This stresses the idea that carb and calories intake counting used for dietary management has become less preferred in favor of a more generalized nutritional information about the quality of the food compositions. Nutrient profiling is the science of ranking foods according to their nutritional composition for reasons related to preventing disease and promoting health (WHO).

This idea has led to the creation of many nutritional rating systems. Examples of these systems include Nuval and ANDI. In addition, Leonard H. Epstein and his colleagues have developed the Traffic-Light Diet in the 1970’s. In this dietary approach, Epstein used a tri-color palette to create an easy-to-follow diet for overweight children. The notion of traffic-light diet had for two decades inspired new research due to its groundbreaking nature. The traffic-light diet is a structured eating plan that divides food by the color of the traffic signals. Green is for low-calorie food (go) that can be eaten at any time, orange (caution) is for moderate–calorie food that can be eaten occasionally, and red (stop) is for high-calorie food that should be eaten rarely. Since it was launched, the Traffic Light Diet has been used widely by pediatricians to encourage healthy eating habits among their patients. Many studies have been conducted utilizing the “Traffic-light” dietary approach and showed promising results. The Traffic Light Diet is used as a part of a comprehensive treatment, and the results show a significant decrease in obesity in preadolescents children. Significant changes in eating patterns have been reported when comprehensive obesity treatment has been combined with the Traffic-Light Diet. Reductions in “red foods” have been observed after treatment with significant associations between changes in intake of “red food” and weight loss or decrease in percent of
overweight. In our study, we adopted the dietary approach of Traffic Light Diet to present the nutritional information.

The Role of Technology

mHealth (short for mobile health) is a term for using mobile devices for health services and information. These devices can be mobile phones, patient monitoring devices, tablets, personal digital assistants, or other wireless devices. Although evidence for the efficacy of mHealth is generally sparse, research has shown that the use of the hand-held devices can improve the dietary intake of healthy food groups, such as whole grains and vegetables. Also, the use of mHealth has the potential to reduce health costs, and to improve well-being in various ways, for instance, through the promotion of a healthy lifestyle by constant monitoring and self-management. In their systematic review, Kroeze et al. conclude that there is sufficient evidence in favor of computer-tailored interventions for improving dietary behavior. These findings have also been supported by Long and colleagues in their review on technology employed for dietary assessment. This suggests that mHealth may have a significant effect on individuals sustaining a healthy lifestyle.

Method

Research Approach

This study follows the design science research approach, DSR, suggested by Hevner and Chatterjee. Alan and colleagues also present design science as a legitimate research paradigm to be employed in Information System research projects, where the goal is to solve practical problems. DSR aims to design IT-based artifacts to gain a better understanding of the problem in an iterative process. It involves the two main activities of building and evaluating. In this paper, we have developed two main artifacts. First is the Intelligent Nutrition Engine, the algorithm that is used to rank different food recipes based on their nutritional compositions. Second is Easy Nutrition, a mobile-based application that was designed to present how the algorithm performs to classify different food recipes. To ensure the utility and quality of these artifacts, we evaluated the prototype of Easy Nutrition for its usability and the understandability of its interfaces.

The Intelligent Nutrition Engine

We developed the Intelligent Nutrition Engine. This algorithm encompasses five different nutrients: the three major macronutrients that derive calories, which are fat, protein and carb and two micronutrients, which are dietary fibers and sodium. The algorithm checks the calories, the percentage of macronutrients, and also the amount of micronutrients in a selected recipe. These nutrients determine a healthful, or unhealthful choice. For people with diabetes, we consult the nutrition therapy recommendations by the American Diabetes Association to find the important nutrients that have to be considered, along with the appropriate limit for each nutrient. Some of these criteria have slight different specification for comorbid type-2 diabetes and hypertension. For example, the sodium recommendation for the general population is less than 2,300 mg/day. However for individuals with both diabetes and hypertension, further reduction in sodium intake should be individualized (no more than 1,500 mg/day). In addition, for comorbid T2D and hypertension, no more than 7% of fat should come from saturated fat. These criteria have been reviewed and validated by a registered dietician in Loma Linda university medical center. The list of these nutrients is outlined in Table 1.

<table>
<thead>
<tr>
<th>Macronutrients</th>
<th>Carbs</th>
<th>45 and 65 %</th>
</tr>
</thead>
<tbody>
<tr>

</tr>
<tr>
<td></td>
<td>For those with hypertension: No more 7% of this percentage should come from saturated fat</td>
<td></td>
</tr>
<tr>
<td>Protein</td>
<td>15 and 20 %</td>
<td></td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Micronutrients</th>
<th>Dietary fibers</th>
<th>20-30 grams</th>
</tr>
</thead>
<tbody>
<tr>
<td>Sodium</td>
<td>no more than 2300 mg</td>
<td></td>
</tr>
<tr>
<td></td>
<td>no more than 1500 mg daily for those with hypertension</td>
<td></td>
</tr>
</tbody>
</table>
Harris Benedict Equation

All these nutrition amounts/percentages are based off one’s daily calories intake. Because the recommended caloric intake differs based on age, gender, height and weight, we apply the Harris Benedict Equation to determine that basal metabolic rate (BMR) based on these factors (See Equation 1)

**Equation 1** Harris Benedict Equation

\[
\text{BMR for Men} = 66.47 + (13.75 \times \text{weight in kg}) + (5.003 \times \text{height in cm}) - (6.755 \times \text{age in years}) \\
\text{BMR for Women} = 655.1 + (9.563 \times \text{weight in kg}) + (1.850 \times \text{height in cm}) - (4.676 \times \text{age in years}).
\]

The final formula encompassing all these nutrients as well as the calories will produce one single holistic number that represent the overall nutritional quality of a particular recipe (Figure 1). For the sake of simplicity, we will present this number in a traffic-light scale that ranges from red to green through some intermediate colors. This is illustrated in Figure 1.

Figure 1. The nutritional score presented behind a traffic-light scale.

The cursor would start right in the middle of the traffic-light scale as an initial score for any given food recipe, as can be seen in Figure 1. The cursor would move to the right as a certain nutrient is within the recommended percentage/amount. On the other hand, the cursor would move to the left if a certain nutrient exceeds the maximum limit or fail to meet the minimum limit of the recommended range. This algorithm will be applied to Spoonacular, the largest online food API in order to rank different food recipes accordingly*

**Design of Easy Nutrition**

We developed an initial prototype of Easy Nutrition. Using Easy Nutrition, end-users will have the option to find online recipes that are tailored to their favorite cuisine and learn about their nutritional quality though our Intelligent Nutrition Engine. This algorithm will present the nutritional quality of the recipe in a traffic light scale as can be seen in Figure 2. This particular example shows that “Mahi Mahi Tacos” recipe is moderately unhealthy choice as the cursor is more toward the red indicator.

* Details of the algorithm and how it works can be requested from the first author (mayda.alrige@cgu.edu).
If the user is interested to know more about the nutrients that lower the overall nutritional quality, he/she can click on the “nutrition” tap to find out which nutrient is beyond the recommended range, as can be seen in Figure 3. Other pertinent information for each recipe is presented as well. These include the ingredients, instructions, and some healthy tips on how to maximize the nutritional value of the selected recipe.

Evaluation

Evaluation is a significant part of any design science research, to ensure the artifact(s) utility, efficacy and quality. To this end, we evaluated Easy Nutrition from a socio-technical perspective in a three-stage plan. The present study conducted the first stage of the evaluation plan, which is a pilot study to test the usability and understandability of our approach represented in Easy Nutrition. Put differently, in the first stage, the goal is to test whether or not presenting the nutritional quality in a traffic-light scale appeals to consumers and motivates them to select healthier, more nutrient-dense recipes. Since this stage is a pilot study, we intended to obtain participants’ feedback for improvement. Once we have established that the technology is sufficient to be employed, we will finalize the full version of Easy Nutrition and evaluate it in the second stage. The second stage aims to test Easy Nutrition as an enabling tool to help users increase their knowledge and understanding of the nutritional quality of their food and hence improve their dietary behavior. Based on participants’ answers to the questions related to their dietary behavior questions, we will generate a healthy behavior score. This score will be used as a baseline for post comparison. An increase in this score suggests improving in the dietary behavior in a pre-post intervention study. In the third stage, we will test Easy Nutrition effect in managing diabetes. In this paper, we will present the results of the first stage.

Participants

The first stage targets adults both with and without diet-related chronic conditions to evaluate the usability and understandability of our approach. The inclusion criteria are basic familiarity with smartphones so they can navigate through the app. This study is conducted in compliance with the ethical principles of Institutional Board or Review (IRB), at Claremont Graduate University.

Intervention: Procedures and Measures

Users were asked to perform basic tasks on the prototype of Easy Nutrition so they grasp an idea of what it is like to present the nutritional information in a traffic-light scale. After navigating through the app, participants were asked to answer a set of questions about Easy Nutrition usability. The System Usability Scale is utilized for this purpose.
SUS is a reliable and valid instrument used for usability assessment. It is a 10-item questionnaire that has five response options (strongly agree to strongly disagree). Prior research suggests that a SUS score above 68 is considered above average and that the website or mobile-app under investigation is usable. On the other hand, anything below 68 has to go under a lot of improvement to increase its usability. To obtain the SUS score, we followed the instructions of interpreting a participant’s score for each question that ranges from 1 (for strongly disagree) to 5 (for strongly agree). We added all the converted scores for the 10 questions for all the participants. Then, we divided this number by 24 (number of participants) and finally multiplied it by 2.5 to convert the original scores to 100-point scale.

In addition, in order to assess user satisfaction with the way we are presenting the nutritional quality of a recipe, we adopted the QUIS instruments. QUIS is the Questionnaire for User Interaction Satisfaction. QUIS aims to gauge users’ subjective satisfaction with specific aspects of the human-computer interface, such as screen visibility, terminology, system feedback and learning factors. Each area measures the users’ overall satisfaction with that facet of the interface on a 9-point scale. The questionnaire is designed to be configured according to the needs of each interface analysis by including only the sections that are of interest to the researcher.

Our goal is to capture users’ reaction mainly to the way the nutritional information is presented. We utilized the latest version of QUIS, in particular version 7.0 (the short form). Specifically, we used three measures out of nine: screen, terminology and users’ overall reaction to the application. As this is a pilot study, we concluded our survey with four open-ended questions to obtain users feedback regarding Easy Nutrition and the way we present nutritional information in a traffic-light scale.

**Results**

We utilized the Email channel to invite individuals to participate. Out of 50 recipients, about 6 participants have partially completed the survey, and 24 have fully completed the survey. 5 out of 24 participants have been diagnosed with diet-related condition, 2 are pre-diabetics, 2 are diabetics, and one had previously been diagnosed with Cancer (Figure 4).

![Figure 4](image)

**Figure 4** The number of participants with diet-related health condition

**Usability**

After navigating through the prototype of Easy Nutrition, participants were directed to an online survey, which asked them about the usability of Easy Nutrition. As mentioned above, we utilized the System Usability Scale (SUS). The usability score of Easy Nutrition came to 71.13. This is a good indicator that Easy Nutrition fits the context of dietary management and is appropriate to use in this context.

---

1 For a full list of the questions, please contact the first author at (mayda.alrige@cgu.edu).
Users’ Satisfaction

To capture participants’ subjective satisfaction, we asked them questions about their experience interacting with Easy Nutrition. For this purpose, we utilized the QUIS instrument, which asks questions about the app screens, terminologies and users’ overall reaction to the interfaces. As opposed to SUS, QUIS is a diagnostic tool, which means it provides a basis for improvement. This is because it asks very detailed questions about all the elements that make up the app interface, such as messages, characters, highlights, screen layouts, and sequence of screens. Participants in this study were totally satisfied with all interfaces relevant aspects in Easy Nutrition including the way we present the nutritional quality of the recipe in a traffic-light scale. Figure 5 and Figure 6 illustrate users’ satisfaction on 9-point scale.

One of the useful feedback comments we have obtained is to use some labels (e.g. “nutrient-dense” vs. “poor nutrition”) in the traffic-light scale that is used to represent the nutritional quality of the food recipe. The participant’s comment states that, “in order for Easy Nutrition to reach its full potential, I recommend adding some brief labels in conjunction with the scale”. We will consider such feedback when developing the full-version of Easy Nutrition for the second stage of this research. We will address this by labeling the traffic-light scale to range from poor nutrition (by the red side) to excellent nutrition (by the green side).

Discussion and Conclusion

The current study applies the concept of nutrient profiling on the domain of dietary management to help consumers gain a better understanding of the nutrition in their food and maximize the nutritional value of their choices. To this end, we have developed an algorithm, the Intelligent Nutrition Engine, to produce a single nutritional indicator of the food recipe. This algorithm takes into account the amount of calories, carbs, fat, protein, sodium and fibers. The Intelligent Nutrition Engine works by comparing the amount/percentages of these nutrients in a recipe against the recommended range. We applied this algorithm to rate some food recipes and present their nutritional quality in a traffic-light scale. To test the usability and understandability of this approach, we developed and piloted a mobile-based application called Easy Nutrition. We evaluated Easy Nutrition for its usability and understandability of its interfaces in a small sample size of 24 participants. The results of this pilot study show that Easy Nutrition is usable,
and that all of its interfaces are easy to understand. In addition, the feedback we obtained from these consumers gave us some basis for improvement.

This research contributes to the body of knowledge in two different levels: to the society and to the science. The first level of contribution is presented to the society as a nutrition-based dietary tool, called Easy Nutrition. Easy Nutrition presents the nutritional content of different food recipes in a traffic-light scale. The nutritional information is better absorbed if they are presented in a practical, easy to follow and easy to understand manner. The second and more important level of contribution is presented to the science as a new method for nutrition education. This is the Intelligent Nutrition Engine that is used to rank food recipes based on their nutritional quality. Nutrition education is a key component when it comes to dietary management. Thus, it is very important to find a simple, intuitive mechanism to present nutritional information. Our algorithm is based on the notion of behavioral nutrition approaches stressed by Bader and her colleagues23. The notion behind behavioral nutrition approaches is to increase the likelihood that individuals will implement the nutritional strategy learned. With Easy Nutrition, we don’t offer general nutritional information. Rather, the nutritional information is presented through individual recipes in a practical19 manner. This study can add to the evidence base that nutritional behavior strategies may be a modern adjunct to diabetes (or any other diet-related chronic condition) dietary management. Our study suggests that Easy Nutrition may have some beneficial effects to improve the dietary behavior of consumers.

In addition, the steps of this algorithm can be viewed as a set of design principles. The algorithm can be tailored to tackle different health conditions. Both the nutrients and the criteria for each nutrient can be tailored according to the health condition being treated. For example, cardiovascular diseases have certain nutrition therapy recommendations that are slightly different than those for diabetics. While diabetes management give priority to carbs consumption, CVD gives a special attention to fat consumption. The selection of the nutrients and the criteria for each nutrient can be adjusted to target different diet-related health conditions.

Abstract

The aim of this study is to utilize the Defense and Veterans Eye Injury and Vision Registry clinical data derived from DoD and VA medical systems which include documentation of care while in combat, and develop methods for comprehensive and reliable Open Globe Injury (OGI) patient identification. In particular, we focus on the use of free-form clinical notes, since structured data, such as diagnoses or procedure codes, as found in early post-trauma clinical records, may not be a comprehensive and reliable indicator of OGIs. The challenges of the task include low incidence rate (few positive examples), idiosyncratic military ophthalmology vocabulary, extreme brevity of notes, specialized abbreviations, typos and misspellings. We modeled the problem as a text classification task and utilized a combination of supervised learning (SVMs) and word embeddings learnt in an unsupervised manner, achieving a precision of 92.50% and a recall of 89.83%. The described techniques are applicable to patient cohort identification with limited training data and low incidence rate.

Introduction

Open globe injury (OGI) refers to full thickness wound of the eyeball. OGIs range from small and self-sealing penetrations or lacerations to globe rupture with prolapse of intraocular contents or obliteration of the whole globe. The Birmingham Eye Trauma Terminology (BETT)1 defines and classifies OGIs as shown in Figure 1.

OGIs are considered a major cause of significant loss of vision, blindness and/or total loss of the eye. Given the possibility of such catastrophic outcomes, OGI treatment, outcomes, and risk factors are an active field of research, for example2–9. OGI clinical research poses challenges, as such injuries are typically rare. It has been reported that in the US, penetrating eye injury accounts for 3.81 injuries per 100 000 injuries annually10. In the context of military operations, however, the occurrence of OGI is more prevailing. Eyes injuries make up a significant portion of all casualties experienced in battle by our service members and veterans. OGIs are a significant number of these. Furthermore, unlike in peacetime where unilateral injuries are the rule, ocular war injuries are bilateral in 15 to 25% of cases11.

In this study, we utilize the Defense and Veterans Eye Injury and Vision Registry (DVEIVR), a web-based application, to develop methods for comprehensive and reliable OGI patient cohort identification. Congressionally mandated, DVEIVR was established to longitudinally track diagnosis, surgical intervention or other procedures, other treatments and follow up of active Service members and Veterans with significant eye and vision injuries from point of injury through rehabilitation starting 9/11/2001 and forward12. The DVEIVR registry includes abstracted data derived from initial battlefield acute care and subsequent definitive care encounters. The goal of DVEIVR is to aid researchers and providers in discovery of post-injury care pathways designed to prevent vision related injuries, protect and preserve the visual system, and restore vision. The DVEIVR data provided for the study is de-identified and complies with the DoD Privacy Office requirements, therefore exempted from IRB review.

In the context of DVEIVR, structured patient data can be used to somewhat reliably identify OGI patients. For example, ICD9 Diagnosis Codes 871.1 (Ocular laceration with prolapse or exposure of intraocular tissue), 360.61 (Foreign body in anterior chamber), etc. or Exam Types Globe - Anophthalmic, Globe - IOFB are reliable indicators of OGI. However, structured data is not always a comprehensive indicator of OGIs3. Diagnosis Codes can be ambiguous.
Figure 1: The BETT Classification of Open Globe Injuries.

and used to describe both OGI and closed globe injuries. Furthermore, codes and structured data in early post-trauma clinical records could be inaccurate for a number of practical reasons. We have observed a number of OGI incidents identified only in free-form text (clinical notes). The following brief notes are all clear indicators of the presence of an OGI:

**HISTORY OF PRESENT ILLNESS:** ruptured right globe in 2004 with a metal FB going through nasal right cornea through lens and into the vitreous. Pt underwent vitrectomy and phaco iol surgery right eye in 2006

**CHIEF COMPLAINT TEXT:** EYE TRAUMA INTRAOCULAR FOREIGN BODY

**ENCOUNTER COMMENT:** SPECIFY: Other (GLOBE EXPLORATION ); FINDINGS: EBL ¡0.1 CCNO GLOBE WALL PENETRATION AND DISRUPTION NOTED WITH THROUGH EXPOSURE AND EXPLORATION

In such cases, structured data could be missing (e.g. no ICD9 Diagnosis Code), the ICD9 Code used could include eye injuries referring to both OGI and non-OGI instances, e.g. 871.4 (Unspecified laceration of eye), 369.9 (Unspecified visual loss), or the code may have been incorrectly selected (e.g. a foreign body coded as *intraocular* with an associated free text treatment comment that the foreign body was removed using a *q-tip*, inferring the wound was actually superficial).

Given the importance of identifying all available OGI patients, we explored the use of Natural Language Processing and Machine Learning (ML) to identify OGI patients from clinical notes. The nature of the notes poses a number of challenges: the notes are typically very short, abundant in domain-specific concepts (ophthalmology in the context of warfare and veteran care), with a high rate of abbreviations and typos. The described techniques are applicable, in general, to patient cohort identification with challenging datasets, limited training data, and low incidence rates.

**Dataset**

The dataset consists of de-identified patient data from the DVEIVR database exported in May 2016. It comprises of both structured and unstructured fields describing diagnoses, treatments, procedures, visits, and exams. The data contains 26,131 unique patients and 76,809 unique encounters.

We utilized the available structured OGI information to semi-automatically generate a training data set. Tables 1 and 2 list structured information values found to be reliable indicators of OGI patients. All free-form text fields associated with structured OGI information were identified and labeled as positive examples. A randomized sample of the remaining records was used as negative examples. As descriptive free-form text associated with OGI structured data does not always indicate OGI by itself, the positive dataset was manually reviewed and false positive examples were discarded. This resulted in a training dataset consisting of 1,645 free-form text notes indicating OGI (positive examples) and 10,732 negative examples.

The characteristics of the training dataset poses a number of challenges. First, the number of positive examples is small for the purposes of text classifications. In addition, individual examples are typically very short. The median

The number of words per example is only 7. Furthermore, as in most clinical texts, abbreviations, spelling variations, typos, and misspellings are quite common. All these factors contribute to a relatively large vocabulary size, while at the same time both the number of positive examples and the number of words per example are relatively small. Lastly, the vocabulary of the military ophthalmology domain is distinctive from general-domain clinical notes and doesn’t quite fit general purpose medical ontologies and terminologies.

**Method and Results**

We modeled the task as a binary classification of free-form clinical notes. It has been shown that Support Vector Machines\(^\text{14}\) achieve superior results in most text classifications tasks, including short texts (e.g.\(^\text{15,16}\) ). SVMs were selected as a sensible first choice. The individual clinical notes were represented as a bag of words (1-grams)\(^2\). The tokens were all converted to lower case and non-alphabetic characters were discarded. In addition, tokens that are present in more than 50% of all documents or less than 3 times across all documents were also discarded. This resulted in a dictionary of size 4,032 unique tokens. Tokens were weighted using the term-frequency / inverse-document-frequency scheme (tf-idf). We performed 10-fold cross-validation using linear kernel SVMs. We increased the positive class weight to address the unbalanced dataset (fewer positive examples). Best results achieved with positive class weight of 2. This resulted in a precision of 90.25 and a recall of 87.78 as shown in Table 3.

While the available positive training data is quite limited, it seemed sensible to attempt to utilize all available free-form text notes from all 76,809 patient encounters. Word embeddings\(^\text{18,19}\) have gained popularity as a way of capturing semantic knowledge of words without relying on available training data. Unsupervised algorithms have also been

\(^2\) Including bi-grams slightly deteriorated the model performance, a behaviour not atypical for text classification tasks\(^\text{17}\).
Table 2: List of Exam Detail Types used as reliable indicators of Open Globe Injuries.

| Exam Detail Types                                      | Used to represent variable pieces of texts such as sentences and paragraphs as fixed-length feature representations (Paragraph Vectors) \textsuperscript{20}. Studies have shown that Paragraph Vectors outperform bag-of-words models on a number of text classification tasks \textsuperscript{20, 21}. We used the free-text notes from all patient encounters to train Paragraph Vectors. The paragraph vectors the training notes were then fed to a logistic regression classifier and a neural network. In both cases results significantly under-performed the bag-of-words model. The underperformance of Paragraph Vectors is possibly due to the idiosyncrasies of the data: short text snippets, occasionally providing information on several, not necessarily related topics.

However, word embeddings revealed to be a powerful source of identifying semantically related abnormalities and procedures, variant spellings, abbreviations, and typos. Given the rare occurrence of OGIIs, the intuition was that identifying all possible tokens expressing key OGI concepts would improve our model performance. Using all available free-form text, we generated word vectors for all words in the vocabulary \textsuperscript{3}. The words in the training set were then clustered using Agglomerative Clustering. The average cosine distance between word vectors was used as a measure of similarity between clusters. The automatically derived clusters revealed to accurately capture related vocabulary words. Table 4 shows samples of word clusters derived with the described approach. The samples show that word embeddings accurately captured semantically related concepts (e.g. Cluster 7 lists various antibiotics); abbreviations

\textsuperscript{3}We used word skip-gram model, vectors of size 400, and window of size 4.

Lastly, we addressed the issue of negation (e.g. \textit{no globe rupture}) as negated conditions and procedures are quite common in the dataset. We ran a customized version of the NegEx\textsuperscript{22} algorithm to identify negated words and phrases. Encoding negated tokens in a bag-of-words model as separate token (e.g. \textit{rupture} vs \textit{no rupture}) is a common approach to treating negation. However, given the limited dataset and the large vocabulary size, we instead simply discarded the negated tokens.

We again performed 10-fold cross-validation using linear kernel SVM and positive class weight set to 2. Both precision and recall increased from 90.25 to 92.50 and from 87.78 to 89.83, respectively, while the vocabulary size was reduced significantly.

Related Work

There is a vast amount of literature on the use of free-form text and clinical notes for the purposes of patient cohort identification. A review of approaches to identifying patient phenotype cohorts using electronic health records\textsuperscript{23} describes a number of studies using clinical notes, most often in combination with additional structured information, such as diagnosis codes. The study asserts that clinical notes are often the only source of information from which to infer important phenotypic characteristics.

Most studies map textual elements to standard vocabularies, such as the Unified Medical Language System (UMLS). For example, Bejan et al.\textsuperscript{24} describe a system for pneumonia identification from narrative reports using n-grams, UMLS concepts, and assertion status. Similarly, Elkin et al.\textsuperscript{25} encoded radiology reports using the SNOMED CT Ontology and developed a set of rules to identify pneumonia cases. Carroll et al.\textsuperscript{26} used as features a combination of ICD-9 codes, UMLS concepts, and medication names and build an SVM classifier for the identification of rheumatoid arthritis patients.
A number of studies use rules, such as keywords and regular expressions, to identify the phenotype of interest. Friedlin et al. compare methods for identifying pancreatic cancer patients and utilize a tool that uses a combination of regular expressions and algorithms to detect keywords and their context. Xu et al. develop a system to detect patients with colorectal cancer that uses a combination of heuristic rule-based approach and the MedLEE system to extract relevant concepts. Sohn and Savova improve the Mayo Clinic Smoking Status Classification System by introducing a rule-based component for patient-level smoking status assignments.

A growing number of studies utilize the use of Machine Learning (ML) on the task of patient cohort identification from clinical narratives. The i2b2 (Informatics for Integrating Biology to the Bedside) project organized a challenge with the task of determining the patient smoking status from free-form discharge notes. The 11 participating teams utilized a variety of rule-based and ML approaches, including Naive Bayes, Decision Trees, AdaBoost classifiers, logistic regression, and neural networks. The most common ML algorithm was SVMs, as reported by 5 participating teams. The ShARe/CLEF eHealth 2013 task was organized to evaluate the state of the art in disorder recognition and normalization of the clinical narrative. Most of the participating systems employed hybrid approaches by supplementing features to a machine-learning algorithm and the best performing system utilized Conditional Random Fields and Structured SVMs. Lin et al. develop a system for automatic prediction of rheumatoid arthritis disease activity from the Electronic Medical Records (clinical narratives and lab values). They report that the best performing combination was linear kernel SVMs with UMLS concepts, feature selection, and lab values. Rumshisky et al. utilize Latent Dirichlet Allocation and SVMs to predict early psychiatric readmission from narrative discharge summaries.

Conclusion

We demonstrated an approach to identifying rare patient phenotypes (OGIs) utilizing free-form text in a challenging domain: military ophthalmology. The characteristics of the clinical narratives include extreme brevity, idiosyncratic terms and abbreviations, typos and misspellings. Using available structured data, we were able to construct a free-text training dataset with minimal manual review. We then employed supervised Machine Learning methods for classification of clinical notes. Best results were achieved utilizing clustering of the vocabulary (unigrams) using word embeddings and performing SVM classification by increasing the weight of the positive class to account for the imbalanced dataset. We were able to achieve an overall F1-score of 91.14. The described methods are applicable to short clinical text classification in narrowly specialized domains.

Abstract

Radiology reports are a rich resource for advancing deep learning applications in medicine by leveraging the large volume of data continuously being updated, integrated, and shared. However, there are significant challenges as well, largely due to the ambiguity and subtlety of natural language. We propose a hybrid strategy that combines semantic-dictionary mapping and word2vec modeling for creating dense vector embeddings of free-text radiology reports. Our method leverages the benefits of both semantic-dictionary mapping as well as unsupervised learning. Using the vector representation, we automatically classify the radiology reports into three classes denoting confidence in the diagnosis of intracranial hemorrhage by the interpreting radiologist. We performed experiments with varying hyperparameter settings of the word embeddings and a range of different classifiers. Best performance achieved was a weighted precision of 88% and weighted recall of 90%. Our work offers the potential to leverage unstructured electronic health record data by allowing direct analysis of narrative clinical notes.

1 Introduction

The Picture Archiving and Communication Systems (PACS) stores a wealth of unrealized potential data for the application of deep learning algorithms that require a substantial amount of data to reduce the risk of overfitting. Semantic labeling of data becomes a prerequisite to such applications. Each PACS database serving a major medical center contains millions of imaging studies “labeled” in the form of unstructured free text of the radiology report by the radiologists, physicians trained in medical image interpretation. However, the unstructured free text cannot be directly interpreted by a machine due to the ambiguity and subtlety of natural language and variations among different radiologists and healthcare organizations. Lack of labeled data creates data bottleneck for the application of deep learning methods to medical imaging\textsuperscript{1}.

In recent years, there is movement towards structured reporting in radiology with the use of standardized terminology\textsuperscript{2}. Yet, the majority of radiology reports remain unstructured and use free-form language. To effectively “mine” these large free-text data sets for hypotheses testing, a robust strategy for extracting the necessary information is needed. Methods for structuring and labeling the radiology reports in the PACS may serve to unlock this rich source of medical data.

Extracting insights from free-text radiology reports has been explored in numerous ways. Nguyen et al.\textsuperscript{3} combined traditional supervised learning methods with Active Learning for classification of imaging examinations into reportable and non-reportable cancer cases. Dublin et al.\textsuperscript{4} and Elkin et al.\textsuperscript{5} explored sentence-level medical language analyzers and SNOMED CT-based semantic rules respectively, to identify pneumonia cases from free-text radiological reports. Huang et al.\textsuperscript{6} introduced a hybrid approach that combines semantic parsing and regular expression matching for automated negation detection in clinical radiology reports.

In recent years, the word2vec model introduced by Mikolov et al.\textsuperscript{7,8} has gained interest in providing semantic word embeddings. One of the biggest problems with word2vec is the inability to handle unknown or out-of-vocabulary (OOV) words and morphologically similar words. The challenge is exacerbated in domains, such as radiology, where synonyms and related words can be used depending on the preferred style of radiologist, and a word may only have been used infrequently in a large corpus. If the word2vec model has not encountered a particular word before, it will be forced to use a random vector, which is generally far from its ideal representation. Thus, we explore how the word2vec model can be combined with the radiology domain-specific semantic mappings in order to create a legitimate vector representation of free-text radiology reports. The application we have explored is the classification of reports by confidence in the diagnosis of intracranial hemorrhage by the interpreting radiologist.
Our two core contributions are:

1. We proposed a hybrid technique for a dense vector representation of individual words of the radiology reports by analyzing 10,000 radiology reports associated with computed tomography (CT) Head imaging studies. (Word embeddings are publicly released in: https://github.com/imonban/RadiologyReportEmbedding)

2. Using our methods, we automatically categorized radiology reports according to the likelihood of intracranial hemorrhage.

We derived the word embeddings from large unannotated corpora that were retrieved from PACS (10,000 reports), and the classifiers were trained on a small subset of annotated reports (1,188). The proposed embedding produced high accuracy (88% weighted precision and 90% recall) for automatic multi-class (low, intermediate, high) categorization of free-text radiology reports despite the fact that the reports were generated by numerous radiologists of differing clinical training and experience. We also explored the visualization of vectors in low dimensional space while retaining the local structure of the high-dimensional vectors, to investigate the legitimacy of the semantic and syntactic information of words and documents. In the following sections, we detail the methodology (Sec. 2), present the results (Sec. 3) and finally conclude by mentioning future directions (Sec. 4).

2 Methodology

Figure 1 shows the proposed research framework that comprises five components: Dataset retrieval from PACS, Data Cleaning & Preprocessing, Semantic-dictionary mapping, Word and Report Embedding, and Classification. In the following subsections, we describe each component.

![Figure 1: Components of the proposed framework](image)

### 2.1 Dataset

The dataset consists of the radiology reports associated with all computed tomography (CT) studies of the head located in the PACS database serving of our adult and pediatric hospitals and all affiliated outpatient centers for the year of 2015. Through an internal custom search engine, candidate studies were identified on the PACS server based on imaging exam code. The included study codes captured all CT Head, CT Angiogram Head, and CT Head Perfusion studies. A total of 10,000 radiology reports were identified for this study. In order to provide a gold standard reference for the vector-space embedding algorithm, a subset of 1,188 of the radiologic reports were labeled independently by two radiologists. For each report, the radiologists read the previous interpretation and then graded the confidence of the interpreting physician with respect to the diagnosis of intracranial hemorrhage. For each study, a numeric label was provided on a scale ranging from 1 to 5 with labels as follows: 1) No intracranial hemorrhage; 2) Diagnosis of intracranial hemorrhage unlikely, though cannot be completely excluded; 3) Diagnosis of intracranial hemorrhage possible; 4) Diagnosis of intracranial hemorrhage probable, but not definitive; 5) Definite intracranial hemorrhage. These labels were chosen to reflect heuristics employed by radiologists and treating physicians to interpret the spectrum of information produced by the imaging study.
2.2 Data Cleaning & Preprocessing

All 10,000 radiology reports were transformed through a series of pre-processing steps to truncate the free-text radiology reports and to focus only on the significant concepts, which would enhance the semantic quality of the resulting word embeddings. We developed a python-based text processor - Report Condenser, that executes the pre-processing steps sequentially. First, it extracted the ‘Findings’ and ‘Impressions’ sections from each report that summarizes the CT image interpretation outcome, since our final objective was to classify the reports based on radiological findings.

In the next pre-processing stage, the Report Condenser cleansed the texts by normalizing the texts to lowercase letters and removing words of following types: general stop words, words with very low frequency (<50), unwanted terms and phrases (e.g. medicolegal phrases - “I have personally reviewed the images for this examination and agreed with the report transcribed above.”, headers - ‘FINDINGS’, ‘IMPRESSION’, ‘Additional comment’). These words usually appear either in all the reports or in a very few reports, thus of little or no value in document classification. We used the NLTK library for determining a stop-word list and discarded them during indexing. Examples of the stop-words are: a, an, are,...,be, by,...,has, he,...,etc. The Report Condenser also discarded datestamps, timestamps, the radiologist details (e.g. names, contacts) and other recurring phrases in reports. Removal of these terms significantly reduced the number of words that the system had to handle.

Following the removal steps, Report Condenser searched the updated corpus to identify frequently appearing pairs of words based on pre-defined threshold value of occurrence (> 500) and concatenated them into a single word to preserve useful semantic units for further processing. Some examples of the concatenated words are: ‘midline shift’ → ‘midline shift’, ‘mass effect’ → ‘mass effect’, ‘focal abnormality’ → ‘focal abnormality’.

In the next step, Report Condenser identified and encoded negation dependencies that appear in the radiology reports via simple string pattern matching. For example, in the phrase ‘No acute hemorrhage, infarction, or mass’, negation is applied to ‘acute hemorrhage’, ‘infarction’ as well as ‘mass’. Therefore, the Report Condenser encodes the negation dependency as: ‘No acute hemorrhage’, ‘No infarction’, ‘No mass’. Such phrases were identified automatically by analyzing the whole corpus and transformed accordingly.

2.3 Semantic-dictionary mapping

The main idea of the Semantic-dictionary mapping is to use a lexical scanner that recognizes corpus terms which share a common root or stem with pre-defined terminology, and map them to controlled terms. In contrast with traditional NLP approaches, this step does not need any sentence parsing, noun-phrase identification, or co-reference resolution. We used dictionary style string matching where we directly search and replace terms, by referring to the dictionary. We implemented a lexical scanner in python which can handle 1 kilobyte of text per millisecond. On average, the size of each radiology report after cleaning was 1 kilobyte and our scanner took less than 10 seconds to complete the whole mapping process for 10,000 radiology reports. We applied the following two-stage process.

1. Common terms mapping: First, we used the more general publicly available CLEVER terminology to replace common analogies/synonyms for creating more semantically structured texts. We focused on the terms that describe family, progress, risk, negation, and punctuations, and normalized them using the formal terms derived from the terminology.

2. Domain-specific dictionary mapping: For this case-study, we used the domain-specific RadLex ontology for mapping the variations of radiological terms that are related to hemorrhage, to a controlled terminology. We created an ontology crawler using SPARQL that grabs the sub-classes and synonyms of the domain-specific terms from Radlex, and creates a focused dictionary for “Intracranial hemorrhage” radiology reports. Using the dictionary all the equivalent terms of hemorrhage are formalized in the corpus as: {‘apoplexy’, ‘contusion’, ‘hematoma’, .. } → ‘hemorrhage’.

413
In Figure 2, we present the outcome of preprocessing and dictionary mapping by showing free-text reports and the corresponding processed texts side-by-side. In our corpus, average word count of original free-text reports is 285 and the average word count of processed reports is 98, which is approximately 3x reduction in size.

### 2.4 Word and Report Embedding

After pre-processing and dictionary mapping, the corpus of 10,000 processed reports (see examples in Figure 2) was used to create vector embeddings for words in a completely unsupervised manner using the word2vec model that can be trained on a large text corpus to produce dense word vectors. Two unsupervised algorithms were introduced to obtain word to vector representation: Continuous Bag of Words (CBOW) and Skip-gram. Those algorithms learn word representations that maximize the probabilities of a word given other contextual words (CBOW) and of a word occurring in the context of a target word (Skip-gram).

Our semantic dictionary mapping step considerably reduced the size of our vocabulary by mapping the words in corpus to their root terms, thereby making the words in the vocabulary more frequent. CBOW is several times faster to train than the Skip-gram, with slightly better accuracy for frequent words. The CBOW architecture also captures the semantic regularities of words. Thus, CBOW approach appeared to be more suitable to be integrated into our framework, and, as expected, results of preliminary experiments with Skip-gram and CBOW showed CBOW to be the better performing model.
We first constructed a vocabulary from our pre-processed tokenized corpus that contains 10,000 free-text radiology reports, and then learned vector representations of words in the vocabulary. We build our predictive model using the Gensim 2.1.0 library\(^\text{12}\). The CBOW word2vec model predicts a word given a context where context is defined by the window size. The loss function of CBOW is: \( E = -v_{w_o} \cdot h + \log \sum_{j=1}^{V} \exp(v_{w_j} \cdot h) \), where \( w_o \) is the output word, \( v_{w_o} \) is its output vector, \( h \) is the average of vectors of the context words, and \( V \) is the entire vocabulary. Once the model constructs the vectors, we can use the cosine distance of vectors to denote similarity, thereby deriving analogies. The resulting word vectors can be used as features in many natural language processing and machine learning applications.

As the training algorithm, we used both Hierarchical Softmax as well as Negative Sampling. Based on preliminary results, we found Negative Sampling to be better training algorithm. Mikolov et al.\(^\text{8}\) also described Negative Sampling as the method that results in faster training and better vector representations for frequent words, compared to more complex hierarchical softmax. The cost function of Negative Sampling is: \( E = -\log \sigma(v_{w_o} \cdot h) - \sum_{w_j \in \omega_{neg}} \log \sigma(-v_{w_j} \cdot h) \), where \( \omega_{neg} \) is the set of negative samples, \( w_o \) is the output word, \( v_{w_o} \) is its output vector and \( h \) is the average of vectors of the context words.

Finally, the document vectors were created by simply averaging the word vectors created through the trained model. According to Kenter et al.\(^\text{13}\), averaging the embeddings of words in a sentence has proven to be a successful and efficient way of obtaining sentence embeddings. Each document vector was computed as: \( v_{doc} = \frac{1}{||V_{doc}||} \sum_{w \in V_{doc}} v_{w} \), where \( V_{doc} \) is the set of words in the report and \( v_w \) refers to the word vector of word \( w \).

### 2.5 Visualization of the embeddings

Our idea is to visualize the vector representation of words and documents to validate the semantic quality of the embeddings in two different levels. In the first level, the visualization of the trained individual word embeddings can verify the positioning of synonyms (and related words), antonyms and other word-to-word relations, and can show at the very low scale that if our vector embedding is able to preserve legitimate semantics of the natural words and clinical terms. Second, the visualization of the document vectors can fulfill the purpose of analyzing the proximity of documents that have different levels of likelihood of intracranial hemorrhage. If the documents corresponding to the same class (risk) appear close to each other and form clusters, we can infer that our embedding can be useful to boost the performance of any standard classifier.

Our trained embeddings are expected to be high dimensional and may lie near a low-dimensional, non-linear manifold. Therefore, standard linear dimensionality reduction techniques (e.g. Principal Component Analysis) are not well-suited for preserving the distance between similar data points in low-dimensional representation of the vector space. We adopted t-Distributed Stochastic Neighbor Embedding (t-SNE) technique\(^\text{14}\) to visualize the trained embeddings using sklearn python library. t-SNE is a technique for dimensionality reduction that is particularly well suited to serve our application since it is capable of capturing much of the local structure of the high-dimensional data very well, while also revealing global structure such as the presence of clusters at several scales. It employs Gaussian kernel in the high-dimensional space and defines a soft border between the local and global structure of the data. For pairs of data points that are close to each other relative to the standard deviation of the Gaussian, t-SNE determines the local neighborhood size for each data point separately based on the local density of the data. We describe the results of t-SNE visualization of word and document vectors in the following section (Sec. 3.2).

### 2.6 Classification

In this study, the resulting document vectors were used as features to develop a computerized hemorrhage likelihood assessment system that aims to assign a ‘risk’ label to the free-text radiology reports while being trained on the subset of reports with the ground truth labels created by the experts (see Sec. 2.1). We observed that our dataset had imbalanced distribution of training data, i.e. class 2, 3, and 4 had fewer instances than class 1 and 5. Thus, we grouped classes 2-4, and re-defined the class labels to ensure variation of the likelihood of intracranial hemorrhage as: (1) ‘no risk’ - no intracranial hemorrhage; 2) ‘medium risk’ - probability of having intracranial hemorrhage; (3) ‘high risk’- definite diagnosis of intracranial hemorrhage. The re-definition of the class labels were validated by forming a mutual agreement between the two expert radiologists. In Table. 1, we show the number of examples per class for
the final three categories. To quantify the performance of the classifier, the 1,188 annotated reports were randomly divided into 80% training set (950 reports) and 20% test set (238 reports). To demonstrate the true power of our vector embedding, we performed experiments using three classifiers - Random Forests, Support Vector Machines, K-Nearest Neighbors (KNN) in their default configurations.

2.7 Evaluation

We experimented with different types of kernels in SVM classifier (Radial kernel & Polynomial kernel), and different values of ‘k’ in kNN (k= 5,10) classifiers. To investigate the benefits of the proposed hybrid framework, we also tested each classifier’s performance by creating vector embeddings of the radiology reports without the domain-specific semantic mapping (Sec. 2.3) where we skipped replacing the radiology terms and their synonyms using RadLex. However, we still substituted the common terms using the CLEVER base terminology for preserving the semantic structure of the radiology reports. In the Result section (see Sec. 3.3), we describe the performance of each classifier on the hold-out test set (238 reports) in a tabular format. Standard precision, recall and F1 score were used as metrics to quantify the classification performance.

3 Results

3.1 Word analogies

On feeding the entire corpus to the system, the final size of the resulting vocabulary was 4,442 words. We created word embeddings or semantic vector representations of words appearing in the corpus, from which several kinds of analogies could be derived by computing the similarity. The similarity score between the word vectors was computed as cosine similarity which is inner product on the normalized space that measures the cosine of the angle between two words:

$$\text{Similarity} = \frac{A \cdot B}{\|A\| \|B\|} = \frac{\sum_{i=1}^{n} A_i B_i}{\sqrt{\sum_{i=1}^{n} A_i^2} \sqrt{\sum_{i=1}^{n} B_i^2}}.$$  

Table 2 shows some synonyms/closely associated words and the cosine similarity scores of their respective word embeddings. Table 3 shows some antonyms and the cosine similarity scores of their respective word embeddings. The data demonstrate that the system has formed embeddings such that pairs of synonyms have high similarity scores while antonyms have negative similarity scores.

3.2 Vector Visualization

Figure 3 shows the 2D visualization of word vector embedding constructed using the t-SNE approach (Sec. 2.5) where each data point represents a word. A total of 4,442 words are visualized in the figure. As seen from the figure, similar words reside fairly close together and form a cluster in the map without even inclusion of any prior knowledge. This map illustrates that our word embedding can preserve semantics of the terms.

Figure 3: All word embeddings (4,442 words) - visualized in two dimensions using t-SNE

In Figure 4, we also highlight a group of clinical terms particularly relevant for this case-study and their negations using the same t-SNE visualization technique. The figure illustrates ability of the embedding to automatically organize concepts and implicitly learn the relationships between them. To show the word-to-word relations, we visualize only a few significant terms and their negations, but same technique can be used to infer other analogies among the terms present in our vocabulary (e.g. synonyms, antonyms, finding-finding, finding-diagnosis).

We also visualize the subsequent vectors of complete reports projected in two dimensions using the t-SNE technique (Figure 5). This visualization has been created only for the 1,188 annotated reports since the main idea is to see if our proposed embedding can be useful to compute clusters with varying risk factors. From the Figure 5, we can see that the reports denoting high risk of intracranial hemorrhage cluster together, and the reports with intermediate risk are mostly residing close to high risk reports. Though this is a two dimensional projection of the original high dimensional document vector, the result clearly shows that the embeddings carry signals that could be very informative to automatically annotate the reports using state-of-the-art classifiers.
3.3 Classification performance

We used the document vectors to classify each report into one of three classes denoting varying likelihood of intracranial hemorrhage (see Sec. 2.6). As mentioned earlier in the paper, our radiology report embedding is flexible enough to be combined with both parametric and non-parametric classifiers. We experimented with three state-of-the-art classifiers - Random Forests, Support Vector Machines and K-Nearest Neighbors (KNN).

To give more insight into the quality of the learned vectors, we used the grid search approach to tune the two main hyperparameters of our embedding for the targeted annotation, i.e. Window Size and Vector Dimension. The hyperparameter search was done individually for each classifier using cross-validation on the training data set. The effects of the hyperparameters on the resulting classifier performance are shown in Figure 6 where the optimal points of the classifier’s performance are highlighted. Based on the optimal points, we selected the hyperparameters and evaluated the classifiers’ performance on the test set. For instance, Random Forest was evaluated with the word embeddings that

</tbody>
</table>

The classifiers’ performance on the test set is reported in Table 4 with optimal hyperparameters. We also present performance of the classifiers only using unigrams as features which can be considered as the baseline performance to be compared with word embedding. While the reported performance accuracy (F1-score) of baseline with unigrams is on average 71%, the word embedding resulted F1 score over 80% for most cases which demonstrates that our vector representation was able to capture the significant facets of the radiology reports. The Random Forest classifier yielded a weighted precision of 88.64% and weighted recall of 90.42% with 730 dimensional word vectors, and closely outperforms all the other classifiers used in this study. However, KNN \((n = 10)\) produces a weighted precision of 88.60% and weighted recall of 89.91% that is close to the Random Forest’s performance, employing a reduced optimal word vector dimension (130).

In Table 4, we present the classifiers’ performance with and without dictionary mapping as well as with unigrams as feature. In general, the word embedding improves the performance of the baseline classifiers and every classifier’s performance is consistently better with the proposed hybrid technique. However, performance difference is incremental for the particular case study which is hypothesized to be due to the choice of dataset in which all the reports are associated to a very narrow domain and from the same institution, i.e. CT Head reports, and thus the variation in the vocabulary is relatively small. We expect that superiority in the performance of the proposed hybrid method may be more significant when multi-topic and multi-institutional free-text reports will be considered where the semantic and syntactic variations are more prominent.

4 Conclusion

In this study, we have shown how to efficiently learn dense vector representations of individual words as well as entire radiology reports by using a hybrid technique that combines word2vec and semantic dictionary mapping. Our experimental results show that our proposed embeddings were able to learn the actual semantics of the ra-
diological terms from free-text reports. Thanks to the embeddings, we successfully annotated the radiology reports according to the likelihood of intracranial hemorrhage with 89.08% F1 score. We have publicly released (https://github.com/imonban/RadiologyReportEmbedding) our trained embeddings that have been used to test the classifiers performance (Table 4), which can be directly reused to support similar radiological applications, e.g. inferring relations between clinical terms, annotation of radiology reports, etc. The techniques introduced in this paper can be used also for creating vector representation from clinical notes of different domains (e.g. oncology) given a domain-specific ontology that can be used to reduce underlying term variations in the corpus.

In the prospective future studies, we will compare alternative neural word embedding methods (e.g. GloVe) since we believe that the performance of any such method will be boosted by the semantic mapping, as the models are initialize with random vector for out-of-vocabulary words which is far for reality. In the future version of the pipeline, we will incorporate log-likelihood ratio and mutual information for identify frequently appearing pairs, and will consider different linear functions (max pool, average pool, min pool etc.) to create document embedding from word vectors.

ABSTRACT

Reference models are an essential instrument to provide structure and guidance in the creation and use of data elements within an organizations’ electronic health record (EHR). Standardization of data elements is imperative to ensure clinical data is consistently and reliably captured for use in clinical documentation, care communication, and a variety of downstream data uses. Ongoing assessment and refinement of reference models and data elements are necessary to ascertain clinical data capture is applicable and inclusive across a variety of caregivers and domains. We performed a gap analysis on current state nursing data elements against two validated interprofessional reference models: skin alteration and pressure ulcer assessments. We present our findings along with recommendations for reference model refinements. We also highlight additional findings of inconsistencies and redundancies within data elements used for nursing documentation and highlight recommendations for improvement.

Introduction

An important aspect of an Electronic Health Record (EHR) is to capture and apply clinical data as a means to support patient care and improve outcomes.1,2 Utilizing data collected within an EHR is foundational to the National Academies vision of a ‘learning health system’, which supports that a health system can effectively use, learn from, and share health data to guide and improve the overall quality of healthcare.3,4 Standardization of clinical data is essential to effectually capture, interpret, share and reuse data in a consistent and meaningful way.5 The integrity and representation of data collected and documented within an EHR is vital for the reliability and accuracy of downstream usage.6,7 EHR data are used to support activities at the point of care, such as communicating clinical information and coordinating care within and across organizations. Additionally, secondary use of data (downstream data reuse) includes analytics, safety and quality reporting, regulatory compliance, and clinical decision support algorithms. Conversely, a lack of reliable and complete data elements results in semantic inconsistencies and poor data integrity that may increase the potential for errors when data are used to inform patient care decisions and for secondary uses.5,8,9,10

Detailed clinical data element reference models, referred to here simply as reference models, support the consistency of data capture by standardizing structured clinical data elements (SCDEs) necessary to represent a specific clinical topic.5,11 The resultant standardization of data capture ultimately promotes increased data integrity and reliability in downstream data uses. For a reference model to be most effective a detailed gap analyses should ensure that it is clinically relevant across interprofessional clinical end-users and domains and applicable to a variety of EHR workflows and functionality. Importantly, these detailed gap analyses should include refinement on an ongoing basis to incorporate new clinical knowledge or EHR functionality, even after initial validation by clinical subject matter experts.

Skin alteration assessment documentation, including assessment of wounds and pressure ulcers, is an important multi-disciplinary clinical topic that has clinical, regulatory compliance, and financial impacts to organizations. Pressure ulcers are one of the “Present on Admission (POA)” indicators hospitals are required to document for each inpatient admission.12 Moreover, based on the Hospital-Acquired Condition (HAC) Reduction Program, Stage III and IV pressure ulcers acquired during a patient’s hospitalization are not reimbursable.13 Accurate documentation of pressure ulcers upon admission, pressure ulcer risk identification, managing pressure ulcer prevention measures and appropriate documentation of pressure ulcer staging throughout a hospital stay therefore have become increasingly important to prevent erroneous incidence of non-payment of services. Furthermore, documenting wound assessment...
in a structured and consistent manner is paramount to proper assessment, treatment, and optimal wound management and outcomes.13,14

Background

Partners HealthCare System, a large Boston-based non-profit hospital and physician’s network, implemented an enterprise-wide Electronic Health Record (EHR) in May 2015. An enterprise Structured Clinical Data Element (SCDE) workgroup was formed and tasked with the principle responsibility of identifying high priority clinical topics and cataloging, evaluating, and standardizing enterprise SCDEs for those clinical topics. The group is comprised of clinical, informatics, and EHR analyst experts from across the organization.

Previous publications outlining work done within our organization describe the process used to guide the governance of reference models for use in our EHR, including development, validation, implementation, and evaluation. In one publication, a 10-step approach for reference model governance is outlined: 1) identify clinical topics, 2) create draft reference models for clinical topics, 3) identify downstream data needs for clinical topics, 4) prioritize clinical topics, 5) validate reference models for clinical topics, 6) perform gap analysis of EHR SCDEs compared against reference model, 7) communicate validated reference models across project members, 8) request revisions to EHR SCDEs based on gap analysis, 9) evaluate usage of reference models across project, and 10) monitor for new evidence requiring revisions to reference model.15 A subsequent publication specifies detailed methods used to identify priorities for the definition of clinical data reference models and to identify and resolve gaps between existing EHR data collection tools and validated reference models.11 Based on that prior work, skin alteration and pressure ulcer were identified as high priority clinical topics.11

The skin and pressure ulcer reference models were created with an interprofessional group of SMEs across our organization’s various sites and with diverse stakeholder participation. The resultant skin reference models include 48 data elements within the 10 distinct categories: 1) skin Inspection, 2) skin alteration type, location and condition, 3) skin alteration size, 4) wound bed, 5) wound tunneling, 6) wound undermining, 7) wound exudate, 8) wound drain 9) wound dressing, and 10) Skin Alteration Sub-Types. The pressure ulcer reference model includes a total of 22 data elements without additional categorization. The intent of the models is to represent basic skin and pressure ulcer documentation and does not include pediatrics or clinical specialties. The reference model was then compared to and validated against existing “form-based” enterprise data elements being used in the Though the content from legacy systems may have been leveraged in the creation of the reference models, the gap analysis was based solely on the live enterprise EHR. The form-based format of capturing clinical documentation is typically used by physicians and other care team members in the inpatient and outpatient setting. However, nursing documentation in the inpatient setting requires a somewhat different approach due to differences in workflow and clinical documentation requirements. Instead of a form-based format, a flowsheet format is used for most inpatient nursing data collection. Though nursing representation was included in the reference model creation and validation, the uniqueness of the nursing workflow, the differences in data capture needs, and the EHR format limitations required an additional detailed gap analysis (comparison of skin alteration and pressure ulcer reference models with current state flowsheet data elements used to capture skin and pressure ulcer documentation) to ensure reference model comprehensiveness and to guide refinement recommendations for implementation in nursing flowsheet documentation.

Methods

The analysis was conducted over a 10 week period of time totaling approximately 100 hours of work. An initial preparatory step in this analysis was to identify all current state flowsheet data elements used to capture skin and pressure ulcer documentation across the enterprise. Our SCDE workgroup identified all unique skin and pressure ulcer flowsheet data element sets used in our EHR for analysis. An EHR data element extraction was completed based on the identified data element sets and queried for all associated data elements and the respective value-sets. Flowsheet data elements are nested within data element sets as structures that organize small groups (e.g., typically less than 10) of clinically-related data elements. A data element may belong to multiple sets. These sets, and the data elements that comprise them, are further stratified based on their intended use and EHR functionality. In the use case of skin alteration and pressure ulcer assessments the stratifications are: 1) documentation of simple skin alteration assessment at one point in time (e.g., skin color), 2) documentation of static data for a complex skin alteration that allows for comparative assessments overtime, such as the location of a pressure ulcer, and 3) documentation of dynamic data for a complex skin alteration that allows for comparative assessments overtime, such as pressure ulcer drainage. The different types of data element sets described above assist in organizing the
flowsheet structure and functionality; however, the gap-analysis performed in this study was completed at the data element level since the value-set list associated to that data element was a significant feature of the comparison and any required alignment. The same process for comparison was used across all data elements.

For each unique flowsheet data element a gap analysis was performed using predefined metrics (See Table 1) against both the skin alteration and the pressure ulcer reference models using the following fields: 1) data element name, 2) data element set associations, 3) data element type (i.e. boolean, value list, numeric, and string), 4) value-set (where applicable). Value-sets for each category list data element were considered when determining whether a similar documentation artifact was an exact match or a partial match. This was an important designation since the aim of the comparison was to align both the data elements and any associated value-sets.

Our team has previously reported on methods used for gap analyses of EHR data elements compared against reference models. Here we use an adaptation of the MUC-5 (Fifth Message Understanding Conference) Evaluation Metrics. We used the MUC-5 Evaluation metrics to compare the 2 reference models: skin alteration and pressure ulcer against current state flowsheet data elements. These metrics identify if flowsheet data elements are a match, a partial match, extra, missing, or out of scope. Data elements used to assess skin concepts unrelated to a skin alteration were out of scope for the reference models. Additionally, because the reference models were not initially validated against the pediatric or newborn population, data elements used exclusively in pediatric or newborn sets were deemed out of scope for reference model inclusion, pending further expansion of the reference model for those populations.

Once the initial data element level mappings were complete, the extra and partial match data elements underwent a further analysis to determine recommended inclusion in the reference model using pre-determined recommendation metrics (See table 2). The value sets of the partial match category list data elements were also cross mapped against the reference model value-sets and evaluated for value-set alignment. Recommendations were considered based on scope and breadth of the reference model and clinical alignment to skin alteration and pressure ulcer concepts and integrity of clinical data capture (See table 3). Once the author performed the analysis, the methods and results were checked by a second author to ensure accuracy and completeness. Additionally, the analysis and recommendations for inclusion were reviewed with the SCDE workgroup for feedback and consensus.

Results

Data extraction results

We identified and extracted 73 unique skin and pressure ulcer flowsheet data element sets used in our EHR. 465 unique flowsheet data elements were nested within the 73 identified sets. The data elements and data element sets were broken out based on their intended functionality for documentation: 1) simple skin alteration, 2) static data for a complex skin alteration, and 3) dynamic data for a complex skin alteration (See Table 3).

Data element gap analysis results

Figure 1 shows the results of the 465 unique current state flowsheet data elements against both the skin and the pressure ulcer reference models based on the predefined metrics. Of particular importance to the intent of this analysis are the 46% of current state flowsheet data elements mapped as “extra” - not included in the reference model, and the 29% qualified as a “partial match” - indicating that the general theme of the data elements matched, although may contain a value-set disparity or the concept was defined at a broader or narrower level in another data element. The 15 data elements (3%) that qualified as an exact match were, not surprisingly, those used within validated assessment tools (e.g. Braden scale assessment concepts) or those with a concrete definition such as with the measurement concepts (e.g. length and width), or a Boolean concept with a very specific and unambiguous meaning (e.g. “Is wound present on admission”). Interestingly, we identified 3 data elements that exist in the reference models though are missing from current state flowsheet data elements.

![Frequency of Mapping Code for EHR Data Elements Compared to Reference Model Frequencies](image)

**Figure 1. Frequency of Mapping Code for EHR data elements Compared to Reference Model Frequencies**

Out of scope data elements were included in the list of 465 extracted data elements due to their inclusion in some of the 73 sets (i.e. neurovascular wound assessment set) and general proximity in documentation due to the sequence of clinical assessments. In this example, though capillary refill is an important clinical assessment of overall skin health and potential risk of skin impairment, the intent of the reference model does not capture that breadth or specificity. These combined data elements that were not in scope totaled 21% (n=98), with 5% (n=21) defined as pediatric/newborn related and reserved for future reference model scope extension.

**Recommendation results for data element inclusion in reference model**

Of the 215 flowsheet data elements identified as extra (i.e., included in the flowsheet data element sets though not in the skin alteration or pressure ulcer reference models) 1 data element, “wound shape”, was determined to be a candidate for inclusion (See figure 2). Wound shape is considered an important part of the nursing wound assessment documentation and may be a clinically essential indicator when considering the wound location, appropriate wound measurement, and as a factor for overall wound management. The recommendation to include the “wound shape” data element was presented at the SCDE workgroup and attained group agreement with the caveat that future work include an analysis of data usage for this data element and validation with SMEs to confirm clinical relevance.

The reference models were created to comprise a broad level of skin alteration assessment and pressure ulcer assessment documentation. The scope did not include specialty areas such as NICU, pediatrics, or dermatology. Whereas the vast majority of “extra” flowsheet data elements (99%) were specialty focused, this content was not
relevant for inclusion in the models. Future work could expand the scope of our reference models to include these specialty domains.

No flowsheet data elements were coded as either: 1) Do Not Include-No evidence, or 2) Do Not Include-Inherent in existing data element. Whereas the majority of the extra flowsheet data elements were more specific than the reference models there was not a recommendation of any extra flowsheet data elements to align with the reference models (See figure 2).

![Figure 2 Data Element Recommendations for Inclusion in Reference Models](image1)

**Recommendation results for “partial match” value-set reference models/flowsheet alignment**

Of the 138 flowsheet data elements identified as a partial match (i.e. flowsheet data element similar to reference model data element), 33 flowsheet data elements had value-sets that were recommended for extension to existing reference models value-sets. Those 33 flowsheet data elements were then mapped to 9 reference model data elements (See Table 4). The skin alteration reference model includes 7 data element value-set adjustments whereas pressure ulcer includes 5 data element value-set adjustments. Three data elements overlap across both models.

Twenty-two partial match flowsheet data elements were not recommended for inclusion because the concept was inherent at a different level of specificity within another data element or value set. Two of the partial match flowsheet data elements were determined to be out of scope and no flowsheet data elements were excluded due to lack of evidence. Furthermore, it was recommended that all of those same 33 data elements and an additional 81 flowsheet data element value sets (a total of 114) be aligned with the reference models data element value-sets (See Figure 3).

**Additional findings**

Throughout the gap analysis there were many instances identified of inconsistency within and across flowsheet data elements. Wound drainage color, wound description, and wound odor for example are discrete clinical wound assessment concepts, however, in some instances the concepts were grouped together into one data element with a combined value-set. Additionally there were multiple data elements describing the same concepts in differing ways. There were also unique data elements describing a concept with different value-sets.

The concept of “wound location” demonstrated a key challenge of EHR flowsheet implementation. In our reference models only two clinical concepts are needed to capture a generic wound location: 1) anatomical location (i.e. abdomen, foot) and 2) anatomical location qualifier (e.g. right, left, and medial, proximal). However, EHR flowsheets constrain the ability to reuse generic location data elements due to ambiguity in associating the correct location data with the correct skin alteration for a patient with multiple skin alterations. There was also notable variation in the value-sets for these anatomical location data elements that was not related to flowsheet constraints. In some instances, the value-sets included both the location and the location qualifier (i.e. abdomen, foot, right, left, medial, proximal) (See Table 5). In addition to the redundancy and overlap amongst wound location data elements, there were yet another group of data elements for location that were free text and were used for simple skin alteration assessments.

Discussion

Based on the gap analysis it is our recommendation that the skin alteration and pressure ulcer reference models are refined to include 1 additional data element, “wound shape”, and 9 value-set adjustments. We also recommend that 114 of the current state flowsheets data elements be modified to align with the validated reference models to minimize redundancy and inconsistency across data elements and value-sets. Moreover, data type alignment to minimize free text documentation is an important part of flowsheet adjustments. We also recommend future analysis to identify additional inconsistencies in flowsheet data elements and value-sets and usage data analysis to help determine clinical need and guide further refinement.

Overall, the results of the analysis provide evidence that the validated skin alteration and pressure ulcer reference models sufficiently comprise a broad level of skin and wound clinical concepts required to accurately capture nursing domain clinical concepts within flowsheet documentation. The findings also provided useful insight into inconsistent and overlapping data elements, as well as free text data elements, that require adjustment to align to the reference models and the need for future analysis to identify inconsistencies.

Pragmatic reference models are an important mechanism to guide the end user in collecting clinical data in a consistent and meaningful manner. Without a means for relevant and complete data capture, downstream data usage and patient care are negatively impacted. Continuous refinement of reference models used within an EHR is an important activity to ensure relevant and complete clinical data capture. Similarly, continuous refinement of the EHR over time is also an ongoing process that requires appropriate resources. Though the skin alteration and pressure ulcer reference models were initially validated with SMEs and for implementation in the form-based documentation in our EHR, the nursing flowsheet data elements required additional review and validation.

Importantly, reference models should remain pragmatic, reflecting real use needs and any constraints imposed by EHR systems.

Next steps

The data element usage data for the recommended additions to the reference models will provide insight into how many times the data element “wound shape” is being used as an indicator of clinical relevance and rationale for exclusion. Future work evaluating skin alteration and pressure ulcer assessment concepts, and other clinical reference model topics, should include evaluation of usage data as a tool to identify relevant and important documentation fields. Similarly, usage data can provide information about nurses’ interactions with the data element value-sets for optimization of values. Additionally, validation of the skin and pressure ulcer reference models by comparing against the EHR content of other organizations may help to reduce any unintended institutional bias and to assure external validity of our findings.

Limitations

Data was limited to 1 EHR implementation and 2 reference models developed and validated at our organization. Process should be reusable at other size and types of healthcare organizations, even if models and flowsheets are different. Findings may vary however at other sites and gap analyses should be conducted at other sites to identify generalizability of findings for reference model refinement recommendations.
Conclusion

Refinement of existing reference models that guide SCDE build and resultant data collection tools across an enterprise EHR system is an important activity. Skin alteration and pressure ulcer documentation is considered a high priority model due to regulatory, billing, and downstream CDS impact. Through a gap analysis of current state data elements against our skin alteration and pressure ulcer enterprise reference models we confirmed the comprehensiveness and relevance of the models to accurately capture nursing domain clinical concepts for flowsheet documentation. Based on the analysis, one data element, “wound shape”, was identified as a potential addition to the pressure ulcer model. Additionally, nine data elements are recommended for value-set expansion. We also identify many instances of current state data elements and associated value-sets that are not aligned with the models and have made recommendations for EHR modifications.

Abstract

Patients with multiple chronic conditions often face competing demands for care, and they often do not agree with physicians on priorities for care. Patients’ values shape their healthcare priorities, but existing methods for eliciting values do not necessarily meet patients’ care planning needs. We developed a patient-centered values framework based on a field study with patients and caregivers. In this paper we report on a survey to evaluate how the framework generalizes beyond field study participants, and how well the framework supports values elicitation. We found that respondents frame values in a way that is consistent with the framework, and that domains of the framework can be used to elicit a breadth of potential values individuals with MCC express. These findings demonstrate how a patient-centered perspective on values can expand on the domains considered in values clarification methods and facilitate patient-provider communication in establishing shared care priorities.

Introduction

In the United States, two-thirds of adults over 65 have multiple chronic conditions (MCC), and this population continues to grow.1-2 Compared to individuals with single chronic conditions, individuals with MCC have poorer quality of life, more physical disabilities, more frequent adverse drug events, and higher mortality.3 Individuals with MCC face competing care demands, especially when self-care for one condition conflicts with self-care for another condition. For example, a patient may want to exercise to improve cardiovascular health and control their diabetes, but if they also have osteoarthritis, exercise could be very painful. Conflicting self-care demands are further compounded by the everyday complexities of living with chronic illness, including individual preferences, resources, and diverse lifestyles.4 Choosing the right care priorities for individuals with MCC is important since the ability to self-manage competing demands can affect the quality and length of life.5

To help individuals with MCC and their health care providers establish shared care priorities, first we must understand patients’ values. Patients’ personal values—what they “consider important in life”6—underlie the decisions they make about their health and health care. Health services research has emphasized the importance of understanding and honoring patients’ values, particularly for establishing shared care priorities with MCC patients.7 Although the importance of orienting care around patient-important outcomes is well documented,8 few clinical guidelines include ways to incorporate patients’ personal values in care planning.9,10

Many research studies have designed and evaluated methods for providers to elicit and clarify patients’ values, particularly for shared decision making.11-14 While diverse, most values clarification methods (VCMs) focus on specified treatment preferences that are pre-defined without the ability for patients to introduce their own concerns or explore the underlying values that shape their care preferences.11 Since patients with MCC mostly manage health outside of clinical contexts, it is important for patients and providers to communicate about what patients value in their daily lives when establishing shared care priorities. Our prior work underscores this need by revealing that some individuals with MCC filter what they share with healthcare providers because they do not perceive personal values from daily life as pertinent to their healthcare.15 There is a need to better understand personal values from the perspective of patients to inform the design of tools that can improve patient-provider communication about care planning.

Based on prior field work15-17 with 31 individuals with MCC and 17 family caregivers, we formulated a patient-centered values framework that characterizes the types of personal values that patients described as most important to their well-being and health. We conducted home visits that included photo elicitation18 as part of a semi-structured interview. Prior to the visit we mailed the patient a camera that produced instant photographs and asked them to take pictures to show what was important to their well-being and health in daily life. When we visited the
patient’s home, we began the semi-structured interview by asking them to explain what was important in each photograph. Next we discussed topics including daily activities, self-management, tradeoffs (e.g., times when the patient found it difficult to balance what was important to them), how their values related to their health, and how they communicated with their healthcare providers. Interviews were recorded and transcribed verbatim. Analysis of the transcripts was guided by grounded theory methods, and included open coding, focused coding, and writing memos. Two authors (AB, CL) open coded transcripts independently, wrote code memos to define and clarify codes, and met regularly to coordinate, refine, and consolidate codes. Wherever possible, we labeled and defined codes using the language of participants. As codes stabilized, we conducted focused coding on the remaining transcripts, and recoded the initial transcripts to ensure consistency. As we coded, we wrote memos to group codes into themes. These themes are the domains that comprise the patient-centered values framework. Throughout the analysis process, all authors participated in regular meetings to discuss and clarify codes and themes. A paper reporting this field study and the resulting patient-centered values framework is currently under review.

The framework expresses the breadth of patients’ personal values across six domains: principles, relationships, emotions, activities, abilities, and possessions. Principles are beliefs and standards to live by, such as honesty or independence. Relationships are connections with others, such as family or friends. Emotions are feelings, affect, or mood, such as joy or serenity. Activities are pursuits such as working, reading, gardening, or volunteering. Abilities are physical or mental capacities or skills, such as mental sharpness or mobility. Possessions are tangible objects or spaces, such as photographs, a car, or a woodshop.

The values framework expands the breadth of domains considered in values clarification methods and could be used to inform patient-provider discussions about shared care priorities. Yet, it is important to evaluate how well this framework translates beyond individuals in our prior field work to other individuals with MCC. The aim of the study we report here was to evaluate the values framework through a survey with a larger sample of individuals with MCC and inform the design of tools that facilitate communication between patients with MCC and their healthcare providers about personal values in the context of care planning. We investigated two research questions:

RQ1. How similar to the framework do respondents frame values? (i.e., Do they generate similar kinds of values that participants in the prior field study described? Do they assign values to similar categories?)

RQ2. Is there a difference in how respondents rate the importance of values from different domains in the framework?

Related Work

We adopt the definition of values from Friedman et al.: “what a person or group of people consider important in life.” Although values are central to the patient-provider relationship, there remain critical gaps in how to elicit patients’ values and incorporate them into care planning discussions. We investigate how evaluation of our patient-centered values framework could build on and overcome limitations of existing values clarification methods by considering values from the perspective of patients.

There has been significant research into values clarification methods (VCMs), which are techniques to help patients clarify what matters to them in the context of specific health-related decisions, such as decision aids that utilize pros and cons or ratings. Examples of VCMs include decision aids to help patients choose the best treatment for type 2 diabetes and decision aids to help patients select lifestyle changes for improving cardiac health. Witteman et al. reviewed 98 VCMs, developed a taxonomy of VCM design features, and discussed limitations of VCMs. Most methods reviewed were designed for patients to complete as an independent activity (59%) rather than with a provider, used closed-ended and pre-set options (61%), and few encouraged patients to explore values as part of an iterative discovery process (9%). These key limitations could increase the chance that providers miss opportunities to identify what is important to patients broadly, and fail to incorporate those values into care planning that is so important for MCC. Furthermore, care planning for individuals with MCC involves juggling multiple concerns and decisions, but existing VCMs generate values about single health conditions. Out of 98 VCMs reviewed, 23 related to chronic illness, but none explicitly addressed MCC. Of the 23 VCMs related to chronic illness, nine focused on cardiovascular health, eight focused on other chronic conditions, and six focused on advance care planning. This suggests a lack of VCMs for care planning for individuals with MCC who face conflicting self-care demands.

The first limitation identified by Witteman et al. that is relevant to our goal of informing the design of VCMs for individuals with MCCs is that most VCMs are completed by patients independently. In our work, we conceive of the patient-centered values framework as a conversational tool to stimulate patient-provider discussions about values.
The second limitation of VCMs relevant to our study is that most VCMs are closed-ended and do not enable individuals to generate and incorporate their own attributes or elements for consideration. For example, the VCM designed by Breslin et al. helped individuals decide which medication to use to treat type 2 diabetes based on attributes such as how each medication affected blood sugar and weight, but these attributes were predefined, not patient-generated. Of the VCMs Witteman et al. reviewed, 60 out of 98 did not allow the individual to add elements or attributes to a decision. In this study, we sought to explore the nature of open-ended “free response” elicitation of values compared to closed-ended elicitation of predefined “domain-driven” values. There may be benefits and drawbacks to each approach. Understanding how responses to these types of elicitation methods could vary will inform the design of VCMs to support individuals with MCC.

The third key limitation of VCMs identified by Witteman et al. is that VCMs often offer little support for iterative exploration of values. Out of 98 reviewed, 21 VCMs explicitly did not allow users to explore and revise their values, but rather required they identify and express values in a single attempt. Another 65 technically allowed revision (e.g., to page back and change response) but did not explicitly encourage it. It is important for patients to be able to revise their values as their understanding of a decision develops. In this study, our survey structure enables us to develop a better understanding of how elicitation of multiple values in series might affect the kinds of values participants shared. In addition, we can make some judgments about how different kinds of elicitation methods in series (e.g., initial free-response followed by domain-driven followed by a second round of “informed free-response”) might elicit values of different types, specificity, or importance to the patient.

Given these limitations of existing VCMs, we sought to evaluate how our values framework might be used to inform the design of methods for eliciting patient values that are applicable beyond singular health-related decisions to meet the needs of individuals with MCC. Specifically, we explored the utility of “free-response” versus “domain-driven” elicitation of values, and we explored the relative importance individuals place on domains within the framework.

**Methods**

To evaluate our values framework, we conducted a phone survey to ask patients with MCC to generate and categorize values into domains (RQ1) and then rate the importance of those domains (RQ2). After completing the survey, participants received $30 by mail. Survey procedures were approved by the Institutional Review Board at Kaiser Permanente Washington Health Research Institute (KPWHRI).

**Recruitment**

Participants were recruited from Kaiser Permanente Washington (KPW), an integrated healthcare system in Washington State. Participants were required to have type 1 or type 2 diabetes and at least two of the following common conditions: depression, osteoarthritis, or coronary artery disease. Eligibility was determined based on diagnosis codes stored in the electronic health record. We chose these illnesses because all require a high degree of self-management, and self-management tasks for these conditions may either overlap or compete with one another. For example, recommendations to improve outcomes for diabetes and coronary artery disease encourage physical activity, but arthritis might limit significant physical activity. In other combinations, such as diabetes and depression, treating both together is optimal.

Participants had to have a primary care provider in a KPW clinic, had to be enrolled in a KPW plan at the time of recruitment, and had to have had at least two visits with a primary care physician in the preceding 12 months. Participants were excluded if they had been diagnosed with HIV, AIDS, dementia, or other major psychiatric diagnoses for the preceding 10 years, and were excluded if in the preceding six months they had two or more in-person visits to medical oncology or radiation oncology or if they were enrolled in hospice or palliative care. We purposively sampled for educational status, aiming for a distribution similar to the U.S. population, which is approximately 50% with educational level high school or less, and oversampled minority racial and ethnic populations. Eligible patients who met the sample criteria received a letter explaining the purpose of the survey and the survey procedures, then received a phone call from a member of the KPWHRI Survey program to administer the survey by phone. In total, 54 respondents completed the survey. Of those, 17 had participated in our prior field study and 37 had not.

**Procedures and Analysis**

The phone survey had three parts: (1) generating and categorizing values; (2) rating the importance of values; and (3) demographics.
Generating and categorizing values: We approached the generation of values in three ways: free-response, domain-driven, and informed free-response (Table 1). The survey first asked respondents to name two things that are important to their well-being and health through free response (values 1-2). Respondents generated these values freely without knowledge of the domains in the values framework (i.e., “free-response”). Second, the survey asked respondents to generate values for each of the six domains from our patient-centered values framework after being read a short definition for each (values 3-8). During this “domain-driven” approach, respondents were given the choice to not provide an example if they felt the domain was not important to them. Third, respondents were given the option to provide up to five additional values of their choosing (values 9-13). These optional additions reflect values elicited through free-response after respondents were exposed to domains of the values framework (i.e., “informed free-response”).

Table 1. Elicitation methods to generate patient values

<table>
<thead>
<tr>

</tr>
<tr>
<td>Informed free-response</td>
<td>9-13</td>
</tr>
<tr>
<td>“Can you think of anything else important to your well-being and health?”</td>
<td></td>
</tr>
</tbody>
</table>

For categorizing values, the survey asked respondents to assign the free response values (values 1-2, and 9-13) to the six domains (i.e., principles, relationships, emotions, activities, abilities, and possessions). For each value (e.g., “value x”), participants responded to: “Earlier you told me that ‘value x’ is important to you. Of the categories we just discussed, where does ‘value x’ belong: activities, possessions, relationships, emotions, principles, or abilities?” Respondents were given the option to assign a value to multiple domains if they wished. If the respondent did not believe the value fit in any of the domains, the respondent was given the option to name a new domain where the value fit, and to provide a description.

To answer RQ1, we first examined the coverage of values generated through free-response, domain-driven, and informed free-response elicitation methods by counting the number of values resulting from each of the three methods. We then examined how respondents categorized those values by assigning them to domains of our values framework. We inspected values that respondents chose not to assign to one of the six domains and any new domains they suggested. Finally, we compared how respondents categorized values with how the research team categorized those same values. Team-based categorization was reached through consensus and was done in a blinded manner in which team members were unaware of how respondents categorized values. Three members of the research team (“coders”) assigned by consensus each respondent-generated value to one of the six domains from the values framework. Coders assigned values to domains based on domain definitions formulated from our prior field study based on home interviews. Values that did not fit any domain, that lacked sufficient context to assign to a domain, or for which consensus could not be reached were distributed to two additional team members to assign to domains independently. The three coders used the independent assignments to reach consensus on categorization of the remaining values. We assessed agreement between respondent-categorized and team-categorized values with Cohen’s Kappa (K). Throughout the coding process, the three coders and two additional team members maintained a record of responses for which reaching a consensus categorization required discussion. This record included notes clarifying the definitions of domains from the values framework and notes about potential extensions to the framework.

Rating the importance of values: The survey asked respondents to rate how important each of the values they generated (i.e., values 1-13) are to their well-being and health on a 5-point Likert scale (anchors were 1 = “important”, 3 = “very important”, and 5 = “the most important”). To answer RQ2, we compared respondents’ importance ratings among value domains with a Friedman test ($\chi^2$) and conducted post hoc pairwise comparisons using Mann-Whitney U tests with a Bonferroni correction. We chose Friedman and Mann-Whitney U as non-parametric tests because the data are Likert ratings and not normally distributed. We applied the Bonferroni correction to reduce the chance of type I error with multiple pairwise comparisons.
Demographics: The survey asked respondents to provide their age, sex, race, ethnicity, and education level, which we summarized with descriptive statistics in Microsoft Excel.

Results

Table 2 shows demographics of the survey respondents.

Table 2. Respondent demographics (n=54)

| Age mean (SD) | 65.4 (10.7) |
| Age range     | 45-87       |
| Sex n (%)     | 31 (57.4%)  |
| Race n (%)    |             |
| American Indian/Alaska Native | 1 (2%) |
| Asian         | 4 (7%)      |
| Black/African American | 6 (11%) |
| Native Hawaiian/Pacific Islander | 1 (2%) |
| White         | 31 (57%)    |
| More than one race | 8 (15%) |
| Other         | 3 (6%)      |
| Hispanic/Latino n (%) | 5 (9%) |
| Education n (%) |     |
| Some high school, but not a graduate | 4 (7%) |
| High school graduate or GED | 10 (19%) |
| Some college or 2 year degree | 24 (44%) |
| 4-year college degree | 5 (9%) |
| More than 4-year college degree | 11 (20%) |

Generating and categorizing values

Free-response: The 54 respondents generated a total of 107 values through free-response (i.e., values 1-2). Only one respondent did not generate both values. Free-response values were diverse—some were medically oriented (e.g., “good medical care”, “my heart”, “keeping my cholesterol down”, “good communication with doctors”) whereas others reflected everyday priorities that were personal in nature, such as “family”, “happiness”, and “proper frame of mind”. Respondents categorized 103/107 (96%) of these values into one or more of the six domains of the values framework. In fact, respondents applied 69 of the 103 values (67%) to 2 or more of the 6 domains. The distribution of assignment of the 103 values to domains was: relationships (56%), abilities (55%), activities (54%), emotions (47%), principles (33%), and possessions (22%). Because respondents could assign each value to more than one domain, the total of this distribution is greater than 100%. Respondents suggested new domains for 3 of the 4 uncategorized values, including the domain “self-discipline” to assign the value “get out of pain with my back”, the domain “health provider and patient relationships” to assign the value “concern”, and the domain “diet and exercise” to assign the value “keeping my blood sugar low”. A new category was not suggested by the respondent for the remaining uncategorized value “being independent”.

The research team categorized 88/107 (86%) values generated from respondents through free-response. The 19 uncategorized values lacked sufficient detail for the team to assign to any of the six domains, such as “my weight”, “cost”, “having my health care records be accurate and up to date”, “prompt appointments with my primary doctor”, “getting my medication when I need them”, and “health issues are seen in the context of my life”. Agreement between respondent-categorization and team-categorization of the 88 values was moderate, $K = 0.47$. Because we allowed respondents to assign values to more than one domain (i.e., multiple categorization), this estimate may be higher than if we required each value to be assigned to only one domain; the research team’s categorization could match with any of the domains to which respondents assigned a given value.
Domain-driven: Respondents generated a total of 318 values that were specific examples across the six domains (i.e., values 3-8). Nearly all respondents generated a value for all six domains. Six respondents (11%) were able to generate examples for only five domains. One respondent could not generate an activity and two respondents reported that possessions were not important to their well-being and health. One respondent reported “I don’t know” when asked to provide an example for the “relationships” domain. Two respondents reported “I don’t know” when asked to provide an example for the “emotions” domain.

By the nature of the task, the domain-driven values were categorized by respondents. The research team categorized 310/318 (98%) of these values. The 8 uncategorized values lacked sufficient detail for the team to assign to any of the six domains. Examples included respondent-generated principles “listening” and “caring” and respondent-generated abilities “communication” and “my health.” Agreement between respondent-categorization and team-categorization of the 310 values into the six domains was high, $K = 0.85$. The proportion of respondent-categorized and team-categorized values that agreed included: 96% relationships (n=53), 94% possessions (n=51), 92% activities (n=53), 88% principles (n=52), 86% emotions (n=51), and 68% abilities (n=50).

Informed free-response: After eliciting values through free-response and domain-driven methods, we asked respondents if there was anything else important to their wellbeing and health. Respondents could generate up to 5 additions (i.e., values 9-13) and resulted in a total of 78 values. Thirty-three respondents (61%) added one more value, 19 (35%) added 2 more values, 13 (24%) added 3 more values, 10 (19%) added 4 more values, and 3 (6%) added 5 more values. Examples tended to reflect everyday priorities that were personal in nature (e.g., “family”, “hobbies”, “feel safe”, “being able to go out and do things”) and few medically oriented values (“following closely the directives of my doctor”). Respondents readily categorized all but 2 of these 78 additional values (97%) into one or more of the six domains. The distribution of assignment of the 76 values to domain was: emotions (66%), activities (66%), relationships (63%), abilities (61%), principles (42%), and possessions (34%). This distribution is similar to initial free-response, but the percentage assignment increased for each category. The 2 uncategorized values were “watching my security” and “ability to take off time for myself to not worry about health”. Respondents applied 60 of the 78 values (77%) to multiple domains.

The research team categorized 74/78 (95%) values that respondents optionally added. The 4 uncategorized values lacked sufficient detail for the team to assign to any of the six domains, which included “my health”, “being healthy”, “having challenges”, and also included “watching my security” which was uncategorized by respondents. Agreement between respondent-categorization and team-categorization of the 73 values into the six domains was high, $K = 0.78$. Similar to free-response values, we suspect agreement was high due to multiple categorization.

Relative importance of value domains
Table 3 shows importance rating for values generated through free-response, domain-driven, and informed free-response methods. For domain-driven values, relationships were rated as most important on average whereas possessions were rated as least important on average. There was a significant difference in importance ratings among the 6 domains ($\chi^2 = 44.84, p <0.001$). This analysis excludes ratings for the six respondents who did not generate examples for all six domain-driven values. Post hoc comparisons resulted in 4 significant differences in importance ratings between: relationships and possessions ($U = 639, p<0.001$), relationships and activities ($U = 599, p<0.001$), principles and activities ($U = 671, p=0.002$), and principles and possessions ($U = 707, p=0.004$). These findings follow from the most important (i.e., relationships and principles) and least important (i.e., activities and possessions) according to ratings.

Discussion

Principal findings from this survey are that respondents frame personal values in a way that is consistent with our patient-centered values framework—they assigned nearly all values to at least one domain of the framework, and agreement of that assignment with the research team was high (RQ1). Respondents rated the importance of domains of values significantly different—namely, they rated relationships and principles significantly more important than activities and possessions (RQ2). In addition, we gathered insights that open-ended methods may encourage elicitation of both medically oriented and personal values connected with everyday lives outside the clinic, especially when offered the opportunity to express free-response values after learning the domains of the values framework.

**Precision and Clarity of Values Domains**

The level of agreement between respondents’ and team members’ categorization of personal values tells us about the precision with which value domains were defined, and the clarity with which respondents perceived the domains. There was moderate to high agreement for each elicitation method, with the highest agreement for domain-driven elicitation. Participants could generate personal values in response to the domains, and the research team consistently placed those values into the same domains from which they were elicited. This finding provides evidence that the definitions of the domains are conceptually precise, and that the wording we used to describe the domains to patients is clear. Table 4 includes each value domain, its definition, and representative examples. We updated the definitions of principles, emotions, and possessions to clarify their meaning. These updates reflect discussions we had during consensus categorization of survey respondents’ values. For principles, many respondents shared standards and virtues, which were reflected in the original definition, but respondents also shared aspirations that guided their behavior much like standards or virtues. For emotions, respondents often expressed values that were embodied and experiential, such as comfort, or relief from pain. Finally, respondents highlighted the nature of their relationship to possessions, such as objects being owned or cherished. These updated definitions improve the clarity and accuracy of the patient-centered values framework and boost its utility for use in values elicitation and care planning.

**Generalizability of Framework**

Because respondents could categorize nearly all values from free-response and informed free-response, this provides evidence that the values framework can account for a breadth of potential values patients with MCC express. More work is needed to further substantiate the generalizability of the framework, since it is possible that individuals with characteristics different than our sample might have values that do not fit the framework. Our sample is limited to
individuals in Washington State who have insurance, receive care within an integrated health system, and have a specific spectrum of chronic conditions. Also, 17 of the 54 respondents participated in a previous study in which we asked them to photograph things that were important to their well-being and health, and then interviewed them about those values. Those interviews were included in the 31 used to develop the patient-centered values framework.15–17 We cannot rule out that this overlap in samples limits the generalizability of the findings.

Utility of Priming for Free-Response Elicitation
Placement of domain-driven elicitation in the middle of the survey allowed for two types of free-recall elicitation: elicitation that occurred before participants learned of the values framework (i.e., “initial free-response”), and elicitation after the framework was introduced (i.e., “informed free-response”). Comparing agreement across initial free-response, domain-driven elicitation, and informed free-response, both the type of elicitation (free-response versus domain-driven) and the participant’s familiarity with the values framework (initial versus informed free-response) may be associated with different levels of agreement on categorization between respondents and the research team. Higher agreement for domain-driven versus initial free-response elicitation may suggest that domain-driven elicitation generates values that align more closely with domains of the framework. Thus, the type of elicitation may influence the level of agreement. However, higher agreement for informed free-response than initial free-response suggests that familiarity with the framework may also influence the level of agreement. Future studies could further explore reasons for these differences, and assess how such insights might inform the design of approaches for eliciting patient values.

Review of survey responses suggests qualitative differences in the content and categorization of values elicited through initial free-response versus informed free-response. Respondents’ values generated from initial free-response tended to be more medically oriented, focused on the healthcare system (e.g., “time at doctor visits”), than values generated through informed free-response elicitation. Our prior work15–17 suggests that the field study methods used to formulate the values framework (i.e., photo elicitation and extended, semi-structured interviews in participants’ homes) were effective for encouraging participants to think about well-being and health in their daily lives, outside of healthcare contexts. This kind of in-depth values elicitation may not be feasible in clinical settings due to time and resource constraints. We have also found that patients tend to withhold personal values in clinical contexts when they do not perceive those values to be pertinent.15 Given the time and resource intensiveness of field study methods, it is promising that introducing the domains of the values framework has potential to broaden the values patients share. Domain-driven and informed free-response queries appear to be efficient approaches to eliciting values that might otherwise require in-depth examination. Together, our prior work and the current findings support the idea that priming patients with definitions of values domains should be a key consideration when eliciting values of patients with MCC. Future work could explore how different methods of priming participants yield different kinds of values, as well as the clinical utility of the types of values elicited through different methods.

Relative Importance of Domains
We did not observe a difference in the importance respondents ascribed to values elicited by free-response and informed free-response elicitation. Respondents rated the importance of free-response values very high and these ratings were close to the highest-rated domain-driven values. Further, we observed a significant difference in the high rating of importance for relationship and principles domains compared with the lower rating of importance for possessions and activities domains. More work is needed to understand the care and design implications based on differences in ratings for different domains. A rating of 3.8 or 3.9 still falls between “very important” and “most important,” so our findings support including these domains when eliciting the values of patients with MCC for overall well-being and health. More research is needed to understand what these ratings mean in the context of care planning and decision-making.

Multiple Categorization
When given the choice, respondents often placed free-response values into multiple categories. Multiple categorization probably inflated agreement substantially, since our team’s categorization of a value could match on any domain to which the respondent assigned the value. This choice is both a limitation and a strength of our study design. The fact that respondents employed multiple categorization is interesting and insightful. From a conceptual standpoint, the prevalent use of multiple categorization among respondents supports the idea that the value domains might not be mutually exclusive. This is compatible with findings from our prior work that individuals with MCC often perceive values to be interrelated.16 For instance, if an individual values “gardening with her granddaughter”, this same value may be categorized under activities (i.e., gardening) and relationships (i.e., with granddaughter). Looking toward the design of tools for eliciting values for planning care, the prevalence of multiple categorization
means it may be more likely that domain-driven elicitation generates values that cross domains than values that do not. As long as individuals are given the opportunity to include more than one value per domain, this approach may also provide a more comprehensive set of values compared to free-response alone. Understanding how values cross domains and relate to other values has implications for care planning. For example, when facing declining health, patients and their health care providers might consider how this could affect a web of related values and values domains rather than focusing solely on medically-oriented effects, such as physical function. Methods and tools could be designed to facilitate discussions that link health concerns with patients’ values, and support care planning to mitigate these concerns.

Implications for Informatics

These findings have practical applications for health information technology to support conversations between patients and providers about patients’ personal values. A patient-facing questionnaire deployed in a personal health record (PHR) could capture personal values from patients and display them to the provider. This would enable the patient to respond while at home, which could facilitate reflection on personal values in daily life. The questionnaire could be formatted to mimic the elicitation methods tested in our survey. Such a questionnaire would be more likely to elicit a breadth of patient values if it used domain-driven or informed free-response methods. As we know from limitations in VCMs, patients would need to be able to revise and elaborate on personal values over time. Patients’ personal values could then be displayed in existing locations in clinical information systems, such as alongside patient demographics or social history, or could be incorporated into care planning or decision support tools.

Conclusion

We evaluated how a patient-centered values framework generalizes to a larger sample of patients with MCC. Through a series of free-response and domain-driven queries, we elicited respondents’ values, asked them to place those values into the domains of the framework, and asked them to rate the importance of values generated. We found that respondents framed values similarly to the framework, suggesting that the domains of the framework are clear and conceptually precise, and that the framework provides a promising tool for eliciting patient-centered values. These findings provide insight into the potential utility of the values framework for supporting care planning conversations between patients with MCC and their health care providers. Future work should build on these findings by exploring ways to link patient values with health concerns in the context of care planning, what patients’ ratings of the importance of values mean in the context of care planning, and the clinical utility of values generated through different elicitation types.

Improving the ‘Fitness for Purpose’ of Common Data Models through Realism Based Ontology

Abstract
Common data models are designed and built based on requirements that are aimed towards fitness for purpose. But when common data models are used as lenses through which reality is observed from the perspective according to which they are built, then they exhibit restrictions that distort such view. Realism-based ontology design, when done properly, does not have these limitations as its fitness for purpose is only determined by the degree to which reality is represented the way it is. Therefore, we can use the principles that realism-based ontologies adhere to, not only to design application ontologies serving some specific purpose, but also to assess whether and where common data models fall short in their representational adequacy and how they can be corrected. If a realism based ontological perspective on the portion of reality the some common data model is trying to represent is compared with the perspective of the common data model itself, it is possible to determine how the latter deviates from the former and to suggest solutions to correct the misrepresentations found. Applying this method to the common data model of the Observational Medical Outcomes Partnership, revealed two major categories of errors: one where relationships are restricted based on the constraints of the data model, and one where the representation of reality is oversimplified.

Introduction
The University at Buffalo’s Institute for Healthcare Informatics’ (IHI) has as primary function the aggregation of disparate distinct data sources such as in-patient, out-patient, claims and clinical study datasets into a centralized integrated data repository (CIDR). It is a design criterion of the IHI to create this resource for healthcare data in maximal compliance with the principles of Ontological Realism1, 2 insofar doing so does not interfere with (1) the need for timely access and (2) the availability of resources. This is done in the spirit of not letting the perfect come in the way of the good. The IHI realizes this function by providing a secure environment where data analysis, cohort discovery and other secondary data use requirements can be evaluated and accomplished. Although the production of a CIDR is the primary principal mission of the IHI, the researchers at the University at Buffalo (UB) have a need for advanced analytics in the interim. One pathway forward is to adopt a Common Data Model (CDM).

Traditional CDMs are designed around a ‘fitness for purpose’ paradigm according to which the data are organized in a way that solves specific organizational necessities thereby allowing portability and integration or federation of other datasets. Some of these requirements can dictate the use of specific implementation designs. For example, Informatics for Integrating Biology and the Bedside (i2b2)3 proposes a CDM that is designed specifically for cohort discovery. i2b2 achieves this by using a single fact table to represent observations about patients. The fact table is dimensionally described by what are called ‘dimension tables’ – patient dimensions, provider dimensions, and encounter dimensions are examples. This data model implements a paradigm which is known as a star schema database. The i2b2 star schema database as applied to integrated data coming from, for example, electronic healthcare records (EHR) is highly efficient in identifying patient cohorts using inclusion and exclusion criteria in queries which run over observations in the fact table. Data coming from EHRs undergo a complex mapping process that makes use of standardized terminologies (or in-house grown terminologies) and which applies to each row that is loaded into the observation_fact table. In that way, the assertion in the EHR becomes transformed into what is called a ‘fact’ as perceived through the data model although, of course, what is the case in reality might be different from what is stated to be a ‘fact’. Users can browse these terminologies and use them to identify in the data collection patient cohorts composed out of patients about whom a specific observation which maps to the specific terms of interest is asserted (or not). The determination of ‘fitness for purpose’ of i2b2 is to provide a high-speed query system to recognize patient cohorts for (mostly) clinical trials. Although i2b2 solves this particular obstacle elegantly, it falls short, in our opinion, when ‘fitting’ it to other evaluation criteria specifically those imposed by realism based ontology (RBO).
generally considered necessary for active safety analysis. Further examples of CDMs include the Observational Medical Outcomes Partnership (OMOP), the Patient-Centered Outcomes Research Network (PCORnet), the healthcare management organizations’ research network (HOMOR) virtual data warehouse, and the Study Data Tabulation Model (SDTM) of the Clinical Data Interchange Standards Consortium (CDISC). Several of these CDMs have been subjected to studies for their ‘fitness for purpose’ for storing data extracted from electronic medical records (EMRs) specifically for the purpose of secondary data use in research. The OMOP pilot program, for example, terminated June 2013, but development still proceeds at the Observational Health Data Sciences and Informatics (OHDSI) collaborative. OHDSI has released version 5.0 of the CDM and has helped develop a software tooling chain to facilitate extract, transform and load (ETL) processes from a diversity of source systems. These tools are designed to aid mapping of data sources to terminologies, loading source data into CDM-compatible data repositories, and data analysis on these repositories. The intent of the CDM is thus to provide a ‘common model’ for data coming from all healthcare information systems to be transformed and loaded into CDM-compatible data stores for the purpose of research, analytics, and data integration. It is intended to do this with minimal transformations and data loss. We chose the OMOP CDM as our intermediary data model for (1) the way it can deal with what is generally called ‘findings,’ (2) the variety of open source analytical tools available, and (3) its wider purpose. It has also been qualified in some studies as the ‘least lossy approach’ among several CDMs tested.

The work described here is the result of scrutinizing the OMOP CDM from a RBO perspective specifically on the ways the data model presents a distorted view on the reality of the world it is referencing. The primary principle of comparison is restrictions based on the ‘fitness for purpose’ of the CDM and how those restrictions inhibit referencing reality adequately. Several publicly available ontologies, and, perhaps more importantly, the principles that they adhere to, were used as references including the Basic Formal Ontology version 2 (BFO2) 10, the Information Artifact Ontology (IAO) 11 and the Ontology for General Medical Sciences (OGMS) 12.

Methods

We followed the approach outlined in ontological realism 13 which takes very serious the distinction between data and data models on the one hand versus what the data and data models are about on the other hand. This allows us then to determine the differences between the CDM’s ‘fitness for purpose’ versus the ‘fitness to reality’. One can for example, metaphorically, view the data model as a container with a defined shape and size and built out of a certain material that restricts in certain ways what it can be filled with. In the case of the CDM, the restrictions are brought about by the structure of the tables, the cardinality of relationships, and the constraints implemented in the model. The ‘shape’ and ‘size’ of the container determine the qualities of that model – how well the model represents reality and the technical requirements or the ‘fitness for purpose’. The structure of a data model, specifically in this case, a relational data model, is a lens through which one can view certain portions of reality (PoR) – sometimes exactly the way they are, sometimes, as we will demonstrate, not without distortions – while others are shielded off. According to the RBO-perspective, PoRs are composed of types (PERSON, ROLE, PROCESS – types are standardly written in SMALL-CAPS, while particulars are written in italics) and particulars – instances of types that carry identity (the two authors of this paper are both particulars which instantiate the type PERSON; with respect to the work presented in this paper, they each had particular roles each one of which was an instance of ROLE, and so forth). Types relate to other types by virtue of the way all particulars of these distinct types relate to each other. Such relationships between types can be expressed by axioms in a variety of formal ways. For example, in the Basic Formal Ontology (BFO) 10 an axiom stating that an EXTENDED ORGANISM 14 Instance-Of EXTENDED ORGANISM then John Doe is also Instance-Of MATERIAL ENTITY. Also John Doe’s Height is a particular which carries identity and which Inheres-In John Doe. This John Doe’s Height is a particular quality and is Instance-Of the universal QUALITY. It is not an Instance-Of the universal EXTENDED ORGANISM.

The OMOP CDM’s ‘fitness for purpose’ is ‘to accommodate data from the observational medical databases that are generally considered necessary for active safety analysis’ thereby being ‘analyist-friendly’ to meet the requirement to ‘allow the analytic methods to execute quickly enough to be practical’ 15, p55. On the other hand, the RBO-perspective is purpose independent, with the exception of reflecting the structure of reality 13. Therefore, it is hypothesized that the OMOP CDM’s ‘fitness for purpose’ limits the OMOP-perspective to a reductionist representation of reality and thus that the fields used in the tables deviate from realist types. Or in other words: comparing the two perspectives might lead to a conclusion that the OMOP view is an oversimplification (reductionist view) of or an unfaithful (deviant) view to reality.
The PoR which is represented by means of the OMOP perspective can also be represented by means of an RBO view by using RBO compliant ontologies such as the Basic Formal Ontology (BFO)\(^{19}\), the Information Artifact Ontology (IAO)\(^{14}\), the Ontology for Biomedical Investigations (OBI), and the Ontology for General Medical Science (OGMS)\(^{14}\). These ontologies, and the principles that they adhere to, can be used to provide context in the comparison of the RBO-perspective vs the OMOP-perspective. By comparing these two perspectives we can qualify the accuracy of representation to reality and understand why and in what way certain design restrictions distort the representation of reality. The OMOP-perspective should primarily reference types and relationships amongst types so that the data which are stored in OMOP-compatible data repositories represent relationships between particulars in exactly the same way the RBO-perspective would reference particulars, relations between those particulars, and relations between these particulars and types.

From the RBO-perspective, relational data models, including those used in EMRs, practice management systems, and CDMs are composed of individual parts – tables, relationships, columns and so forth. Under an RBO-perspective, these components are INFORMATION CONTENT ENTITIES (ICE)\(^{17}\). A particular ICE Is-About some entity in reality. For example, a patient medical record number (MRN) is an ICE which Is-About some person with a patient role that Inheres-In that person. A PatientID column in a relational database based on the OMOP CDM represents the type PERSON whereby each particular cell of that column represents an Instance-Of PERSON. On the other hand, a diagnosis is an ICE that references some output of a clinical diagnosis process that Is-About a disease, while a disease Inheres-In some person.\(^{14, 18}\) This may seem trivial – or perhaps overly complicated – to a clinician at the point of care, but the distinction is important to accurately represent reality: the diagnosis and the disease are separate and distinct entities but are often represented in CDMs as the same entity.

With this in mind, we explored whether there are design principles that are standardly used in information modeling approaches that may have had a negative impact on the implementation and development of the CDM. Our process took into consideration the ‘fitness for purpose’ as well as various projects’ conformity to the CDM as described in the literature. Looking with the eye of a realist ontologist to the ‘fitness for purpose’, requirements and design goals of the OMOP CDM may provide insight to where the model references reality objectively and adequately, and where it falls short. For example, a data model that has a requirement to conform to a certain structure to allow business intelligence (BI) tools to be able to ingest and query the data can be a limiting design restriction in itself. BI tools are designed in certain ways for maximum efficiency and to answer queries of a specific kind. A component-based\(^{19}\) ecosystem has been developed around specific versions of the OMOP CDM and the desire to take maximally advantage of the BI tools it brings with it provides an incentive to not stray away from the original design guidelines. The OMOP CDM has had noteworthy improvements from release to release but drastic changes to the CDM would cause decisions to be made about either, the immediate redesign of software – to bring it up to date with the changes in the current version of the CDM – or the acceptance of being out of version compliance. In fact, one of the design principles of the OHDSI consortium is ‘Backwards Compatibility’\(^{20}\). Additional issues to contemplate when designing a relational data model are the normalization of data – data duplication, restricting the number of joins required to traverse the data. Joins are expensive, and building constraints that provide data consistency but does not constrain the model in a way that clashes with the ‘fitness for purpose’ is a challenging problem.

We began this comparison by downloading the data definition language (DDL) for the OMOP CDM version (v5) from the GitHub repository maintained by the Observational Health Data Sciences and Informatics (OHDSI) collaborative\(^{21}\). The DDL scripts are instructions on how to create the tables, relationships, indices and constraints that makeup the OMOP CDM and were loaded into a locally installed PostgreSQL server. After these scripts finished running, we ran additional scripts on the database for the purpose of creating documentation such as an entity relationship diagram (ERD) that visually represents a relational database schema. ERDs allow the visual inspection of tables, their types, and the relationships to other tables (constraints) by means of tables and field descriptions, cardinality of relationships, etc. Afterwards, we downloaded the documentation supplied by the CDM v5\(^{22}\) and used it to compare the ERD with the purpose to derive the informal semantics of the OMOP CDM, specifically the lens representing OMOP CDMs PoR used to view entities and their relationships – the ‘OMOP-perspective’. We then queried PubMed to identify information pertaining to source data conversion into the OMOP CDM to proactively avoid problems reported in the literature. We performed an analysis to decisively compare common downsides and gained knowledge from other organizations experiences and perspectives to improve our approach.
Results and discussion

We have identified thus far two different ways in which the OMOP CDM design goals conflict with an RBO-perspective on the data represented in OMOP CDM-compatible data stores (Table 1). One design principle of the CDM is reported as follows: ‘The CDM aims at providing data organized in a way optimal for analysis, rather than for the purpose of operational needs of health care providers or payers’\(^\text{20}\). Operational needs and data analysis needs differ indeed. Data normalization in operational systems is for instance focused on making transaction speeds satisfy the requirements of the operational environment, which in the case of EMRs comes down to the ability of quickly entering and retrieving data about a single patient. This constitutes a relatively small amount of data with respect to the totality of data held over all patients in the EMR system so that the search space is quite small as well. Analyst queries on the other hand have to run over very large amounts of data while also returning large result sets. Although speed is an issue, it is not as severe as in EMR systems. For example, waiting hours for an analytics question to be answered using the data in a secondary use data store is for sure annoying, but does not need to disrupt the workflow of the data analyst. But it would be unacceptable to have the query run for days and weeks, what would be the case if a typical analytics question would be run over the back-end of the EMR system itself, rather than over the secondary use data store of which the model is optimized to handle these kinds of queries. By examining the CDM, specifically the Person-table, Observation-table, Provider-table and Location-table we start to see where some conflicts with the RBO-perspective as brought about by this sort of optimization arise from.

</tr>
</tbody>
</table>

The Person-table is composed of many fields which hold data with specific data types, as for instance in the person_id-column. The OMOP specification documents this field as being ‘A unique identifier for each person’\(^\text{23}\). From the RBO-perspective we would phrase this that in relation to what occupies a specific cell in the person_id-column there exist a particular person_id which is an Instance-Of PERSON_ID, this type being itself a subtype of ICE. That particular person_id Is-About (at some point in time) a unique particular that is an Instance-Of PERSON. What is stored in the person_id-column of an OMOP-compatible data store is then a Concretization-Of that particular person_id. That concretization has ‘in the database on disk’ probably the form of a specific pattern of magnetization points. When that person_id is concretized on paper, it is most likely in the form of a (alpha-)numerical string. The paper can be destroyed separately from the database, or even both can be destroyed. But that would not result in the person_id to be destroyed, and for sure not the person about which this is the ID. There is in the RBO-perspective no ‘death through nullification’ for which the now abandoned HL7 RIM was once critiqued\(^\text{24}\).

Figure 1. RBO-perspective Person vs Provider
On the other hand, examination of the Provider-table documentation reveals that the column provider_id-column is defined as ‘A unique identifier for each Provider’ 25. Under the RBO-perspective, a PERSON is a subtype of MATERIAL ENTITY which itself is a subtype of INDEPENDENT CONTINUANT while a PROVIDER is a subtype of ROLE which itself is a subtype of REALIZABLE ENTITY that Inheres-In a PERSON. PROVIDER is trivially not the same type as PERSON nor is it subsumed by PERSON. Figure 1 illustrates these relationships from the RBO-perspective (rectangles with rounded corners represent instances while rectangles with square corners represent types). The question now is what exactly is meant in the OMOP CDM with ‘provider’: should this be interpreted as meaning ‘provider role’ or ‘person which has a provider role’? And it should make us wonder whether with ‘person’, OMOP really means what we typically understand under that term, or whether they mean ‘patient’. Under the interpretation that the provider table is a lens that captures references to instances of PROVIDER ROLE but not to the particular person that bears the PROVIDER ROLE, one would expect the persons that bears that role to be represented in the person table as well. Although a valid distinction, the goal of this comparison is to compare the implementation of the CDM to its ‘fitness for purpose’. Arguably a simple data analysis question: ‘How many unique entities of type PERSON are referenced in the CDM?’ would return too small a number if PERSONS who bear a PROVIDER ROLE are not included in the person table and only entries in the person table would be counted. On the other hand, if the same question would be answered by a query that returns the total number of both entries in the person table and entries in the provider table, then this would result in a number that is too high if there are persons represented in the dataset that have both a PATIENT ROLE and a PROVIDER ROLE. This is deviant of the RBO-perspective but also deviates from the OMOP-perspective’s ‘fitness for purpose’ with that purpose being accurate analysis of data. Accuracy in this case is thus, as we assume, only expected for certain types of questions that according to the designers are from their perspective relevant to be asked, and not for all types of questions that can be asked over exactly the same domain: thus the two questions asked, although valid from a realist perspective, are not supposed to be asked to OMOP CDM-compatible data repositories.

The root cause of the problem just sketched can be described as a confusion of types. A possible solution to this mis-representation of reality used in the above example may be addressed by expanding the CDM to include a Person-table, Provider-Role-table and a Patient-Role-table. These tables would distinctly identify the realization of patient and provider roles throughout the dataset and allow unique and accurate counting of instances of type PERSON. Constraining each role by a start and end timestamp should be used to temporally qualify roles linearly – allowing deeper analysis and thus increasing the CDMs ‘fitness’ (figure 2).

Another problem discovered is the opposite of the previous one. While the previous problem had to do with incorrect counting of particulars due to incorrect representation of uniqueness and confusion of types, this one has to do with cardinality constraints existing in the CDM. We have examined the Location-table and the Person-table to compare it with the RBO-perspective. As displayed in figure 3, the Person-table has a column named location_id which is defined as ‘A foreign key to the place of residency for the person in the location table, where the detailed address
The model’s definition (DDL) is designed in a way that will only allow one location to be assigned to a person at any given time. This is so because of the structure of the data model which is designed in such a way that a row in the person table can only have one reference to a row in the location table (Figure 3). This type of one-to-one relationships form the least costly joins that can be made in a relational database.

![Figure 3 – Relationship between Person and Location table](image)

From the RBO-perspective, relationships between particulars – the main relata – of which one is of type CONTINUANT always involve an extra particular which is an instance of TEMPORAL REGION. Assertions about such relationships should thus contain references to all three particulars: to both main relata and to the temporal region during which the relationship between the two particulars obtains. Entries in databases in which foreign keys are used as described above to indicate the address of a person, both persons and addresses being continuants, qualify as assertions about relationships that hold over a period of time. However, in the OMOP CDM, only two of the three required particulars are referenced: there is a reference to, say, Person 1 and to the residency of Person 1 (in this case an address – Address A) but there is no reference to the temporal region. Of course, at some point in time, the location_id may need to reference another address when Person 1 moves to another city or even across town – Address B at some other time. A secondary data use question such as “How many instances of type PERSON could have been exposed to pollution from this water source?” would only include whichever single location is associated with that particular PERSON and not consider all the places the person lived in the past. The OMOP CDM documentation does acknowledge that patients over time can have distinct locations, genders, etc., but “it is the responsibility of the data holder to select the one value to use in the CDM”\(^{22}\). A possible solution to correct the representation of reality in this case could be to change the cardinality of the Person-table to Location-table to allow multiple relationships between a person and a location. This can be accomplished by using a bridging table. In the example below we have added a start_dttm and end_dttm (Figure 4) column to the location-table so we can provide a TEMPORAL REGION reference. With this addition, a person’s locations can be tracked over time representing reality more accurately, and providing a stronger use case for secondary data use. The current CDM structure does not limit introducing a new location into the database, but it does not allow creating a historical transaction. If a person changes residency, the location of that residency would change removing the previous location and no record of this transaction would exist.

This is a reductionist problem involving temporality. Relationships amongst particulars one of which is a continuant obtain in some temporal region and it is important for the model to be able to capture this feature of reality. We can analyze other fields using this same logic such as the Gender-column which shows the exact same problem – gender can change over time and this reality is important for secondary data use and accurately representing reality.
Conclusion

It is our belief that we can compare data model designs to designs based on ontological realism to not only show their restrictions but improve their ‘fitness for purpose’. Through an RBO-perspective we have identified thus far two examples of misrepresentation of reality – the confusion of types and cardinality problems related to temporal regions around particulars. Some may argue against the importance of these misrepresentations but as realism based ontologists we argue that representing data accurately to reality directly affects real world secondary data use requirements. By applying realism based ontology, we can ultimately increase the ‘fitness for purpose’ of data models and their respective requirements. As such, a practical implementation of RBO-perspectives can be incorporated into the design of data models improving their accuracy to represent reality. Many aspects of the RBO field have been theoretical in the past and thus, have not been applied in a practical way to existing CDMs. We believe that the maturity of the work that is being done in the RBO fields, specifically in the biomedical domains, and the advances in database technologies, presents a unique opportunity to develop the next generation of data models.

A Simulation Study on Handoffs and Cross-coverage:
Results of an Error Analysis

Abstract

Handoffs and cross-coverage are necessary for maintaining the continuity of patient care, yet both are potential sources of error, and may threaten patient safety and care. Handoffs are the transfer of patient information and accountability from one provider to another. Cross-coverage is the management of patients, of whom physicians have little or no prior knowledge of, during nightshifts. We observed how physicians give a sign-out after receiving a handoff in a simulated session of an evening handoff and start of nightshift. We collected data from thirty physicians from an academic medical center as they signed out six patients after responding to nurse calls. An error analysis of the sign-out data revealed 42 errors overall, with 28 omissions and 14 “erroneous data” errors. We then propose ways to prevent these errors through modification of the electronic medical record and support tools, and through higher awareness of human factors.

Introduction

Failures in communication between health care professionals and diagnostic reasoning errors pose a potential threat to patient safety and quality of care. Root cause analyses of sentinel events have shown an implication of communication issues in up to 70% of cases in a report by the Joint Commission on Accreditation of Healthcare Organizations1. Communication is particularly important during moments of transition of care, or handoffs, which are necessary to maintain the continuity of care, particularly among hospitalized patients. Handoffs are defined as the transfer of patient information and accountability from one healthcare provider to another2. Handoffs take place between day and night teams, or between wards or departments (e.g., between the emergency department and the internal medicine ward). The handoff practice varies widely between departments and institutions, and refers to in-person, verbal handoffs, phone calls, written handoffs or a combination of these. Recommendations for improving handoffs have emphasized the need to standardize the process2, which has been successfully reported with the “I-PASS handoff bundle”3. Recent studies on handoffs have shown the benefits of improving the handoff process on medical errors4, 5.

Cross-coverage is the process used during nightshifts, when the night team pursues the management of patients in the wards6. Night physicians face additional challenges for patient care, as (1) they manage a larger number of patients, (2) they are unfamiliar with the majority of patients, and therefore need to depend on prior assessments and plans performed by the day colleagues, and (3) work with less staffed teams (both nursing and physician teams), with (4) subsequent lower supervision during the night than during the day. Furthermore, night physicians may also manage patients for whom they have not received a handoff. Therefore they need to be able to rapidly extract pertinent information from the medical records, and other available resources (nurses, or patient summaries). This rapid extraction of pertinent content from the medical records has been called “chart biopsy.”7

Paper summaries are an interesting support tool for handoffs, because it allows the receiver to have an overview of the patients’ problems. Systems like UW Cores (University of Washington computerized rounding and sign-out system)8 have shown their effectiveness in improving the workflow process and handoff. During focus groups from a prior study with residents and supervising physicians from our division9, discussions around support tools for handoffs raised concerns about errors and redundancy. Paper-based tools, even if auto-populated, are only an instantaneous snapshot of a patient’s medical chart, and the physicians therefore were concerned that they may be a source of error, if modifications appeared after printing the summary. Furthermore, since logging into the chart is required to see the latest vital signs or for prescriptions, most participants did not see an immediate benefit in having a potentially unreliable paper print-out, even if it could perhaps allow for a more ubiquitous or quicker access to patient information. Unsurprisingly, many physicians actually use hand-written notes (on blank paper or on documents such as the admission notes) as support tools throughout the day, which may have an even higher rate of imprecision or error.
Prior studies on handoffs or cross-coverage have for the large part been observational studies or retrospective cohort studies. These designs have limitations, such as lack of comparability and patient specificity, or recall bias. We therefore conducted a simulated handoff and chart biopsy study, an approach that allowed us to use standardized cases with pre-defined nursing cues, and direct observations of patient management and electronic health record (EHR) use.

The aim of the present study was to study the handoff process among residents and supervising physicians, focusing on the potential errors, to identify their origins. We hypothesized that errors during the handoff simulations could arise from the handoff process, the data collection during the chart biopsy, or the clinical reasoning during cross-coverage. We then explore ways to help avoid these errors through EHR design and medical training. The analysis of the handoff quality in terms of the type of support (paper summary, EHR or none) will be presented in a separate report.

**Handoffs in General Internal Medicine at our institution**

At the University Hospitals of Geneva, the medical teams (2 residents, 2 medical students, and 1 supervising physician) of the Division of General Internal Medicine each manage about 15 to 20 patients. The teams are divided into two zones of about 100 patients, and one nightshift physician cross-covers each zone. A senior physician from the Emergency Department, who is not otherwise involved in the patients’ care, supervises nightshift residents. Therefore, night and day teams are completely different, and rely on handoffs, notes in the medical charts, and interactions with the nursing teams, to maintain the continuity of patient care.

Handoffs take place in a meeting room away from the wards, and last often less than 15 min for the whole zone. This is achieved by only handing off a selection of patients to the night team, selected according to the following criteria: (1) Patients whose condition has recently deteriorated (unstable), or who have recently developed new symptoms of yet uncertain diagnosis, and who therefore require monitoring, (2) patients who require pending action (e.g., following up on lab or imaging results, or pending consultations by a specialist), (3) patients who are considered complex, or whose management is unusual, (4) patients who are receiving end of life care, or (5) patients for whom the day team anticipates potential complications overnight. Simple, stable patients with no expected complications are not handed off to the night team. A locally developed mnemonic in French (Code IDEALE for CODE status, Identity, main Diagnosis, Evolution, expectAtion, to-do List and quEstions) is sometimes used to introduce handoffs to students or new residents.

**Methods**

*Participants:* After approval from the local ethics committee, we recruited volunteer residents (R) and supervising physicians (SP) in General Internal Medicine from our academic hospital between January and November 2015 through convenience sampling.

*Simulation:* Our study design reproduced a Friday evening handoff session in our Internal Medicine wards, and beginning of evening shift for the participant. The simulation had three phases: a handoff phase, a chart biopsy phase, and a sign-out phase. For clarity in this paper, we used the term “handoff” when the participant was the receiver of information, and the term “sign-out” when the participant was the information giver. The overall duration of the simulation was about 45 min.

- In the **handoff** phase, one investigator (KB) gave a standardized handoff of four randomly chosen patient cases, allowing time for questions and interactions with the participant. Participants were randomly selected to receive a paper summary tool, have access to the EHR or to be the control group, with only blank paper for note taking (available in all 3 groups).
- In the **chart biopsy** phase, the participant was left alone to review the EHR for the beginning of a nightshift. During this phase, the participant received four calls from nurses, two of which were about patients that had been handed off, and two for patients without handoffs. We then informed the participant that her shift needed to be interrupted, and asked her to sign-out to a colleague. This phase lasted about 25 min, or whenever the participant felt prepared to sign-out, to avoid time pressure bias.
- In the **sign-out** phase, participants chose which patients they wanted to discuss, and presented them to an investigator (KB) who had no prior knowledge of the patients.

*Data collection:* We collected demographic data on the participants, such as level of experience and years of practice. We audio-recorded and transcribed the simulations. For this paper, we focused on the sign-outs, which were de-identified for subsequent analysis.
Scenario preparation: We created 8 fictitious clinical cases of commonly encountered diagnoses in internal medicine wards, inspired from real patient cases. A brief summary of the cases is provided in Table 1. For each scenario, we prepared a mock-up prototype based on our local electronic medical record (EHR), a nursing call, and a paper summary. We chose to use mock-ups of the EHR rather than real patient charts for several reasons. First, we wanted to be able to control all the information that participants had access to for each patient. Second, the mock-up helped avoid an additional cognitive load for participants, by adjusting the chart dates for the study. In a prior study with a similar design \(^{10}\), participants found the date issue confusing, especially since each patient had different hospitalization dates. Third, we did not want any post-test date information to be visible in the patient chart that could affect EHR use, or clinical reasoning (ie., "patient deceased", or test results from a later date). Although using a mock-up restricted the EHR functionalities, (i.e., search engines in the EHR were not functional, CT scans were limited to a few screen shots), the prototype allowed all the main interactions with the EHR, and all the dates in the EHR were adjusted to the dates of the participants’ sessions to decrease confusion and to optimize the realism of the simulation. Seven of the cases were used in the handoff randomization, whereas the medication error situation (Case E) was used solely in the randomization of nurse call, and thus was never handed off. Cases are listed in Table 1.

*This case was not handed off during the study, and was solely used for nurse calls

Some explanations about the cases help understand the encountered difficulties. In Case A, the participant received a call about acute chest pain, in a patient admitted for an inaugural episode of heart failure from ischemic heart disease. Patient management was quite simple in this case, but needed to be conducted urgently. In this scenario, the main difficulty resided in the retrieval of information about all the cardiology work-up the patient had received since his admission.

Case B was about a patient admitted ten days earlier for liver failure, who presented bleeding (hemoptysis) shortly after being admitted. His anticoagulant therapy was interrupted for a few days, despite the recent (<3 months ago) diagnosis of pulmonary embolism, as discussed with the vascular medicine consultant. The plan was to begin the anticoagulation therapy shortly, since the bleeding had stopped.

Case C was a patient with a history of metastatic prostate cancer who was admitted for pneumonia. The nurse calls about recurrent chest pain, which is of non-cardiac origin, with a range of differential diagnoses.

Case D was a patient with past medical history list that was not updated in the patient summary (it did not include chronic obstructive pulmonary disorder), while the results of the pulmonary function test were reported in the updated problem list, and showed sever lung disease. This discordance was noticed rapidly, and led to questions during the initial handoff, or later verification in the EHR.
Case E was a patient admitted for sepsis, with no particular concerns. She unfortunately takes her neighbor’s medication, leading to the ingestion of a high dosage of beta-blocker and an oral diabetes medication. The erroneous information for her was the indication about the ward she was in.

The patient in Case F was admitted for hyponatremia, and presents with new nocturnal agitation, with a wide range of possible diagnoses. Case G patient was a patient with complicated pneumonia, who had an antibiotic switch the day of the handoff, with the paper summary that had not been updated. All but one participant identified this error during the initial handoff. And finally, case H was a complex scenario of a patient with liver failure and many complications, who presented recurrent fever. His hospital stay was the longest, since he’d already been in the intensive care and intermediate care units.

Paper summaries were a novel feature for our participants, as they are not available in the current EHR system. We designed the summaries as potentially auto-populated fields from the EHR. We included patient identity and age, room and bed, code status, comorbidities, problems and to-do list. We also included hospital duration, which is not easily visible in the EHR. These paper summary features were discussed and validated in focus groups with Rs and SPs in a prior study on handoffs in our institution. The paper summaries were tested on pilot participants for this study, and were subsequently shortened. Dates of the summaries were also adjusted to the participants’ sessions.

To address concerns raised about the reliability of paper summaries, we included imprecisions and even discordant information in the paper summaries. For example, we reported a patient on one antibiotic, which was actually switched the day of the simulation sessions. This type of error is commonly encountered as a missed update, or an inappropriate copy-paste. In another case, we failed to update the past medical history list (probable COPD, no pulmonary function testing) after working-up a patient, which revealed severe COPD.

The verbal handoffs were also standardized for each case, with answers for anticipated questions from the participant. Other questions were answered with vague responses, which were meant to lead the participant to look up the information in the EHR. Although the paper summaries contained imprecisions or errors, all verbal handoffs contained the correct information.

Analysis: In this study, we studied all the elements given in the sign-out phase, and focused particularly on errors. Errors were defined as omissions, or erroneous information that was given during the sign-out. We also analyzed the imprecisions in the sign-out phase. The definitions of these terms for our study are presented in Table 2. An expert physician conducted a thematic analysis, and coded the transcripts using Atlas.ti v1 for Mac, taking into consideration the handoff status and nursing call interventions. A second expert physician cross-checked the initial coding. Differences were discussed to reach a consensus.

<tr>
<td>Imprecison</td>
<td>Facts that were incomplete or approximate, but with little or no impact on the comprehension or management of the case. For example, an age reported as 80-something rather than 83 years would be an imprecision.</td>
</tr>
</tbody>
</table>

We report the sign-out durations by level of expertise. We use descriptive statistics to present the errors and imprecisions. We compared the mean number of errors in cases between the 3 arms with crude and adjusted (for experience level) linear regression models with robust standard errors. We then analyzed whether the sources of errors were in relation to the EHR data, paper summaries, annotations, or initial verbal handoff. Finally, we studied how to prevent these errors, through content and design of the EHR or paper summaries, or through human factors.
Results

Participants
We recruited 30 participants, 16 residents and 14 supervising physicians (Table 3) with an average of 5.4 years of experience. Overall, SPs had 6.5 years more clinical experience than the Rs. Only two of the participants reported having received handoff training. Six of the interns and seven of the supervising physicians had heard of a locally developed handoff mnemonic. Table 3 shows that the randomization resulted in a slightly larger paper summary group, who also had more supervising clinicians.

Participants were all familiar with the local EHR system.

Sign-out description
The sign-out phase duration was 12.2 min on average (range 6.0 – 30.0), with a non-significant difference between SPs (11.3 min) and Rs (13.0 min), with p=.33. One SP participant, P12, chose to present only 3 patients during sign-out, and therefore had the shortest duration. All other participants presented the six patients.

A junior SP participant, P17, was the other extreme of the sign-out duration. He was particularly thorough during the sign-out process, and took time to look up information in the EHR to complete his sign-out. He took nearly five times the amount of time of the shortest sign-out for six patients (30 min vs 6.5 min), despite some pressure from an investigator, and had 2 errors and 5 imprecisions. P17’s explanation for not being able to be more concise was the complexity of the cases.

Errors and imprecisions
According to our definitions of errors, we found 42 errors overall among the 180 sign-outs, or 23.3 per 100 cases. Twenty-eight of the errors were omissions, 14 were erroneous facts. There were 100 imprecisions in the 180 sign-outs. Eight discordances between coders (all for imprecisions) were discussed to reach a consensus. We present the errors and imprecisions per case in Table 4.

*Case E was solely used for nurse calls.

Cases A and H had more errors than the other cases, even though cases B and G also had more imprecisions. This can be visualized more easily in Figure 1.

Figure 1. Errors and imprecisions by case
As the number of participants of the three types of support tools differed among the groups, we present error and imprecision rates per case in Table 5. The 0.23 mean level of total errors per case did not differ between the 3 arms, in the crude (p=0.98) and adjusted models (p=0.99).

Overall, the small discordances or errors in the paper summaries were identified by the participants, and were not the cause of errors in the sign-out.

| Table 5. Errors and imprecision rate per case for each type of support |
|-----------------|----------------|----------|-----|
| Sources of errors | EHR access | Paper summary | Control | Total |
| Omissions | 0.13 | 0.17 | 0.17 | 0.16 |
| Erroneous facts | 0.09 | 0.06 | 0.08 | 0.08 |
| Total errors | 0.22 | 0.23 | 0.25 | 0.23 |
| Imprecisions | 0.43 | 0.56 | 0.67 | 0.56 |

Sources of errors

A closer study of the errors and their sources reveals that errors arose at different times of the handoff process. During the verbal handoff, physicians may receive erroneous information from their colleague, or they may receive correct information, but misunderstand the facts, or simply record them imprecisely. One physician had trouble giving his sign-out because he had trouble re-reading his own notes, for example. Although we standardized the handoff content, participants were given the opportunity to ask questions about each patient before moving to the next patient. These interactions were important to clarify information, or to address issues that the received anticipated for the night. The questions asked ranged from medication specifications (“Which antibiotic is he on?”) to lab test results, or contingency plans. For example, participants were asked to follow-up on a lab test for ascites in Case H, and many participants asked if the day team had discussed which antibiotic to prescribe if the liquid showed signs of peritonitis.

The analysis of the erroneous facts in our dataset revealed areas of weakness in the handoff and chart biopsy process. Four of the erroneous facts were related to comprehension of the timeline of events. For example, P21 mistook the bleeding complication in Case B that occurred at admission one week prior as an event of the day, and therefore found the work-up to be incomplete, and made erroneous recommendations. In this example, the error was initiated during the verbal handoff, despite P21 having received paper summaries. Another participant mixed the data from two different patients during the sign-out, not realizing immediately that the EHR was open on another patient’s chart. The other erroneous facts were in the recommendations given, due to clinical reasoning or medical knowledge.

In the analysis of the omissions, we found that these occurred at different parts of the handoff process. Some participants forgot to report nurse calls, others did not document key points such as vital signs when responding to nurse calls. And yet other omissions related to the retrieval of various reports in the EHR, when this information had not been integrated in the progress notes.

Sign-out structure

Overall, participants tended to present patients by ward during the sign-out, rather by degree of urgency or order of initial handoff. Some physicians were a little disorganized, and sometimes only remembered some patient information after having moved to the next patient, such as in the case of P1: near the end of the sign-out, P1 suddenly came back to the first patient, asking whether he’d reported that this patient had also presented fever, and that a septic work-up needed to be done.

Discussion

Handoffs and cross-coverage have both been identified as moments of potential threat for quality and safety of patient care. Observational studies have studied incident reports, rapid team responses, or medical errors in the patient charts. Our error rate of 23.3 per 100 cases is in the range of other studies on handoffs and errors. As a comparison, Starmer et al reported an overall rate of medical errors of 33.8 per 100 admissions, and 24.5 per 100 admissions in their studies on handoffs and medical errors.

Our statistical analysis of the errors did not show any differences among any support tools or no support. This could be due to the small number of errors in the study, since our study was not powered for this outcome. Also,
the sources of error are not all related to information retrieval or interpretation. Erroneous facts due to clinical reasoning or medical knowledge deficits may not necessarily be improved by changing the type of support tool.

Interpretation of our error and imprecision rates need to be performed with caution. Our analyses examine differences in facts from our data sources, but not all facts are relevant in a handoff. In fact, physicians need to select the pertinent features in a patient case to remain concise. Omissions therefore may not all be bad. The difficulty lies in the selection process of the pertinent features to disclose.

Furthermore, imprecisions are probably related to the high cognitive load of the handoff process. Beyond the case complexity in terms of clinical reasoning, the EHR and available resources can also lead to difficulties. As we found in the results, one of the cases required finding recent reports of the cardiology work-up (Case A). It is this step that led to errors for our participants, because pertinent documents were mixed with all the other documents. Although the search function of our EHR mock-up was limited, compared to the EHR the participants were used to, we note that the participants did not take the extra time to find the documents. When the results were not easily retrievable from the progress notes, for example, some participants presumed that the results were not yet available, and abandoned their search.

**Human factors and training**

Human factors play an important role in the handoff process. Although higher awareness of the challenges of the handoff process could be addressed through training, the participants of our study seemed to reflect the current state of handoff training. Only two participants (SPs) had received any handoff training prior to this study. Most participants had heard of a locally developed mnemonic for handoffs in our department. Although none of the participants actually used this mnemonic, they found it useful to illustrate or to teach handoffs to students or peers.

Our findings show that errors generated early in the handoff process can persist throughout the sign-out, simply because there is little verification of the information received. Communication failures are very common in clinical care, present in up to two thirds of preventable events. Therefore verification of verbal information is essential, and is emphasized in successful handoff training programs like I-PASS. Moreover, training in handoffs should also draw awareness on the reliability of note-taking: handwriting styles, speed, and comprehension can all affect the quality of the notes. This reliance on notes and paper support tools led one participant to state contradictory facts about a patient, reading from the past medical history list, and then moving on the problem list, without realizing this. The other participants reported the updated status from the problem list only.

Implications for training based on the prior example would be to make sure participants use their clinical reasoning skills to choose the pertinent elements when signing out. Some participants briefly explained their reasoning process when giving recommendations. Having a shared understanding, or at least having the opportunity to clarify certain points of the handoff is commonly included in handoff recommendations. Another important manner to prevent errors from the onset would be for the receiver to summarize key elements for each patient, to ensure correct comprehension. This is the last component of the I-PASS handoff bundle.

**Support tools functionalities**

The low verification of facts by the users emphasizes the need for any handoff support tool to be able to present the most recent information available in the EHR, and to allow manually triggered updates. Although synchronizing support tool data with the EHR helps avoid transcription errors, it could also potentially be a source of errors, if they override previous information, lack traceability or provide information that is not yet processed by the physician in charge. For example, if the support tool presents a management plan based on an initial set of lab results, lack of a notification for new results may engender a misunderstanding about the reasoning underlying the plan. Also, there should be little need for repetitive documentation that could favor copy-pasting, such as for problem lists, or any other kinds of lists.

Having a patient’s information summarized in one place helps maintain a structured handoff. The structure of the handoff is important to share mental models of the patients, and to avoid having to jump back to previous patients to provide additional information. While most participants were able to maintain a patient-by-patient sign-out, some got confused with their annotation methods, particularly with the occurrence of new events. Having a designated place to write additional information, such as nursing calls, can help physicians stay organized. Although paper support tools are easier and often more efficient to annotate, the space to write is limited and is not standardized, making it more difficult for the annotations to be shared with the oncoming physician.
Design implications

In this section, we make some suggestions to help avoid errors during the handoff and chart biopsy process. Based on the errors identified in our analysis, we found several important measures to consider improving in the design and content of the EHR and the connected support tools. Our study design with standardized handoffs and repeated simulations with the same cases helped us identify and understand some of the potential sources of errors during handoffs and cross-coverage in more depth. Our findings also emphasize the importance of the initial verbal handoff, which can convey errors or imprecisions that are often not verified later in the process. In this manner, the handoff process resembled the children’s game of “telephone.” It is therefore particularly important to avoid introducing errors at any stage of the handoff or sign-out process.

Our EHR is a home-grown system, used by all healthcare providers in our hospital. Although data entry is specific for each type of professional, the content of the EHR is accessible to all. The EHR is structured in various tabs, and include the following:

- A list of reports, admission notes and discharge summaries
- Progress notes and consultation notes, which are unstructured, but usually written up as problem lists
- Vital signs, and administered medications in a chart
- Prescribed medications
- Labs
- Imaging
- Nursing notes

As in many EHR systems, most of the content of the tabs are presented in chronological order. The documents of each tab are presented separately, which means that physicians need to jump from one tab to another to concatenate the information from the reports, admission notes and progress and consultation notes. Collection of this data in the EHR, or “chart biopsy,” may be facilitated when the day team compiles the information in the progress notes. An eye-tracking study of physicians reading electronic notes, however, showed that large sections are ignored, which emphasizes the need to revise the content of electronic notes. Furthermore, reports from the end of the day shift however may not be included in the daily summary, if there is no “new report” alert (which can simply be bold characters, colored text, for example) in the EHR. One way to improve this process would be have better traceability of prescribed labs and work-up tests, and notifications for the final reports. These notifications should reach the patient’s physicians, day or night team, to help guarantee that all results can be acknowledged in a timely manner, and interpreted in the patient’s context.

Improving the design of the EHR system to better support the clinical workflow process would be another way to help prevent errors. The EHRs needs to support several different goals such as billing, quality monitoring and clinical documentation for patient care. The structure of the clinical documentation component in our EHR is similar to the paper charts we initially used, with various sections (i.e., tabs in the EHR). Designing a support tool for handoffs needs to support the workflow and reasoning process of physicians, pulling information from different areas of the EHR into a coherent overview of a patient’s clinical state and trajectory. Although a “snapshot” of the patient’s current state is supported in many EHRs via a dashboard summary page, the challenge lies in tracing the patient’s evolution during the hospital stay, which may not be well described in the progress notes.

When we consider these requirements, mobile solutions seem to offer opportunities for patient-safe options due to their ubiquitous use and possibilities of personalized alerts. Handoff support tools need to be readily available at all times, to provide the relevant information needed to review patient care throughout a shift. A thoughtfully designed mobile app can pull together information from different parts of the EHR, individualized according to user preferences and each patient’s clinical context. Mobile solutions can allow alerts to target the most appropriate user to help avoid alert fatigue.

Understanding the sequence of events that occurring during a hospital stay can be difficult, if relying solely on the EHR. Our EHR provides a detailed graph of vital signs and medications over time, but tracing the history of events can be tricky. Users may try different approaches from different tabs, using search engines in the prescription history, or skimming through the progress notes. Improving the timeline view, in particular using event-based visualization could help address this issue. Furthermore, some authors have looked at handoffs as narratives, that can help care-providers understand the patient’s story, and the sequence of events that have occurred during the hospitalization.
Improving the progress notes in the EHR could also help improve information retrieval. Progress notes are often structured as a problem list and plan, and allow physicians to attribute priorities to the patient’s problems, describe the plan, gather the results and provide contingency statements if needed. Currently, the tab structure in our EHR system makes sharing of information across tabs tedious, having to switch back and forth from one tab to another. Building a medical chart around the problem list, which integrates the important findings in a single place could help avoid excess switching. If we consider the clinical reasoning process, we blend parts of the history taking, the physical examination, labs and imaging results into each problem.

The analysis of “erroneous facts” errors revealed difficulties with timeline and event sequencing. During the verbal handoff, the receiver needs to combine many actions, listening and understanding the case, taking notes, anticipating complications, and having to deal with potential interruptions (phone calls, for example). Although receiving a summary is helpful, care must be taken to provide a simple outline with minimal administrative information to avoid cognitive overload. When participants need to read long paragraphs about each problem, their attention to the handoff giver is low, and can lead to misunderstandings.

Strengths and limitations
Handoffs, in particular the verbal handoffs, are difficult to study in a real clinical setting. Differences in patient cases, or changes in patient state do not allow for comparisons of performances. Therefore, we chose to use a simulation setting to reproduce the handoff and cross-coverage context. Although the number of cases was lower than the total average number of cases handed off in the wards, we believe that six cases allow us to address concerns of case specificity. This number is also sufficient to challenge the participants’ cognitive load, and allowed for a realistic, albeit busy, beginning of a nightshift. Standardization of the initial handoff also facilitated the comparison among participants. Although participants reported that complexity of cases was similar to real patients, standardization limits the variance and sources of complexity that complicate communication during handoffs.

The analysis for errors was based mainly on facts reported during the sign-out process. We did not include an analysis of the clinical reasoning process during patient management for this report.

Finally, this study focuses on internal medicine physicians, so the findings may not necessarily be generalizable to other medical specialties. The wide variation in handoff practices also limits its generalizability in other institutions or departments.

Conclusion
Based on a simulated handoff and chart biopsy study, we performed an analysis focused on the errors and imprecisions that were observed during the final sign-out, with no significant differences in error rate by type of support tool. Our findings emphasize several ways to help avoid errors in the handoff process, in the design of EHRs and of support tools, as well as by addressing human factors in future training programs. We propose facilitating the cross-coverage process by providing event-based medical charts, which regroup documents from related events together. Support tools for handoffs should be able to easily present updated patient data in a concise way and should facilitate note-taking. Furthermore, handoff training should raise awareness for over-reliance on support tools, and low verification of the collected information. We plan to apply these human factors training suggestions, and emphasize the narrative aspect of handoffs in our next study. Future studies on the handoff process should also include an analysis of the written handoff process.

Abstract

We present a method for rapidly ranking all distinct facts in an electronic medical record (EMR) system by how over-represented or under-represented they are in a patient cohort of interest relative to some larger reference population of patients in the same EMR. We have implemented this method as a plugin for i2b2, the open source data warehouse platform widely used in research health informatics. Our method is highly flexible in terms of what medical terminologies it supports and is vendor-independent thanks to leveraging the i2b2 star schema rather than any one specific EMR. It can be applied to a wide range of informatics problems including finding health disparities, searching for variables to include in a risk calculator or computable phenotype, detection of comorbidities, discovery of adverse drug reactions. The case study we present here uses this software to find unlabeled flowsheets for patients suffering from amyotrophic lateral sclerosis.

Introduction

Amyotrophic lateral sclerosis is a neurodegenerative illness affecting upper and lower motor neurons and anterior horn cells, culminating in death due to respiratory insufficiency or malnutrition \textsuperscript{1}. The progression of this disease is monitored via the amyotrophic lateral sclerosis functional rating scale revised (ALSFRS-R) \textsuperscript{2}, the eating assessment test (EAT-10) \textsuperscript{3}, and the Center for Neurologic Study Lability Scale (CNS-LS) \textsuperscript{4}. A CNS-LS score of 13 or greater has been validated [Moore et al. 1997] as an indicator of pseudobulbar affect (PBA). PBA is believed to be caused by degeneration of connections between the brainstem and the frontal cortex resulting in sudden mood swings and inappropriate laughter or weeping. This impacts patient quality of life and in ALS patients PBA is associated with a worse prognosis. It would be of great interest to be able to extract time series of these scores for multiple patients from the EHR for visualization, hypothesis testing, and predictive modeling with research-quality statistical software such a R \textsuperscript{5}. However, EHR systems are not designed for on-demand bulk data extraction. For many systems process is slow and laborious, with each data-pull requiring the local health IT team to write or modify custom reports. Another necessary step prior to longitudinal analysis of EMR data is a thorough characterization of the populations of interest in order to identify variables to later evaluate for inclusion in the statistical model as predictors or covariates.

![Figure 1. The i2b2 interface showing terms as they appear when normally annotated in the metadata and linked to the star-schema. Any combination of nodes in the hierarchical menu on the left of the screen can be dragged and dropped to the right side to create a query. This is the existing functionality of the i2b2 system. Our extension to it is not visible in this figure, but is presented below, in the Methods section.](image-url)
Integrating Informatics from Bench to Bedside (i2b2) is a data warehouse platform that offers a more flexible data model for research purposes. However, importing data into i2b2 from commercial EHR systems inevitably involves some degree of reverse-engineering and detective work. One common problem that occurs with nursing flowsheet data is that individual flowsheet components are imported into i2b2 but the mapping to their parent flowsheet names is not available. An more general methodological gap in health services research is the need for semi-automated cohort characterization, particularly of rich datasets such as EMR.

Figure 2. Design of Chi²notype plugin (light blue) and its integration with i2b2 (dark blue). The SQL back-end uses two dedicated tables (created in an account specified by the system administrator in a configuration file). The first table, PCONCEPTS, contains all unique combinations of PATIENT_NUM (the ID field i2b2 uses to distinguish patients) and CONCEPT_CD (the ID field i2b2 uses to distinguish EHR concepts). The second table, PCONCEPTS_COUNTS, is initialized with a prefix column (for filtering groups of concepts, as will be described below), a CONCEPT_CD column, a NAME column containing a short human-readable description of each fact (if such a description is available in i2b2), a TOTAL column (which represents the total number of distinct patients associated with each fact in PCONCEPTS), and a RFC_TOTAL column (which represents the value of the TOTAL column for each fact divided by the overall number of distinct patients). With each new patient-set that gets queried, a new pair of columns gets added to the PCONCEPTS_COUNTS table; these correspond to the TOTAL and RFC_TOTAL for that patient set but the names of all columns after the first two are based on the MASTER_ID, INSTANCE_ID, and RESULTSET_ID for that patient-set as recorded by i2b2’s audit log in whichever account i2b2 uses to store data (by default, I2B2DEMODATA). This way, if a patient-set is ever queried again, its existing columns will be found in PCONCEPTS_COUNTS and reused, thus speeding response times. Given such a table, it is trivial to calculate $\chi^2$ statistics, sort the results, and filter the output natively in SQL.

As part of the Greater Plains Collaborative Clinical Data Research Network [ref] we use the HERON open source ETL process [7] developed at the University of Kansas Medical Center. The approach HERON uses is to empirically derive an ontology using agglomerative hierarchical clustering by binary similarity score. While such an approach is a practical means to tackle the global problem of how to represent flowsheet data without prohibitively time-consuming manual curation, it has important limitations. First, it is of limited transferability to other sites; even sites that use the same EHR vendor as HERON’s differ in the meaning of a large fraction of the internal IDs that represent each flowsheet measure. Other sites cannot simply copy the flowsheet ontology as used by HERON--each site must run its own computationally-intensive clustering process. Furthermore, knowing that a given group of measures are similar to each other still does not always reveal what the data recorded in them actually means.

Here we demonstrate a bottom-up, incremental approach that is complementary to that of HERON: empirically finding under-documented EHR facts by means of an analytical tool called Chi²notype which we created to interoperate with i2b2. Chi²notype’s usefulness is not limited to flowsheets -- here we also use it to characterize the demographics, diagnoses, and medications of ALS patients in our system compared to a sub-cohort of those patients who suffer from PBA.

**Methods**

**Cohort** We searched i2b2 for all patients for whom there has ever been reported an ICD9 8–9 or ICD10 diagnosis code of 335.20 or G12.21 respectively excluding problem-list modifiers of "Deleted" or "Resolved". This resulted in a
patient-set of 839 individuals. In i2b2, patient-sets refer to user-defined groups of patient-IDs (de-identified in our case) that can be saved and re-used as inclusion/exclusion criteria for more complex queries and also as input for various visualization and reporting i2b2 plugins. This patient-set was compared to all patients in the EMR system to find data-elements unique to ALS. A second patient-set was generated with the diagnosis inclusion criteria but in addition one or more of the following: diagnosis of emotional lability (799.24 and R45.86 for ICD9 and 10 respectively); or pseudobulbar affect (310.81 and F48.2 for ICD9 and 10 respectively); or a CNS-LS total score \( \geq 13 \). This ALS/PBA patient set was compared to the overall ALS patient set in order to obtain a demographic breakdown for both and to discover features that significantly are different for ALS patients with PBA relative to ALS patients in general.

**Software** We wrote an i2b2 plugin, Chi2notype, for automated cohort-characterization. Chi2notype ranks all EMR facts in the OBSERVATION_FACT table of i2b2’s star schema by their prevalence in a given patient-set relative to a second patient-set that is a strict super-set of the first (by default, all patients that have encounter-level data in i2b2).

In other words, our tool makes it possible to see how over- or under-represented each EHR fact is in any user-defined group of patients.

**Workflow** The basic pattern of specifying a cohort, then a sub-cohort based on it, and then determining EMR data elements significantly over- or under-represented in the sub-cohort relative to the larger cohort can directly produce a demographic table or give hints about the interpretation of under-documented data elements. It can also be used as a building block for more complex workflows. At a high level, the basic steps for retrospective data analysis of EMR data can be viewed as:

1. Convert verbal/conceptual cohort inclusion/exclusion criteria into an unambiguous computer executable query (e.g. i2b2) that relies only on data that is available.
2. Likewise translate predictors, covariates, and response variables into another unambiguous computer executable query. Again, adjust plan for feasibility and interpretability.
3. When the two above queries are finalized, use them to pull visit-level data (for self-service systems such as at our institution) or to create a data request for the appropriate informatics team.
4. Proceed with analysis plan-- development and validation subsets, model specification and variable selection, etc.

Chi2notype facilitates step 1 by making the researcher aware of disparities between the cohort and sub-cohort which are potential confounders but in many cases can be addressed by a balanced sampling strategy or by inclusion as covariates in the statistical model. Disparities that have a plausible link to the outcome of interest can be added to the data element specification of step 2 so they would be available for evaluation as additional predictors during the variable selection of step 4. Likewise, the characterization process can also suggest possible outcomes of secondary interest to include.

The ranking is done by odds ratio. A \( \chi^2 \) statistic is also calculated for each EMR data element as follows:

\[
\sum \frac{|N_{ij} - E_{ij}|^2}{E_{ij}} \sim \chi^2 \text{ where } E_{ij} = \frac{N_j \cdot N_i}{N} \text{ and...}
\]

- \( X_{all} \) = any set of patients from the EHR system
- \( N \) = total number of patients in \( X_{all} \).
- \( \hat{X}_i \) = a cohort selected from \( X_{all} \) such that \( \sum \frac{|N_{ij} - E_{ij}|^2}{E_{ij}} \sim \chi^2 \).
- \( N_{ij} \) = total number of patients in \( X_i \).
- \( N_{i,j} \) = any fact from the EHR
- \( N_{i,j} \) = total number of patients in \( X_{all} \) who have fact \( j \) recorded at least once in their record.

</table>

This is more informative than ranking EHR facts strictly by their prevalence in the patient-set of interest, since with such a ranking there would not be any way to know whether the prevalence of a fact is a phenomenon specific to this patient-set or to the entire population.

By default Chi2notype returns the top-10 and bottom-10 of all EHR facts that occur in at least 10 patients in the reference group. These defaults can be changed by the user (Figure 3), and instead of all EHR facts, individual categories can be selected (based on the SCHEMES table from the i2b2 metadata). The full result-set can be exported as a .CSV file that can be opened with spreadsheet software where custom user-specific filters and functions can be applied. The downloaded spreadsheets have the same column and row structure (i.e. aggregated data not individual visits, which is not purpose of this software, but we have previously published a different app for that scenario [ref]).

To deploy Chi2notype to a pre-existing i2b2 server, one would download it from https://github.com/UTHSCSA-CIRD/chinotytype/, place the individual components in the parts of the file-system directed by the instructions, set up the necessary accounts and permissions, log directly into the database back-end of i2b2, and start using it (it will create the tables it needs automatically when it is first used). This project is still under intense development, but we are happy to help via the GitHub ticket system, those who wish to deploy Chi2notype at their own i2b2 sites. Chi2notype depends only on the database tables used by i2b2 and has no dependencies whatsoever on the underlying EHR. So far this software has only been tested in a Linux environment against an ORACLE back-end, but the SQL code is written to be as close as practical to the ANSI SQL standard, so it should present minimal obstacles to porting to other RDBMS systems (and the open-source license under which we are distributing this software encourages such collaborative modifications).

Results

We filtered the Chi2notype output for the ALS patient-set so as to only return flowsheet measures. We found measures that, while exceedingly rare in the overall patient pool (< 0.1%) were present in 65-71% of ALS patients. Moreover, the exact same prevalence was shared by multiple measures, which suggested that each was obtained from a patient during the same session (Table 1).
These flowsheet components were among the many in our data warehouse for which the parent flowsheets were not automatically mapped by the ETL. However, when the concept codes identified by Chi2notype were searched in the raw EHR data, we found exact matches to the ALSFRS, EAT-10, CNS-LS flowsheets appearing in the EMR clinical front-end user interface. This allowed us to create new i2b2 concept paths which in turn make all these flowsheets and their individual components available as additional inclusion or exclusion criteria for researchers querying our data. Furthermore, another plugin we are developing makes it possible to extract the contents of these flowsheets as columns in a simple, tabular, time-series format side-by-side with other variables of interest to secondary analysis such as visit vitals, medications, and procedures.

We then used the total score from the CNS-LS flowsheet to identify ALS patients who at some point in their history had a score greater than or equal to 13 (or had other indicators of emotional lability among their diagnosis scores) Instead of asking "what flowsheet IDs that lack descriptions are over-represented in ALS patients relative to the whole patient population?", we were asking a broader question about a smaller population: "what diagnoses, medications, and lab values differ significantly between the 150 subcohort of patients who have ALS and PBA versus the overall cohort that includes all ALS patients?". These results are shown in Table 2, and a demographic summary of ALS and ALS/PBA patients is shown in Table 1.
We found, that among ALS patients with PBA, there was an increased incidence of dysphagia, fatigue, emotional lability, as well as difficulties with breathing and speech. Among the drugs that are significantly different in prevalence are dextromethorphan/quinidine which is used to treat PBA, Riluzole which is used to slow progression of ALS, Tizanidine which is used to alleviate muscle spasms, and Jevity which is a nutritional formula used percutaneous endoscopic gastrostomy (PEG) tubes for ALS patients who are suffering from dysphagia. The only data elements whose incidence was diminished among ALS+PBA patients were counts of above-reference values for plasma blood urea nitrate/creatinine and creatine kinase (relative to the total number of patients on whom those tests were done in the two cohorts respectively).

**Conclusion**

Chi²otype is an open-source plug-in for i2b2 that is capable of rapidly and intuitively generating a list of facts relevant to a patient-set of interest for quality control, cohort characterization, and narrowing down the list of candidate variables to consider for inclusion in analysis. We used this approach to identify flowsheet measures that had no human-readable names or annotations, purely on the fact that they are known to be over-represented in the patient-set of interest. We then compared a sub-cohort of ALS patients exhibiting signs of PBA to the overall ALS cohort and found increased prevalence of ALS complications in patients with PBA, consistent with the recently published results of Tortelli et al. [ref].

Chi²otype allows the researcher to quickly find EMR variables that have the strongest positive and negative correlation with membership in a cohort of interest for the purposes of data characterization and rational selection of variables for inclusion in an analytic dataset.

Objective: Build and validate a clinical decision support (CDS) algorithm for discharge decisions regarding referral for post-acute care (PAC) and to what site of care. Materials and Methods: Case studies derived from EHR data were judged by 171 interdisciplinary experts and prediction models were generated. Results: A two-step algorithm emerged with area under the curve (AUC) in validation of 91.5% (yes/no refer) and AUC 89.7% (where to refer). Discussion: CDS for discharge planning (DP) decisions may remove subjectivity, and variation in decision-making. CDS could automate the assessment process and alert clinicians of high need patients earlier in the hospital stay. Conclusion: Our team successfully built and validated a two-step algorithm to support discharge referral decision-making from EHR data. Getting patients the care and support they need may decrease readmissions and other adverse events. Further work is underway to test the effects of the CDS on patient outcomes in two hospitals.

Introduction

In response to the Readmission Reduction (1) and Value Based Purchasing Programs (2) hospitals are increasingly collaborating with post-acute care (PAC) services to mitigate readmission risk. Between 1996 and 2010, discharge of patients to PAC settings, one of the fastest growing sectors of the Medicare program, showed a relative increase of approximately 50%. (3,4) Partnering with and shifting care to the post-acute care setting increases the importance of properly identifying the right patients for the right settings.

Discharge planning (DP), a process undertaken during the hospital stay, is used to proactively identify patients’ needs after hospital discharge and to begin a smooth transition from hospital to home or other care settings. Yet, several issues exist that have the potential to undermine quality of care and patient safety. DP is a complex process conducted by a multidisciplinary healthcare team, (i.e., physicians, nurses, social workers, and physical therapists), in collaboration with patients and their caregivers. Older adults with multiple comorbidities, complex treatment regimens, and the rate at which they churn through the hospital system add to the complexity of decision making. (5-7) Despite best efforts, the DP process is often rushed, with clinicians frequently not having all the necessary information or time to make optimal decisions regarding PAC referrals. (8) Furthermore, studies have revealed great variability in DP assessments and models, (9) clinician risk tolerance and decision-making regarding PAC referrals (10-15) and insurance barriers and a lack of standards for post-acute care decision making during this critical time. (15) Inconsistent practices for DP and identification of the need for PAC services can result in either over-referral for PAC services, a significant Medicare expense, or under-referral, leaving patients with unmet needs. (16) The need for decision support tools to bring structure to this non-standardized, but critical, process is imperative.

Currently, few CDS tools exist that provide recommendations for care after hospital discharge. Barsoum and colleagues developed and validated a tool to identify patients that should not be discharged directly to home after total joint arthroplasty. (17) Holland and team (18) created a tool to identify high-risk patients in need of focused discharge planning. Tseng and colleagues demonstrated improved DP when using a systematic assessment tool versus traditional assessment, (19) while others developed a tool to identify surgical patients who should not be discharged to home. (20) Our earlier work with a CDS called the Discharge Decision Support System (D2S2) identified six statistically significant factors associated with likelihood for PAC referral of older adults, including patient’s age, less than excellent self-rated health, no or intermittent help at home, major walking limitations, depression symptoms and number of comorbid conditions. (10) The D2S2 was commercialized and is translated into practice in 38 hospitals. However, to our knowledge there are currently no CDS tools reported in the literature that provide recommendations for PAC referral for a general hospital population and considers the specific site of PAC services needed. The CDS described here meets those requirements.

Objectives

Our objective was to build and validate an expert clinical decision support system (CDS) for the discharge referral decisions of whether or not to refer patients for post-acute care and if so, to what level of care. The study aim was to
define and validate the most significantly predictive model of factors to mimic nationally-based, multi-disciplinary experts’ post-acute care referral decisions. The hypotheses (H) for model building were: (H1) There will be a statistically significant correlation between the evidence-based factors (case study information) and the experts’ yes/no referral decisions. (H2) There will be a statistically significant correlation between the evidence-based factors and the site of referral. The hypotheses for the model validation were: (H3) The model will predict the expert referral yes/no decision with sensitivity, specificity and positive predictive value of greater than 80%. (H4) The model will predict the site of referral with sensitivity, specificity and positive predictive value of greater than 80%.

Methods

Setting. The data for the algorithm came from the electronic health records (EHR) of patients cared for in six hospitals located in the New England, Mid-Atlantic and Midwest regions of the United States. The hospitals ranged in size from community, regional, to a quaternary academic medical center. Selected hospitals all had a comprehensive, structured documentation system for nursing called Knowledge Based Charting (KBC) within their larger EHR (described below). The study was approved by the University Institutional Review Board (IRB) and the IRB of two hospitals that required review.

Sample. Each hospital provided retrospective, de-identified EHR data for hospitalized patients age 55 and older cared for on medical and surgical units and critical care. They excluded records coded as observation stays and admissions to skilled rehabilitation units, obstetrics and pediatrics. The study team received the files via secure file transfer. Data retrieval occurred between October 2011 and July 2012 and contained 5,333 patient records meeting our eligibility criteria. Hospitals provided between 908 to 1751 patient records each. The team completed an extensive cleaning and re-coding process, described elsewhere, and then merged the files into one uniform dataset. To assure a nationally representative sample, the statistician drew the final study sample of 1,496 patients from the 5,333 to obtain a representative distribution of the 16 most common primary diagnoses of hospitalized patients. The EHR data populated the electronic case studies used for expert review as described below.

Electronic case study contents. Programmers created structured case studies from the 1,496 patient records. The data for the case studies came from the KBC Adult Patient Profile where nurses documented a thorough admission assessment from patients and caregivers and the Assessment/Intervention Flowsheet contained documented assessments from each shift throughout the hospital stay (e.g., cognitive status, functional status, fall risk). We selected 71 data elements from these documents based on our prior research and the literature to represent the factors that describe the patients’ health, admission course, and are associated with post-acute needs and outcomes. The Orem Self-Care Deficit Theory provided the organizing framework for the case studies. Orem posits that nursing care is appropriate when the person is not able to engage in self-care. This theory appropriately supported our study because we believe that patients who cannot perform self-care after hospital discharge need post-acute care. Orem describes 10 categories of basic conditioning factors that may affect self-care: age; gender; developmental state; health state; sociocultural orientation; health care system factors; family systems factors; patterns of living; environmental factors; and socioeconomic factors. For example, the category of health state included primary diagnoses, co-morbid conditions, medications, procedures, wounds and other elements listed in Table 1.

Multi-Disciplinary Experts. Physicians, and masters or doctorally prepared nurses, social workers, and physical therapists were recruited via snowball sampling to review the case studies and provide their decision making expertise. The experts accessed the case studies via a website built to display their assigned case studies, track their progress, and capture their decisions. A detailed description of expert recruitment, the web-based expert knowledge elicitation process, and Delphi rounds is published elsewhere. 

Stratified by geographic region of the United States (north, south, east and west) and discipline (doctor, nurse, physical therapist, social worker), the statistician randomly assigned 171 experts to teams of three to review and judge approximately 13-30 unique case summaries each. Experts were paid as independent consultants per case. Agreement of two out of three experts was accepted as consensus. If all three disagreed on the site of care, the cases went through up to two Delphi rounds seeking majority agreement (2 out of 3). If agreement was not reached the case was not used in the “where to” modeling. Along with their “yes/no refer” decisions and “where to” decisions (i.e. home care, inpatient rehabilitation, skilled nursing facility, nursing home, or hospice) experts identified the factors within each case study that supported their decisions. We used these data to create and validate the two-step expert algorithm.

**Data Analysis**

We randomly separated the 1496 cases into a training dataset and a validation dataset. We used a number of analytical methods to determine the best model for each decision. These included: 1) Penalized/Regularized Logistic Regression Models performed in R using the glmpath package and 2) classification and regression trees (CART) performed in R using regression trees, or the ctree command included in the party package. Factors were added to models based on increasing the predictive ability of the algorithm above that already been obtained, while penalizing for the complexity of the model and structure of the data. Separate models were examined where (a) factors were looked at as "blocks" to be included/excluded together, (b) as indicators for level, and (c) based on severity cut-points. The optimal model was statistically determined based on area under the curve (AUC), and Akaike and Bayesian information criterion (AIC & BIC).

**Modeling yes or no refer.** Patient characteristics selected by experts as important for their decision were not as informative for reducing the data and pinpointing important variables as we had initially hoped. In the final round, for each case by each expert, they selected from one to 71 different items. In all, the experts marked 4,488 characteristics (variables) as important within the 1,496 cases with a mean of 23 per case (SD=10.75). Furthermore, the make-up of important/not-important for referral decision was statistically significant for all variables. Consequently, all 71 variables (Table 1) were initially candidates for inclusion in the prediction models.

Penalized regression uniformly gave the best predictive ability with variable selection based on the BIC criteria. We tested the robustness of the selected variables using 1,000 bootstrap samples. If the predictor did not remain important in at least 50% of the bootstrap samples, its exclusion was tested as a potential refinement of the model. It was retained if its removal affected other variables in the model even if it appeared in <50%. Refinements included: excluding primary diagnosis variables, excluding specific comorbidities, and including combinations of variables as suggested by clustering or CART.

For each of the possible refinements, the ROC curve produced was compared to the ROC curve for the “baseline” model using statistical tests based on both U-statistics and bootstrapping via the pROC package. The “best” (least complex) model with similar statistical properties to the “baseline” model was found to be the one with primary diagnosis and comorbidity variables excluded, and included one of the combinations that was suggested by CART.

**Modeling Where to Refer.** The model for referral location included the variables within 1,204 cases the experts determined the outcome was “yes” refer for care. We excluded 17 cases with uncertain location, even after two Delphi rounds. A number of steps led to the final model: 1) Models for predicting the five referral sites were generated. All methods produced poor performing models, with some models doing worse than chance. 2) Hospice was excluded since only 66 patients were determined as a hospice referral by the experts and the cost of misclassifying a patient to hospice could be high. The main error in prediction was among the facility-based locations. Based on results from steps one and two, we collapsed the referral site outcomes to create the dichotomous referral outcomes of facility versus home care. Since cases who currently reside in a facility were highly likely to return to a facility, these subjects were referred to a facility in the first split of the model. Penalized Logistic Regression models best performed prediction for the remainder of the cases with the outcome facility versus home care.

**Results**

The 1,496 patients were on average 74.3 years old (11.25 SD, range 55-103). Gender distribution was 55.5% female, 83.4% White and 12.1% Black or African American and 98.3% were non-Hispanic. Among a large variety of primary diagnoses, the most common diagnoses were Pneumonia, Atrial Fibrillation, Acute Exacerbation of Obstructive Chronic Bronchitis, Unspecified Septicemia, and Acute Kidney Failure. Average number of secondary diagnoses and co-existing conditions was 10.29 (range 1 to 32, SD=5.73). Table 2 provides a fuller description of the sample.

Hypothesis one (H1). H1 was supported. H1—There is a statistically significant correlation between the evidence-based factors (clinical information) and the experts’ yes/no referral decisions. Of the 71 case summary variables, 16 variables (each associated with particular values or interaction terms), were identified as significantly correlated and important to the decision of whether or not to refer the patient for post-acute care. Significant variables include, for example, employment status, fall risk, several activities of daily living, and number of comorbid conditions. An optimal cut off score indicated the difference between refer and do not refer. Table 3 lists the variables important for the yes/no refer prediction and the percentage of 1,000 bootstrap samples in which they appeared. The remaining factors were discarded as their inclusion did not sufficiently improve the predictive ability of the algorithms while increasing the complexity of the models. In some instances, the same variable with different values yielded significant correlations.

Discharged on Narcotics 52.9
Interaction Ambulation Current X Transfer Change X Caregiver Presence 99.9

*detailed co-efficients, cut off scores, and levels of measurement are omitted to protect intellectual property

Hypothesis two (H2). H2 was partially supported. H2-There is a statistically significant correlation between the evidence based factors and the site of referral. Models for predicting the five referral sites (home health care, in-patient rehabilitation facility (IPF), skilled nursing facility (SNF), nursing home (NH) and hospice) were generated but they proved to be poor performers. Based on the results, we collapsed the site outcomes to depict facility (SNF, IPF, NH) versus home health care referral thus achieving a satisfactory model. For this model there are 13 variables, each associated with particular values or interaction terms, identified as important to the decision of where to refer those patients. Significant variables include for example caregiver availability, pressure ulcer risk, and several activities of daily living, and number of comorbid conditions. An optimal cut off score indicated the difference between home health care referral versus facility. Table 4 lists the variables important for the where to prediction and the percentage of 1,000 bootstrap samples in which they appeared. The remaining factors were discarded as their inclusion did not sufficiently improve the predictive ability of the algorithms while increasing the complexity of the models. In some instances, the same variable with different values yielded significant correlations.

Hypothesis three (H3). H3 was supported. H3-The model predicts the expert referral (yes/no) decision with sensitivity, specificity and positive predictive value of greater than 80%. The Area under the Curve (AUC) was 91.5%, sensitivity was 90.1% (95% CI: 88.1-91.9), specificity was 76.9% (95% CI: 71.0-82.0), positive predictive value was 94.2% (95% CI: 92.5-95.6), negative predictive value 65% (95% CI: 59.2-70.6). While specificity was slightly lower than 80%, increasing specificity resulted in less acceptable sensitivity and positive predictive values and a value of >70% was determined to be highly acceptable in this case, since the risk is to over refer which would not do harm to patients, however, it may have cost implications. The training set had 1251 cases; the validation set 245 cases.

Hypothesis four (H4). H4 was partially supported. H4-The model predicted the type of setting (facility vs home care) with sensitivity, specificity and positive predictive value of greater than 80%. The AUC was 89.7%, sensitivity was 89.2% (95% CI: 84.0-93.2), specificity was 68.0% (95% CI: 53.3-80.5), positive predictive value was 91.6% (95% CI: 86.7-95.1), negative predictive value was 61.8% (95% CI: 47.7-74.6). While specificity was lower than 80%, increasing specificity resulted in less acceptable sensitivity and positive predictive values and a value near 70% was determined to be acceptable in this case; since the risk is to refer to facility care versus home care which would not do harm to patients, however, it may have cost implications. The model was fitted to the validation dataset, using the same beta coefficients and cut-point as found in the validation dataset.

Discussion.

In this study we developed and validated a two-step expert derived algorithm to guide decision making for which patients need a post-acute care referral and which type of setting best matches their needs. Discharge referral decision support algorithms are useful to remove barriers to care imposed by subjectivity and variation in decision-making. We derived our algorithm through expert consensus based on patient need rather than on policy or insurance, which can serve as sources of bias or barriers to appropriate care. The importance of this is shown by Lockery and colleagues who found that patient, family or professional involvement in the DP process did not directly affect discharge placement. Rather DC placement may more accurately reflect insurance status. For those in lower socioeconomic groups with Medicaid that provides less restrictive home health benefits their care is shifted toward home based services, while Medicare policies support institutional care such as SNF or IRF. We purposely did not provide insurance information to our experts and we instructed them to base their decisions solely on need.

More recently, with the advent of the Affordable Care Act with Bundled Payment Programs and Accountable Care Organizations, insurers and providers are seeking the lowest cost site of care rather than the site that may best meet patients’ needs. Such policy shifts reinforce the need for and value of evidence-based decision support that identifies patients based on their clinical characteristics and not on insurance or local conventions. Over time, comparisons of patient outcomes when our algorithm recommends care versus where patients actually go after discharge will demonstrate the impact of such policy shifts on patient outcomes.

Our algorithm may be helpful to discharge planners in assisting with the assessment of patients for post-acute care. A survey of 37 social workers conducting DP in 36 hospitals reported that assessment was their most important and time consuming task with assessment of home support and help with activities of daily living (ADLs) the most demanding and they spent less time on counseling and more time on concrete tasks such as determining services. Automating the assessment of these two concepts with CDS may be of great value in decreasing the work and cognitive load for discharge planners. Wolock and colleagues found discharge planners dealt with psychosocial problems and relationship issues only when they interfered with discharge and large caseloads prevented discharge planners from having enough time to do it all. CDS could lift some of this burden by automating the assessment process, alerting discharge planners of high need patients and recommending levels of care as first steps and a “heads up”, thereby allowing more time for the important counseling interventions that engage patients and caregivers in shared decision-making. Our algorithm operates off of data collected by nurses during routine patient care at admission and throughout the stay, making efficient use of information and negating the need to spend time collecting it again.

The factors deemed important within the algorithm reflect need for post-acute support and those associated with risk for readmission and other poor discharge outcomes. The algorithm cumulatively brings these factors together to determine the patients’ need for post-acute care and suggest whether a facility level (SNF, IPF, NH) or home health
care is most likely to meet their needs. The algorithm heavily weighs the performance of ADLs as critical factors. Multiple studies reinforce the importance of ADL function demonstrating the association between ADL limitations, discharge placement and discharge outcomes.\(^{33,34}\)

In our study, experiencing a decline in ambulation, transferring, and bathing was associated with referral to facility-based care versus home care. Similarly, Mason and colleagues found that the need for skilled nursing care or occupational therapy versus custodial care for ADLs differentiated patients discharged with home care versus facility level care respectively.\(^{35}\) Similar to our model, an algorithm that predicts SNF or inpatient rehabilitation versus discharge to home for colorectal cancer surgery patients includes number of comorbidities and number of previous hospital stays as predictors.\(^{36}\) Unique to our model, having a caregiver was important to the referral decision and having a caregiver who was available 24 hours a day/ seven days per week was important regarding the level of care, facility versus home based.

Our previous algorithm, the D2S2 identifies patients who need post-acute care.\(^{10}\) Translation to practice demonstrated significant declines in readmissions when using the D2S2 compared to not, after controlling for covariates and time.\(^{37,38}\) This study built on that work with a larger, more diverse sample and robust set of data elements and created a two-step algorithm to determine the level of care for those identified for referral. The data elements are available shortly after admission and require no additional data collection. We are testing the new algorithm in a quasi-experimental, pre/post design and comparing patient outcomes using propensity modeling in two hospitals.

Study limitations include a sample limited to 1,496 patients that contains only the most common diagnosis for hospital admissions. We also could not account for every patient factor that may be important to these decisions. For example, the patient and caregiver preferences were not included. Also, the experts were unable to “see” the patient but made their decisions based on a written case study and they made their decisions independently whereas in real life they often collaborate as a team.

**Conclusion.**

Using electronic health record data and expert opinion, our team successfully built and validated a two-step prediction algorithm to support discharge referral decision-making. We achieved highly satisfactory predictive summary statistics on both steps of the algorithm and the factors within it match those commonly identified as associated with post-discharge service need and outcomes. Evidence-based CDS for discharge planning may alleviate some of the workload for discharge planners enabling them to spend more time counseling patients and engaging in shared decision-making. The algorithm was embedded into the EHR of a hospital and tested in a quasi-experimental pre/post design. Next steps include analysis of the experimental data to determine whether the algorithm has an impact on referral rates, site of referral, types of patients referred, and most importantly patient outcomes such as readmission and emergency department use.

Abstract

Formal constructs for fuzzy sets and fuzzy logic are incorporated into Arden Syntax version 2.9 (Fuzzy Arden Syntax). With fuzzy sets, the relationships between measured or observed data and linguistic terms are expressed as degrees of compatibility that model the unsharpness of the boundaries of linguistic terms. Propositional uncertainty due to incomplete knowledge of relationships between clinical linguistic concepts is modeled with fuzzy logic. Fuzzy Arden Syntax also supports the construction of fuzzy state monitors. The latter are defined as monitors that employ fuzzy automata to observe gradual transitions between different stages of disease. As a use case, we re-implemented FuzzyARDS, a previously published clinical monitoring system for patients suffering from acute respiratory distress syndrome (ARDS). Using the re-implementation as an example, we show how key concepts of fuzzy automata, i.e., fuzzy states and parallel fuzzy state transitions, can be implemented in Fuzzy Arden Syntax. The results showed that fuzzy state monitors can be implemented in a straightforward manner.

Introduction

By definition an automaton is “an abstract state-determined machine designed to follow automatically a predetermined sequence of operations or respond to encoded instructions”. Automata are prime examples of general systems over discrete spaces [1]. The concepts of state and transition are core aspects of automata theory. The best known class of automata are deterministic finite-state automata, in which systems can be in exactly one of a finite number of states at any given time. These states are labeled using natural language concepts and/or classifications. Transitions between system states (i.e., linguistic concepts) are triggered by an external input, and may be presented as a function mapping the current state and the input into the next state [1].

Although the concept of a discrete state is attractive due to its simplicity in terms of implementation, it is of limited use for modeling situations and contexts where discrete states cannot be accurately defined using natural language concepts, or where knowledge about the situation is imprecise or incomplete. For instance, an individual’s health cannot be accurately classified by discrete, mutually exclusive concepts at the sole end of the spectrum, such as healthy or sick, nor would it be practical to introduce a myriad of states between these spectrum poles. To address these shortcomings in classification with linguistic concepts, Zadeh introduced fuzzy sets and fuzzy logic [2]. With fuzzy sets, the relationship between linguistic terms and measured or observed data is expressed as a degree of compatibility (DoC) calculated by fuzzy membership functions rather than a discrete, dichotomous classification. In this context, a DoC formally models the unsharpness of the boundaries of linguistic terms. Propositional uncertainty due to incomplete knowledge of relationships between clinical linguistic concepts is modeled with fuzzy logic, allowing for approximate reasoning instead of exact rule inference.

The incorporation of fuzzy sets and fuzzy logic into automata gives rise to the notion of fuzzy automata, which are able to handle uncertainty and continuous space [3,4]. With fuzzy automata, a system can be in more than one state at the same time, whereby the applicability (or membership) of each state is expressed as a DoC. Because of this multi-state membership, multiple simultaneous transitions of state are also possible. The system as a whole is far more expressive because the potentially endless combinations of state values (i.e., applicability of linguistic concepts) can imply richer, more abstract linguistic concepts. Furthermore, multiple (partial) parallel transitions cause transitions between linguistic concepts to be more gradual and thus more intuitive.

The properties of fuzzy automata discussed above, they are well suited for the use in (automated) clinical monitors [5]. In clinical monitoring, streams of patient data are measured in (occasionally brief) time intervals and presented to the clinician. Given the increasing body of patient data being measured in various time intervals, the monitor is growing more complex, both in terms of the number of presented data elements as well as the interpretation of combinations of different data elements. In other words, the more powerful a monitor becomes (from a functional perspective), the greater is the risk of errors of omission in the interpretation of data. By using a fuzzy automaton in
clinical monitoring for the interpretation and aggregation of measured patient data over time, the dimensionality of input data can be reduced and presented in semantically meaningful, clinically relevant linguistic concepts over fixed time intervals, along with a gradual indication of their applicability to the patient.

Standardized technical communication with hospital information systems and electronic health records is an equally important element of meaningful semantic communication with users. The acceptance and dissemination of the aforementioned monitoring systems could be improved by employing known communication standards, especially when the systems are to be embedded into existing clinical monitors. A widely used standard for computerized knowledge representation and processing is Arden Syntax [6], which is a programming language for the collection, description, and processing of medical knowledge in a machine-executable format. Since Arden Syntax version 2.9 was augmented by formal constructs based on fuzzy set theory and fuzzy logic, it is now possible to implement a fuzzy automaton in a clinical system using a standard that intrinsically supports fuzzy methods.

In this paper, we report our preliminary experience concerning the implementation of a clinical fuzzy automaton using Arden Syntax 2.9 (Fuzzy Arden Syntax). As a use case we re-implemented a previously published monitoring system named FuzzyARDS [7], which is a clinical monitoring system for patients suffering from acute respiratory distress syndrome (ARDS) and is based on the DiaMon-1 framework [8]. For easier comprehension, we provide an overview of Arden Syntax and the fuzzy methods incorporated in Fuzzy Arden Syntax, as well as a short description of the DiaMon-1 framework and the FuzzyARDS monitor. Then, using the re-implementation of parts of the FuzzyARDS monitor (referred to henceforth as FuzzyArdenARDS) as an example, we show how key concepts of fuzzy automata, such as fuzzy states and parallel fuzzy state transitions can be implemented in Fuzzy Arden Syntax.

Methods

Arden Syntax

Arden Syntax is a standard for computerized medical knowledge representation and processing. Arden Syntax knowledge bases are fragmented into medical logic modules (MLMs), which are collections of medical rules and knowledge for the purpose of making at least one medical decision [9]. Several properties make Arden Syntax well suited for the computerized representation of medical knowledge [10]. In fact, the program code in Arden Syntax resembles natural language. Thus MLMs are understood more easily by healthcare professionals. Moreover, pure medical knowledge is separated from more technical processing, which improves code transparency. Finally Arden Syntax supports various data types specific to medical documentation, such as time and duration types.

A complete overview of Arden Syntax is beyond the scope of this paper. However, for comprehension of the examples presented in this paper we will provide a short overview of Fuzzy Arden Syntax. For a complete description we refer to the Arden Syntax version 2.9 specification [6].

Each Arden Syntax MLM is hierarchically structured. At the top level an MLM is divided into the categories of maintenance, library, knowledge, and resources. Each of these categories contains category-specific slots. Slots in the maintenance category enable the MLM author to provide metadata on the MLM, such as the MLM title, author, or version. Slots in the library category provide contextual information about the MLM, such as the purpose of the MLM, an explanation of its functionality, and evidence-based resource citations. The medical knowledge of the MLM is implemented in the knowledge category. In the data slot, MLM parameters can be assigned to variables, and data from external sources can be obtained through curly braces expressions. The MLM’s program logic is implemented in the logic slot. Apart from implementing logic, processing can also be deferred through the invocation of other MLMs. Execution ends with a concluding statement which, if considered true, results in the execution of the action slot. Finally, localized messages can be constructed through the optional definition of the resources category.

Fuzzy Arden Syntax

Since version 2.9, the Arden Syntax supports formal constructs based on fuzzy set theory and fuzzy logic. We will present a selection of fuzzy extensions implemented in Fuzzy Arden Syntax in this section. Note that this is not a complete overview of all fuzzy concepts implemented in Fuzzy Arden Syntax; for a detailed description of fuzzy constructs implemented in Fuzzy Arden Syntax we refer to previously published work [11].

The truth value model of Arden Syntax was expanded in order to extend traditional methods of calculation and logic. Prior to version 2.9, the truth value model was dichotomous, supporting only the values “true” and “false”. However, truth values in Fuzzy Arden Syntax may now constitute any value in the range [0, 1]. True and false still exist in this model as the extremes of the range: “false” has a truth value of 0, whereas “true” has a truth value of 1. Based on this
truth value model, Fuzzy Arden Syntax incorporates fuzzy set data types, built-in propositional fuzzy logic operators, and degrees of applicability of conditional branches.

The fuzzy set data type can be used to model and quantify the unsharpness of boundaries in definitions of linguistic concepts. A fuzzy set is declared with two or more value tuples which define the fuzzy region(s). From these tuples, a linear membership function is constructed for the fuzzy set, which is used to calculate the DoC of measured or observed data with respect to the clinical linguistic concept under consideration.

With fuzzy logic operators, propositional uncertainty in relationships between linguistic clinical concepts can be modeled implicitly. Three basic propositional fuzzy logic operations are implemented in Fuzzy Arden Syntax – negation, conjunction, and disjunction. These are equipped to handle all truth values in the extended truth value model. By default, negation of a concept is implemented as 1 minus the truth value of that concept. The standard minimum function is used as the fuzzy conjunction operator, and the standard maximum function is used as the fuzzy disjunction operator.

The new truth value model called for an extension of the evaluation mechanism for conditional branches. Whereas only one conditional branch was executed at a time in the traditional model, in the extended model each branch whose condition amounts to non-zero is executed in parallel. To this end, all simple data types have a degree of applicability, which is set to 1 by default. However, when the program execution splits into multiple parallel branches, each branch is provided with its own set of duplicated variables, and each variable is assigned a degree of applicability which is equal to the relative truth value of the respective branch’s conditional expression. After execution of all conditional branches, variable values can either be aggregated or not. When the branches are aggregated (through the aggregate keyword at the end of the conditional block), duplicated variables are joined using a weighted average (applicability multiplied by the variable value). If not aggregated, the MLM will conclude with multiple return values, each with its own applicability.

As an example, consider the Fuzzy Arden Syntax MLM below in which we use fuzzy sets to classify the severity of ARDS. For the sake of brevity, we have confined the example to the knowledge category.

```plaintext
1   maintenance:   […]
2   library:  […]
3 knowledge:
4   type:   data_driven;;
5   data:    (pao2, fio2) := argument;; // blood gas and inspiration
6   priority:  ;
7   evoke: ;;
8   logic:
9 // Fuzzy set definitions
10  ARDS_severe := fuzzy set (100,1), (110,0);
11  ARDS_moderate := fuzzy set (100,0), (110,1), (190,1), (200,0);
12  ARDS_mild := fuzzy set (190,0), (200,1), (300,1), (310,0);
13
14 // Parameter analysis
15  if ((pao2 / fio2) is in ARDS_severe) then
16    msg := "Patient suffers from severe ARDS."
17  elseif ((pao2 / fio2) is in ARDS_moderate) then
18    msg := "Patient suffers from moderate ARDS."
19  elseif ((pao2 / fio2) is in ARDS_mild) then
20    msg := "Patient suffers from mild ARDS."
21  endif;
22
23 // Program conclusion
24  conclude true;;
25  action: return msg;;
26  urgency: ;;
27 end:
```
The logic in this MLM is based on the most recent ‘Berlin Definition’ of ARDS published in 2012 [12]. According to this definition, the severity of ARDS is determined by the ratio of partial arterial oxygen pressure (PaO2) and the fraction of inspired oxygen (FiO2). Based on the resulting outcome, ARDS is characterized as either mild (200 < PaO2/FiO2 ≤ 300), moderate (100 < PaO2/FiO2 ≤ 200), or severe (PaO2/FiO2 ≤ 100). However, patients with measured values close to these thresholds are also of interest. As such, we created fuzzy sets for all characterizations that extend beyond the defined thresholds (lines 10-12). Next, the PaO2/FiO2 ratio is compared with each fuzzy set, and the resulting truth values serve as conditions in conditional branches (lines 15-21). In case multiple truth values are non-zero, each of these conditional branches is executed. Furthermore, as the branches are not aggregated, this would cause the MLM to return multiple copies of msg, each with its own degree of applicability. For example, if PaO2/FiO2 were 106, this would cause the “severe ARDS” message to be returned with an applicability of 0.4 and the “moderate ARDS” message to be returned with an applicability of 0.6. This could be interpreted as a patient’s ARDS being between the “moderate” and “severe” state.

**FuzzyArdenARDS and DiaMon-1**

The FuzzyArdenARDS application was re-implemented based on the original FuzzyARDS automaton, which was constructed using the DiaMon-1 framework as discussed in [7,8]. This formal framework was developed in order to design monitors capable of abstracting continuously supplied, objectively observed raw data into aggregated, qualitative, linguistic concepts, such as stages of disease. Furthermore, monitors developed with this framework provide early indication of improvement in, or deterioration of, a patient’s health status because the monitors include smooth transitions between stages.

Applications in the DiaMon-1 framework are referred to as state monitors, which employ fuzzy automata to observe gradual transitions between different stages of disease. In this context, a state represents a (linguistic) representation of a patient’s health status or a specific stage of disease. Transitions provide possible pathways between states or stages, which are triggered by inputs such as time or measured data.

A fuzzy state monitor \( SM \) is formally defined as a 6-tuple \( \overline{SM} = (Q, \overline{q}_0, X, \delta, P, f) \). In this definition, the first four parameters jointly constitute the underlying fuzzy automaton: \( Q \) denotes a finite set of states, \( \overline{q}_0 \) is a (potentially) fuzzy subset of \( Q \) that marks the initial state, \( X \) is a finite set of input symbols, while \( \delta: Q \times X \to Q \) is a transition function that maps states and inputs onto states. Furthermore, \( P \) is the parameter value space over all observed parameters: \( p_1 \times \ldots \times p_n \), and \( f \) is a mapping function that maps parameter tuples from \( P \) to a fuzzy subset of \( X \).

Calculation of the monitor state at time point \( t (\overline{q}_t) \) proceeds through an inductive function based on \( \overline{q}_{t-1}, \delta, \) and \( f \). Suppose that at time point \( t, f \) yields fuzzy subset \( \overline{fs}_t \), which is a collection of truth values for all \( x \in X \). Then, using the extension principle [13], the state for each \( q \in Q \) at time point \( t, \overline{q}_t(q) \), can be calculated as follows:

\[
\overline{q}_t(q) = \left\{ \begin{array}{ll}
\lor \{ \overline{q}_{t-1}(q') \land \overline{fs}_t(x) | \delta(q', x) = q, q' \in Q, x \in X \} & \text{if } \delta^{-1}(q) \neq \emptyset \\
0 & \text{if } \delta^{-1}(q) = \emptyset
\end{array} \right.
\]

For the FuzzyArdenARDS application, the automaton states \( Q \) are shown in Table 1.

**Table 1.** Definition of the fuzzy automaton states in FuzzyArdenARDS.

Data processing
The MLMs discussed in this report were created with the ARDENSUITE software [14,15]. The ARDENSUITE is a framework for medical knowledge representation and reasoning, which comprises an integrated development and test environment (IDE) and an ARDENSUITE server, including software modules for interconnecting with data sources (Figure 1).

Figure 1. Graphic depiction of the ARDENSUITE framework. Image adapted from [15].

With the ARDENSUITE IDE, users can write and compile MLMs via the authoring tool. If test data are available, users can also immediately test the implemented MLMs. After compilation, the MLMs are uploaded to the administration module of the ARDENSUITE server. The administration module is a management tool for compiled Arden Syntax projects and supports functionalities such as the activation or deactivation of MLMs in an application, or MLM version management. The core element of the ARDENSUITE server is the ARDENSUITE engine, which executes compiled MLMs. To facilitate access to MLM functionalities by arbitrary clients, the server provides service-oriented access through a web-service component. Using this component, MLM calls and data exchange are facilitated through the Simple Object Access Protocol (SOAP) and Representational State Transfer (REST) web-service standards. Web-service standards can also be used to connect the ARDENSUITE server with SOAP/REST-compatible external database sources through the ARDENSUITE server connector. With this module, external data sources can be accessed directly from within MLM files using query languages (such as SQL), which are then forwarded to the source data base management system using SOAP or REST web services.
Results

In this section, we discuss parts of the resulting MLM implementation of FuzzyArdenARDS. We implemented the core of the FuzzyArdenARDS application in two MLMs. In the first MLM, fuzzy sets are defined and truth values calculated using the SaO2 and FiO2 parameters. Each parameter is supplied as a list of values over the last half hour. The MLM is designed for semi-real-time processing, and is called every 30 seconds, thus analyzing 30 seconds of data at a time. Again, for the sake of brevity, we have confined the MLMs listed below to the knowledge category.

```plaintext

40   for sao2_ref_element in reference_list do
41     lmax_tv := sao2_ref_element is in fs_sdo_begin and sao2_element is in fs_sdo_end;
42     sdo := maximum (sdo, lmax_tv);
43   enddo;
44 enddo;
45 conclude true;;
```
In the above MLM code snippet, truth values are calculated for each of the symbols in \( X \). First, all fuzzy sets are defined (lines 10-15). Then the truth value is calculated for the symbol *adequate oxygenation*. For this purpose, we first need to obtain SaO2 values for the last 5½ minutes; 30 seconds for evaluation and 5 minutes thereafter to calculate the truth value for all data in the evaluation phase according to the mapping in Table 3 (line 18). We then apply the data to the defined fuzzy set and take the minimum truth value as an aggregate result for the last 30 seconds (line 19). In a similar fashion, truth values are calculated for the symbols *hypoxemia* (lines 21-22), *high FiO2*, and *low FiO2* (lines 24-26). For the symbol *rapidly improving oxygenation*, a slightly different approach is needed. First, data elements for the first 30 seconds for evaluation are isolated (line 28). For each of the data elements, we then select prior elements or data elements within a period of 30-90 seconds before the timestamp of the analyzed elements (line 29-31). Data elements of both lists are applied pairwise to their respective fuzzy sets, and a logical conjunction of each pair is calculated (line 32-33). Finally, the maximum of all pairwise logical conjunctions is chosen as an aggregate value for the symbol *rapidly improving oxygenation* (line 34). In a similar fashion, a truth value is calculated for the symbol *slowly decreasing oxygenation* with a time period of 25 minutes.

The second MLM is used to perform the transitions. As parameters, a list of truth values for each state and a list of truth values for each input symbol are provided. Due to space constraints, we only show that part of the MLM implementation dealing with the transitions for the end states *Start*, *Normal*, and *Hypoxic*.

8                      NotRespHighFiO2, ImpAfterHandBagging, NotImpAfterHandBagging];
9  states := new AutomStates with 1 seqto 7;
10
11    // Inputs (array indices) enumerations:
12  AutomInputs := OBJECT [AdequateOxy, Hypoxemia, HighFiO2,
13                      LowFiO2, RapidImpOxygenation, SlowDecOxygenation];
14  inputs := new AutomInputs with 1 seqto 6;
15
16  (state_tvs, input_tvs) := Argument;;
17
18  logic:
19    // Start state has no incoming transitions
20  state_start := 0;
21
22    // Normal state has three incoming transitions:
23  state_normal :=
24      // Rule 1: Start and adequate oxygenation
25      (state_tvs[states.Start] as truth value and
26      input_tvs[inputs.AdequateOxy] as truth value)
27      or
28      // Rule 4: Hypoxic and low FiO2 and adequate oxygenation
29      (state_tvs[states.Hypoxic] as truth value and
30      input_tvs[inputs.LowFiO2] as truth value and
31      input_tvs[inputs.AdequateOxy] as truth value)
32      or
33      // Rule 11: Improved after hand bagging and adequate oxygenation
34      (state_tvs[states.ImpAfterHandBagging] as truth value and
35      input_tvs[inputs.AdequateOxy] as truth value);
36
37    // Hypoxic state has five incoming transitions:
```
Truth values for the seven states in $Q$ are calculated in the MLM shown above. First, to improve MLM readability we constructed objects that enumerate the indices of the state and input value lists supplied through the argument (lines 6-16). The calculation of truth values for each state starts thereafter. By definition, the $Start$ state is only true at the first iteration of the automaton, followed by 0, as it has no incoming transitions. For each other state, the truth value is determined by a logical disjunction over all rules in Table 2 that have the respective state as an end state. The truth value for each rule, on the other hand, is calculated by a logical conjunction over the truth values of the state and transition conditions. As such, for the $Normal$ state a logical disjunction is calculated over transition rule 1 (lines 25-26), rule 4 (lines 29-31), and rule 11 (lines 34-35). The truth values for the other states are calculated in a similar fashion.

**Discussion**

In the present report, we showed how fuzzy state monitors as defined in [8] could be implemented using fuzzy methods supported by Fuzzy Arden Syntax, a standard for computerized knowledge representation and processing. When designing a clinical knowledge base, knowledge engineers work closely together with clinicians to construct the rules. However, the translation process from natural language to a computerized knowledge representation may be prone to error. The average clinician may be unable to, or not interested in, the validation of source code. The original FuzzyARDS program was written in a dialect of the object-oriented language Smalltalk, which is neither considered a mainstream medium nor is easily understood by those untrained in its application. Given that Arden Syntax rules closely resemble natural language, clinicians can verify the implemented knowledge in MLMs (more or less) easily without in-depth knowledge of modern programming languages.

Within the context of fuzzy state monitors, we introduced fuzzy sets as mapping functions that map raw data to clinical linguistic concepts, thereby yielding a degree of compatibility between 0 and 1. Based on these degrees, together with degrees of applicability for each state in a fuzzy automaton, we showed that multiple transitions could occur simultaneously, resulting in a new automaton configuration comprising (again) degrees of applicability for each state in the fuzzy automaton.

The interpretation of the automaton results is an important aspect. It was not discussed here because it would exceed the scope of this report and is dependent on individual applications. In the case of FuzzyArdenARDS, six parameters need to be interpreted in a pairwise manner: oxygenation state (normal vs. hypoxic), response to high FiO2 (response vs. no response), and response to hand bagging (improvement vs. no improvement). Given that values for each of
these states can be a DoC, a richer, a gradual interpretation follows from these pairwise interpretations. For instance, when the “normal” state has a DoC of 0.3 and the “hypoxic” state a DoC of 0.7, the patient’s current oxygenation state may be interpreted as moderately hypoxic.

The limitations of the present report are worthy of note. First, the study is limited to a single application, namely FuzzyArdenARDS. Other fuzzy state monitors and even other types of fuzzy automata need to be implemented with Fuzzy Arden Syntax to ensure the syntax is equipped to support a variety of fuzzy applications and methodologies. Second, the fuzzy sets that we implemented for the FuzzyArdenARDS automaton were “two-dimensional”. In other words, they only implemented fuzzy regions for one parameter. As some rules were defined over two parameters (SaO2 and a time duration), three-dimensional fuzzy sets that provide more accurate modeling for these rules will have to be implemented in the future. Finally, as of yet the program has only been tested on retrospectively collected data.

We reported on the first steps in implementing fuzzy state monitors with Fuzzy Arden Syntax. In the future, we plan to study and address the aforementioned limitations and continue to improve the use of Arden Syntax for real-time monitoring.

Conclusion

The native support of fuzzy methods allows the intuitive implementation of a fuzzy state monitor for clinical application with Fuzzy Arden Syntax.

References

Abstract

The increased adoption of Electronic Health Record (EHR) systems offers new opportunities for clinical research. The Health Insurance Portability and Accountability Act (HIPAA) mandates that medical records need to be stripped of personal identifiers in order to be shared. One particular challenge is how to handle free-text medical records. While many methods have been developed, there is a dearth of software tools than can be easily used by practitioners. We present deidentify, a new de-identification tool, which comes with a graphical user interface and runs on all operating systems. Evaluating its algorithm on a gold-standard corpus of nursing notes, we demonstrate its adequate performance with a recall of 0.919 and a precision of 0.645. Since deidentify comes with a pre-trained model, it can be used when no training data is available, but can also be manually configured. This way, it should be convenient to use for de-identification tasks.

1 Introduction

In recent years, we have witnessed a major transformation in the health care sector with the move to a wide array of clinical information systems such as Electronic Health Record (EHR) systems and Computerized Provider Order Entry (CPOE) applications. Hospital adoption of these systems has increased more than five-fold since 2008, with now more than nine in ten hospitals had adopted at least a basic EHR system.1

For a hospital or physician’s practice, implementing an EHR system often coincides with a move from paper to electronic documentation of progress notes and other documents created by the clinicians. There are many perceived benefits in the use of electronic health record systems. Menachemi & Collum identify three main types: benefits for clinical, organizational and societal outcomes.2 They present findings which demonstrate that EHRs can reduce clinical errors and drive down costs. Societal benefits arise because the electronic availability of patient data enables public health researchers to more easily conduct studies. In addition, most of this research can be done using much larger sample sizes than commonly used in the medical literature. This could lead to more significant and robust findings.

However, there is a growing concern in the medical community that the focus EHR systems place on structured data entry – while being efficient in saving costs and permitting subsequent analyses – does not enable doctors to effectively express clinically relevant information. Resnik concludes that “important clinical information, detail, and nuance would fail to be captured by an EHR standards discrete fields, with potentially serious consequences for the patient”. Instead, he recommends Natural Language Processing (NLP) techniques to extract meaningful information from free-text medical records.3

One main obstacle in working with free-text medical data is the need to de-identify or anonymize all identifiers which could be used to link a medical record to a certain individual. The Privacy Rule of the Health Insurance Portability and Accountability Act (HIPAA) restricts the distribution of all medical data containing protected health information (PHI), thereby limiting the ability of health care organizations to freely share their data with researchers.

HIPAA permits two methods for the de-identification of PHIs: the “Safe Harbor” rule lists 18 identifiers, which have to be removed in order for data to be counted as de-identified. Alternatively, an expert can testify that the employed statistical or scientific method provides only a small risk of allowing identification of individuals that are part of the study.

When working with free-text, the “Safe Harbor” rule provides a fairly straightforward approach for de-identification: Removing all identifiers that fall in one of the 18 categories is said to provide the necessary anonymity and suffices for health records to satisfy the HIPAA data sharing regulations and allows the data to be used for scientific studies.

In the next section, we review several approaches proposed in the literature to de-identify free-text medical records in compliance with the “Safe Harbor” rule. There has been a large body of research in this area, yet in our experience,
there is a lack of practical tools, which allow researchers and clinical practitioners to de-identify patient data out of the box and without large technical expertise. Many scientific papers propose new methodology without actual implementations, others provide accompanying software with many pre-requisites that have to be installed on the user’s operating system. Many were written a long time ago and appear to be unsupported by now.

In this paper, we present a new tool for de-identification of free-text medical data, which addresses the aforementioned concerns: The goal has been to develop a software which is easy to install, supported on all major operating systems (Windows, MacOS, and Linux) and provides a graphical user interface without requiring the user to be an expert in the domain of NLP or medical informatics.

Using cutting-edge web technologies, our deidentify tool is actively maintained, delivers performance comparable with state-of-the-art methods and is distributed under an open-source license. As a native app built on top of Chromium and the Node.js JavaScript run-time, deidentify allows for easy integration of third-party modules given its modularized nature. This should position it as a tool which can be adapted to changing regulatory frameworks and which can accommodate and integrate top-notch NLP techniques.

The paper is organized as follows: In the next section, we review the relevant literature and trace the development of methods used for de-identifying PHIs. In Section 3, we present the methodology used by our deidentify software and show how it scrubs records of all PHIs and removes or replaces them with made-up values. To assess the quality of our de-identification results, Section 4 describes the evaluation scheme used to test our method, the results of which are presented in Section 5. In Section 6, we reflect on the results and compare them to those of existing approaches advocated in the literature. Section 7 concludes the paper by providing an outlook for future research and an assessment of the strengths and weaknesses of our approach.

2 Related Work

Meystre et al. provide a recent overview on the literature of de-identification systems. They identify two broad categories: First, approaches which are predominantly based on pattern matching and/or deterministic rules. Second, de-identification applications mostly based on machine learning methods.

Historically speaking, most of the earlier research in the field can be assigned to the former category. The Scrub system developed by Sweeney deserves special attention. Scrub is one of the few systems which cannot only be used to replace identifiers by placeholders, but instead can replace them with automatically created surrogate data. The Scrub system ensures that there is a one-to-one mapping of PHI data to their replacements, which preserves the readability of the texts and their internal consistency. Unfortunately, the Scrub system is not available for download anymore, a feature it shares with quite a few of the other developed methods.

Of the more recent machine learning approaches, Meystre et al. identify several methods commonly used in the literature, such as Conditional Random Fields (CRF), Decision Trees, Maximum Entropy models and Support Vector Machines (SVM). For example, Aramaki et al. performed above average with a CRF model in the de-identification challenge organized by the i2b2 (Informatics for Integrating Biology and the Bedside) initiative.

The field has been moving towards usage of machine learning methods for some time now, because state-of-the-art methods outperform solely rule-based pattern matching approaches. At least for the more complicated PHIs, their performance differs by a substantial margin. The statistical techniques allow exploitation of complex relationships between PHIs and other text features, which even human experts might be oblivious to. In addition, they are more easily generalizable to different data sets. Yet, the results of the i2b2 de-identification challenge show that systems that combine machine learning with regular expressions yield the best results.

3 Method

PHI Detection

dependent uses a combination of pattern-matching and machine learning algorithms in order to detect all relevant identifiers. In doing so, our goal is simple: To provide an easy, computationally efficient procedure which can compete
with the approaches proposed in the literature. Incorporated into a desktop application, it allows users to perform de-identification tasks without a) prior programming experience, b) knowledge of the underlying procedure, and c) without having to tinker with different parameters in order to produce sound results. Furthermore, our system comes with a pre-trained model that does not require additional training data. We believe that the advantage of having a ready-to-use solution outweighs the downside of the marginal decrease in performance compared to tailored models, the more so since training data is often not available and generating it is a laborious and costly endeavor.

Identifiers such as phone numbers, fax numbers or dates are detected by various regular expressions. These have been designed to cover a wide range of possible ways the aforementioned identifiers can be expressed. For example, there are multiple formats of writing a date (1st of May, 05/01, 5/1 etc.), and the rules have been designed to handle this. A selection of them is displayed in Table 1.

Each record is searched for matches of any of the implemented regular expressions, where the steps of the procedure are ordered such that the most specific ones are checked first.

NER Detection via Conditional Random Fields

For the detection of persons, locations and organizations, we rely on the Conditional Random Field (CFR) model for Named Entity Recognition (NER) developed by Finkel et al.¹⁰ To motivate the use of CFRs, one should emphasize that NER — compared to classification tasks, which predict a single categorical response variable — requires a sequence model because the goal is to detect the underlying state for each word in a sequence of words. One popular choice has been Hidden Markov models (HMMs). HMMs model the sequence of T observed variables \( X = \{x_t\}_1^T \) and their underlying states \( Y = \{y_t\}_1^T \) by making the following simplifying assumption about the joint distribution of \( X \) and \( Y \): \( p(y, x) = \prod_{t=1}^T p(y_t|y_{t-1})p(x_t|y_t) \), with the initial state distribution being denoted as \( p(y_1|y_0) \).

The Markov property in this case refers to the assumption that each state only depends on its direct predecessor and is independent of all other states. As can be glanced from the factorization of the joint probability distribution, the other assumption of the model is that each observed value depends solely on its underlying state. Instead of using the current word as the single feature for each \( t \), it might be more useful to consider a feature vector instead. However, when \( x \) is high-dimensional, estimating the joint distribution becomes either intractable or requires one to place strong independence assumptions on the covariance matrix of the feature vectors.

A solution for this is to model the conditional distribution \( p(y|x) \) instead of the full joint distribution. This avoids making any assumptions about \( p(x) \) and is sufficient for prediction tasks. This rationale gives rise to Conditional Random Field (CFR) models. When \( G \) is a factor graph over \( Y \), a general conditional random field is a conditional distribution of the form

\[
p(y|x) = \frac{1}{Z(x)} \prod_{\Phi_A \in G} \exp \left\{ \sum_{k=1}^{K(A)} \theta_{ak} f_{ak}(y_a, x_a) \right\},
\]

where \( f_{ak} \) are real-valued feature functions, \( \theta_{ak} \) associated weights and \( Z(x) \) is a normalization function.¹⁰

CRF models do not assume independent features and allow for long-range dependencies in the data taking subsequent and preceding words into account, both very desirable properties for a NER system. On these grounds, Finkel et al.¹⁰
argue that CRFs are preferable to Hidden Markov Models (HMMs) and MaxEnt Markov Models (MEMMs) for NER
tasks.

The Stanford Natural Language Processing Group provides a Conditional Random Field (CRF) model with developed
feature extractors and offers models pre-trained on large corpora (CoNLL, MUC-6, MUC-7 and the ACE named
tility corpora), making them useful for application in many different domains, including the health care domain. The
Stanford CRF model uses the following features: the current word, the previous word, the next word, the current word
character n-gram, the current Part-of-Speech (POS) tag, the surrounding POS tag sequence, the current word shape
and the surrounding word shape sequence as well as indicators for the presence of the word in a left or right window
(with a window size of four).

In contrast to training a custom model, using a pre-trained model has the distinct advantage of allowing real-time
processing and alleviates the need for a large data corpus or labeled training data. If required, it is always possible
to switch out the default model used by deidentify for a custom-built model. In most situations this should not be
needed. In cases where single persons or organizations are not detected accurately, one can manually add them to the
database of known entities by means of a visual interface. The list of known entities is compared against the text to be
de-identified and any matches are replaced.

Replacement Strategy

As a result of the previous procedures, the approach retrieves a list of protected health information identifiers detected
in the analyzed free-text documents. These can subsequently be replaced by automatically generated substitutes,
tokens or type identifiers. For each identifier class, our software contains algorithms that can create an appropriate
replacement text. For example, if a detected identifier is a phone number, it is replaced by a randomly generated phone
number that does not belong to a real patient. For most of the identifiers, the replacements are created without taking
the original identifiers into account, i.e. the digits of the new phone number do not depend in any way on the original
phone number. Therefore, reverse engineering of the original values is prevented.

Replacing identifiers in isolation would likely render many texts unreadable, e.g. when a doctor repeatedly mentioned
in a document is replaced by references to multiple other individuals. In order to preserve the internal consistency of
the documents, we ensure that each occurrence of a single identifier is mapped to the same replacement by performing
a database look-up that checks whether the identifier has already been substituted before. If the result is positive, the
previously used replacement is used instead of generating a new one. Hence, each occurrence of a patient’s name will
be mapped to the same fictitious patient name. Thereby, the narrative and meaning of the documents are preserved.

Table 2: In the left column, a made-up note of a doctor to one of his colleagues is displayed. The remaining columns show the outputs of the different replacement strategies implemented in deidentify
The deidentify software is customizable in terms of which identifiers are replaced and the strategies employed to do so. For example, it is possible to replace only identifiers of a specific type or to specify that first names are mapped only to names from the same gender. To support longitudinal studies, the newest version of deidentify also comes with facilities to specify ranges for date replacements, such that consistency of the documents is preserved and one can appropriately place them in time. However, it must be noted that there is always a trade-off in terms of convenience on the one hand and privacy on the other: Obviously, the risk of identifying individuals when the employed replacement strategy is not truly random increases. However, we think that users should make their own judgments and that a tool should offer them options so that it can be adapted to their specific needs.

An example text alongside the different substitution strategies is displayed in Table 2.

Software

The current version of the software and the source code is available in a repository on GitHub: https://github.com/Planeshifter/deidentify/releases. The deidentify software is freely distributed under the GNU General Public License v2. Built upon Chromium and Node.js, it runs on all major operating systems (MacOS, Linux and Windows). Being agnostic to the used operating system, durability of the tool is ensured. Integrating the Stanford NLP CRF classifiers, a run-time version of Java 1.8 or later must be installed for deidentify to work. There are no other prerequisites. The software supports de-identification of texts stored in *.pdf, *.doc(x), or *.txt format.

The software comes with an easy-to-use point and click interface, which allows both de-identification and inspection of individual files as well as batch processing of all files stored in a given folder.

Processing the data is time-intensive due to the advanced machine learning techniques applied under the hood. On an Intel i7-3540M quad-core laptop with 3.00GHz and 8GiB of RAM, the software processed 170,000 words per hour, or 2,833 words per minute.

4 Evaluation

The quality of predictive models is often measured by their recall, precision, and false positive rate. In our context, recall (also known as sensitivity) is the proportion of PHIs correctly identified throughout the doctor’s notes; precision (also known as positive predictive value) represents the proportion of correct findings among the terms identified as PHI. Finally, the false positive rate depicts the proportion of wrongly identified PHIs among non-PHI words. Following the goal of HIPAA to protect the privacy of patient’s health care data, achieving a high recall is quintessential, whereas a high precision is desired in order to preserve the integrity and readability of the text. The same applies for the false positive rate.

Notice that the overall correctness in labeling text as either being a personal identifier or not is not a good measure of performance: Most character sequences are not personal identifiers, and will be correctly treated as such by almost any algorithm. Yet, these will far overshadow any differences in the performance in detecting actual identifiers, which is what we ultimately care about. The cost of making a mistake is different depending on whether we misclassify an observation as a PHI when it is in fact not (i.e., a false positive), which is a minor issue, compared to a false negative, i.e. missing a PHI and thus putting patient’s privacy in jeopardy.

First, we have evaluated our method by measuring precision and recall on a gold standard corpus of nursing notes made available on PhysioNet.10 The data set was originally collected by Neamatullah et al.11 as part of an evaluation of their deid software for PHI de-identification. The data set contains 2,434 records, all of which have been de-identified manually by several clinicians. The authors manually labeled instances of PHIs and replaced them by realistic surrogate data. The records are nursing notes, which were manually inserted by the nurses at the end of their shift and thus contain typos, incorrect punctuation, and false orthography.

Here, we employ the term gold standard to solely signify that we treat the PhysioNet corpus of nursing notes as correctly annotated and of high quality. It is one of the few publicly available data sets of medical notes and has a history of being used a benchmark to evaluate new approaches for de-identifying textual medical records. On the other hand,
many data sets have characteristic features that distinguish them from each other, so that a method attaining the best performance on the PhysioNet corpus may not generally be superior.

However, coupled with the usage of technical terminology and non-standard abbreviations, it is apparent that this the PhysioNet data set represents a challenging corpus for any de-identification software. The following is an excerpt of one of the nursing notes. It shows the use of abbreviations and is furthermore written entirely in capital letters, a fact which significantly complicates the detection of proper nouns in the English language:

58 YO FEMALE READMITTED TO CCU TODAY S/P CATH WITH PA LINE ON MILRINONE. PT WITH PMH MI ‘92, CABG X3 ‘92, REDO ‘95, DDD PACER ‘95, AFLUTTER S/P ABLATION ‘96, AFIB S/P CARDIOVERSION

The motivation behind developing deidentify was the need to deidentify physician’s notes as part of a project on the development of Chronic Kidney Disease. We have used a sample of forty-eight records to evaluate the de-identification performance, in addition to the gold-standard data set from PhysioNet. Our records are doctor’s notes written by CKD specialists to the referring physician after each patient visit. Hence, they have – as can be seen from the following example – the form of a letter:

Dear XXX, I saw your patient, Mrs. YYY, in the office today for follow up of her transplantation. As you will recall she had problems with acute interstitial nephritis which ended up being endstage renal disease in early 2000’s and has subsequently undergone transplantation from one of her family members. She was seen in September at which point her creatinine was stable at 1.1. Her Prograf was somewhat at low limits of acceptable levels (…)

As these short excerpts illustrate, a major challenge of providing an off-the-shelf de-identification software is given by the vast differences between the nature of free-text documents to be stripped of identifying information, which often requires manual intervention to ensure good results.

5 Results

On the gold-standard corpus, our method successfully de-identified 774 out of 822 names belonging either to doctors, patients or relatives. Locations were a bit harder to detect: Out of 367 locations in the test set, 95 were missed by deidentify. Highly structured identifiers such as phone records were correctly identified 100% of the time. Overall, this translates to a recall of 0.919. In total, we identified 1,600 of the 1,724 labeled identifiers in the nursing note corpus. deidentify flagged 2,674 PHIs in the corpus in total. This gives rise to a precision value of 0.645. The results for the different PHI types are summarized in Table 3.

The gold-standard test set by Neamatullah et al.11 poses significant challenges for any de-identification procedure because the nursing notes are not written in complete sentences and not consistently capitalized. From our experience, deidentify performed significantly better on other data, which does not share these characteristics. This is to be expected, as a clear sentence structure and capitalization of words affect the performance of the used NER system.

Nonetheless, the results are comparable to other methodologies proposed in the literature. In terms of recall, we improve upon the work by Neamatullah et al., who obtained a recall of 0.834 on the gold standard corpus for the case where no customized dictionary was used. This is the appropriate comparison since the performance attained by our procedure is also achieved without tailoring its dictionaries to the data set. On the other hand, the precision attained by our method is a bit lower, which might reflect the inherent trade-off between the goals of achieving a high precision and a high recall.

The low precision value achieved for dates might look a bit worrisome. The reason for the large number of false positives is that many lab values referenced in the notes are incorrectly classified as dates and substituted. Correctly disambiguating these from each other is a surprisingly challenging problem, which cannot completely be solved via pattern matching. However, since lab values are usually available in the structured data fields of the EHR, this seems
Table 3: Summary of de-identification performance for different PHI types. For each type and sub-type, the table displays the total number of identifiers from the respective category in the gold standard, and the number of false negatives as well as precision and recall of the deidentify procedure. See Section 4 for a discussion on why these are useful metrics to evaluate the performance of a de-identification procedure.

6 Discussion

The performance of our de-identification strategy is comparable with the results of the deid software by Neamatullah et al.11 for the case without a customized dictionary. This is a fair comparison, given that our results were obtained without the use of a custom dictionary as well. It might well be that there is an upper limit in terms of accuracy that can not be crossed without relying on either a custom-built model or alternatively a curated set of dictionaries containing identifiers to be removed. Using a custom dictionary allows one to add terms that need to be replaced, which any detection algorithm might otherwise find it impossible to flag. One example would be physician initials on notes that should be removed to ensure proper de-identification, but which most algorithms would not be able to correctly flag
as identifying information.

The Medical De-identification System (MeDS) by Friedlin et al. achieved impressive results (a recall of more than 99% of all HIPAA-specified identifiers and an equally impressive precision of more than 90%) using a solely rule-based system.

Uzuner et al. report on the results of a de-identification challenge that was part of the Informatics for Integrating Biology and the Bedside (i2b2) project. The participating teams achieved recalls between 0.80 and 0.96, and precision values between 0.74 to 0.97.

Several of the systems submitted as part of the challenge “took advantage of the specific organization of discharge summaries that are characteristic of the institution from which these were drawn” and did worse when applied to different data. MeDS was able to utilize patient information in the header section of documents as well.

When using deidentify as an off-the-shelf tool, performance is as expected lower than what is achieved by those systems. Yet, the differences are not very large, and one should keep in mind that deidentify can be run with a custom-built model and allows users to manually expand the dictionaries extracted from the texts. However, a direct performance comparison with the tools of Friedlin et al. and Uzuner et al. was not possible since their tools are not publicly available. They share this feature with the vast majority of de-identification tools. In their literature review, Meystre et al. found that just five out of eighteen investigated tools were made publicly available.

In several studies, human annotators performed comparatively well to the studied software systems. Given the laborious nature of manual annotation, de-identification software thus provides huge savings in terms of effort, while at the same time leading to similar less-than-optimal performance.

To preserve patient privacy and to fulfill all legal requirements, we deem it necessary to still refine the results of our procedure by manually expanding the built dictionaries and/or retraining the used NLP models on data similar to those to be de-identified. With the graphical user interface of deidentify, this is an easy task. After an initial run on a selection of notes, one should review the results and collect all instances of missed identifiers. From our experience, the same issues crop up over and over again, and hence even only a small custom dictionary can yield major benefits. For example, we were able to improve the performance of our tool by supplying a list of foreign names that the algorithm missed out on.

7 Conclusion

The need for de-identification of medical records is growing given the proliferation of EHR and other clinical information systems. To comply with the regulations imposed by the HIPAA legislation, protected health information (PHI) has to be removed from medical records so that they can be shared among researchers. Yet, there are not many freely available and easy-to-use tools to perform this task.

We have developed a new de-identification software built using state-of-the-art web technologies for removing personal identifiers from free-text medical records. Our tool uses a combination of pattern matching and machine learning algorithms, leveraging the power of the Stanford Named Entity Recognition (NER) system.

Besides offering good performance, we have implemented several secondary characteristics that a de-identification tool should ideally possess:

- It should provide a graphical user interface (GUI) so that it can be used by non-experts.
- It should be platform independent and easy to setup, without requiring lots of third-party software to be installed manually.
- It should be applicable even in absence of training data.
- It should be open-source and not proprietary software, as to ensure that the source code can be studied by everyone and changes can be made to accommodate specific use cases.

deidentify was designed with these goals in mind, and we hope that it offers a convenient and efficient way to scrub medical data of personal identifiers. This could significantly lessen the burden placed on individuals who wish to conduct research on free-text medical data.
The field of NLP has made considerable progress in recent years, including the rise of deep learning. Extrapolating this trend, it is highly likely that deidentify may be improved in the future due to improvements in Named Entity Recognition (NER) and related algorithms. In the near term, the tool could be improved by a better handling of dates going beyond regular expressions, for example by taking the context into account.

Further improvements could come from the embedding of structured information related to the texts to be identified (laboratory results, medical staff lists, patient information etc.). For example, structured laboratory results could prevent that these values are mistaken for dates when they appear in the free-text documents. The upcoming release of deidentify allows users to supply a selection of whitelisted words for each record, which are not replaced under any circumstances.

The usage of the tool in a variety of settings could provide further insights into its current flaws and how they could be mitigated. This potential emphasizes the benefits of releasing medical informatics software under open-source licenses, as well as providing a platform where potential improvements, feedback, and bug reports can be shared.

Abstract

Many mood tracking apps are available on smartphone app stores, but little is known about their features and their users’ experiences. To investigate commercially available mood tracking apps, we conducted an in-depth feature analysis of 32 apps, and performed a qualitative analysis of a set of user reviews. Informed by a widely adopted personal informatics framework, we conducted a feature analysis to investigate how these apps support four stages of self-tracking: preparation, collection, reflection, and action; and found that mood tracking apps offer many features for the collection and reflection stages, but lack adequate support for the preparation and action stages. Through the qualitative analysis of user reviews, we found that users utilize mood tracking to learn about their mood patterns, improve their mood, and self-manage their mental illnesses. In this paper, we present our findings and discuss implications for mobile apps designed to enhance emotional wellness.

Introduction

The World Health Organization (WHO) has defined mental health as “a state of well-being in which every individual realizes his or her own potential, can cope with the normal stresses of life, can work productively and fruitfully, and is able to make a contribution to his or her community.” Mental disorders such as stress and depression can be burdensome and disruptive, and also increase the risk of becoming ill from other diseases such as cardiovascular disease and diabetes. Despite the importance of mental well-being, initiatives to increase mental health awareness and services have been hindered by the absence of mental health in public health agendas and the lack of integrating mental health with primary care. Creating technology to support self-management of mental health may benefit consumers by empowering them to have a more active role over their own well-being, and making mental health resources more accessible. Along this line, both researchers and industry are increasing their efforts to develop technological solutions that enable individuals to manage their mental health. For example, Google has recently launched Verily, a healthcare lab that aims to digitalize mental health with the help of brain and behavioral sciences.

Mood tracking has been investigated as an approach to help healthy individuals stay in healthy emotional states, and assist individuals with mental diseases, such as bipolar disorder and depression, in their health management. Tracking health related data helps users to gain knowledge about their health, establish the correlation between the tracked data and their health conditions, and proactively engage in healthcare management. Self-tracking mood helps users increase their awareness and proactive self-regulation of their emotional well-being. The ubiquity of smartphones and their apps has enabled their use for a myriad of health purposes. According to a report from Statista, “health and lifestyle” is one of the most popular categories in smartphone apps. Self-tracking is among the most common strategies used by health apps, including tracking preventative behavior such as exercise, as well as monitoring health indicators, such as blood pressure and mood. The latest versions of smartphones provide built-in self-tracking functions for health.

Researchers have argued that many apps lack scientific- and clinical-based evidence in the feature design, and also lack evidence of consumers’ empirical usage. A few studies have investigated Android and iOS apps for specific health conditions, such as mental diseases and weight loss. To the best of our knowledge, little research has investigated the features, consumers’ experiences, and challenges of using mobile apps that are designed for mood tracking. Despite emerging sensing technologies and apps that could potentially detect users’ emotions, since mood and emotions are subjective, the accuracy of such sensing technologies remain unclear. Therefore, we investigate apps that allow users to self-report their mood, and we use self-tracking to refer to keeping track of mood via self-report.
Background

Emotional well-being is an essential part of mental health\textsuperscript{13}. Positive mood can enhance cardiovascular, hormonal and immune functions, promote healthy behaviors such as better sleep and exercise\textsuperscript{14}, and lead to more open-minded thinking and effective problem solving\textsuperscript{15}. Self-tracking mood could facilitate gaining knowledge and awareness of one’s mood patterns and thus help maintain emotional well-being. Researchers have employed various technologies to help individuals to record, analyze, and regulate mood\textsuperscript{16,17}. For example, MobiMood\textsuperscript{18} allows users to register their mood by selecting colors, and Aurora\textsuperscript{19} supports self-tracking by allowing users to select photos that best represent their mood. CopeSmart\textsuperscript{20} users log their mood by selecting a corresponding value on a scale. Other mobile apps have elicited users’ mood using emojis\textsuperscript{21}. Besides self-tracking, apps such as Aurora\textsuperscript{19} and MobiMood\textsuperscript{18} also encourage users to share self-tracked mood data in their social networks to seek emotional support\textsuperscript{22}. Study results suggest that users are willing to share their mood with their friends in social networks\textsuperscript{18,19}. In addition to designing self-tracking technologies for the general population, researchers have also investigated the use of mood tracking to help patients with mental diseases self-manage their conditions\textsuperscript{23}. For example, MoodZoom\textsuperscript{24} helps participants with bipolar disorder to rate anxiety, elation, sadness, anger, irritability, and energy on a 7-point Likert scale. The above studies mainly investigate one particular app in research settings.

Since the use of mobile apps for promoting health has grown exponentially in recent years, researchers have started to systematically review apps to identify features, opportunities, and challenges for healthcare practices\textsuperscript{8}. For example, Payne et al.\textsuperscript{25} have conducted a review on the behavioral functionality of mobile apps in health interventions, and suggested that mobile apps are a feasible and acceptable means of health intervention. However, they have also called for more rigorous research and design guidelines for the functionalities and interfaces of apps available for smartphone. Other researchers have provided comprehensive analyses of the literature on mobile apps for specific health conditions, such as mental illnesses\textsuperscript{9} and weight loss\textsuperscript{10}. These studies pointed out the limitations of evaluating mobile apps for health intervention within a limited number of participants using one specific app. Systematic reviews of health apps have identified a gap between the standards in scientific and clinical research, and the actual features in consumer products. For example, Nicholas et al.\textsuperscript{5} surveyed apps designed for bipolar disorder, and found that the available apps failed to provide essential information to help users assess their conditions, and argued that a new framework for mobile mental health research was essential to provide evidence-based health management. To the best of our knowledge, there has been no systematic review of mobile apps for mood tracking, how features of such apps align with healthcare research findings, and consumers’ experiences with using such apps in their daily lives.

Methods

To investigate features of apps currently available for smartphones, and their users’ experiences, we conducted a review on mood tracking apps, evaluated their features, and analyzed a set of consumer reviews.

App selection

In order to find a set of currently popular apps, a systematic search was conducted in the Android Play Store and the Apple App Store in January 2017. We searched for apps using the following keywords: (Mood OR emotions OR feelings OR affective OR happiness) AND (track OR log OR journal OR record OR diary). Apps were deemed eligible if they met all of the following criteria: 1) mood tracking is the main focus of the app, 2) mood is self-reported (not detected by sensors), 3) the app is in English, 4) it was last updated no earlier than 2014, and 5) it has at least 25 ratings. While consumers might provide ratings and reviews for an app, the number of ratings and reviews might differ, since users might rate an app (i.e., give it a score between 1 and 5 starts) without writing a review (i.e., a free text comment). We chose ratings as a measure of popularity because it was a comparable measure provided by both Android and iOS app stores. Criteria measuring popularity and recent updates were used to exclude apps of poor quality, which are not maintained or heavily used currently. The first two authors independently screened each app by reading its name and description, and examining any screenshots available in the app stores to decide on a set of apps for an in-depth feature and review analysis. Disagreement was dissolved through discussion.

App feature analysis

In this study, we conducted a feature analysis of mood tracking apps. For each app, two of the first four authors down-
loaded the app, extracted the main features, and then coded the features based on the stages of personal informatics tools each apps supports. To conduct the feature analysis, we used a set of key measurements based on the stage-based model of personal informatics systems11 – systems that help users collect, reflect on, and gain knowledge on their personal data11. We employed this model because it is a widely-adopted conceptual framework that can be used to evaluate self-tracking tools for each stage of the self-tracking process. The personal informatics model describes five stages: 1) the Preparation stage consists of planning that occurs before users start collecting personal data, 2) the Collection stage refers to when users record their data, 3) the Integration stage includes formatting and combining data, 4) the Reflection stage involves making sense of and learning from their personal data, and 5) the Action stage, when users act based on the insights gained through reflection. Self-tracking systems should be designed to support each stage11. While there are more recent models of self-tracking practices (e.g., Epstein et al.12), we choose the original model for our analysis because it is more simple, and because the model by Epstein et al.12 includes stages that do not need to be supported by self-tracking tools (e.g., deciding to track and selecting a tool).

App review analysis

In addition to reviewing system features, we analyzed reviews that users left in the app stores for the apps selected. Analyzing user reviews allows us to gain insights from the perspectives of the consumers of mood tracking apps. To do so, we downloaded all reviews from each app that were written prior to January 2017. We used two criteria to screen each review: 1) it is written in English, and 2) it is longer than 20 characters. Due to the large number of reviews, we randomly selected a subset of reviews for qualitative coding. Two independent coders read each app review and noted their themes. After reaching data saturation, we verified the remaining reviews to validate our results. Then, we used axial coding to extract themes present in the data26. Because it is not possible to obtain background information on who wrote each review, we were not able to differentiate between users with different characteristics (e.g., different genders or ages).

Results

App selection

The initial search returned 249 hits on the Android Play Store and 493 on the iOS App Store. After screening and discussion between the first two authors, 32 apps were selected, including 19 Android apps and 13 iOS apps (Table 2). Most of the selected apps are designed for the general population. Only one application – eMoods Bipolar – focuses on a particular health condition. There are two explanations for this. First, apps focused on specific populations, such as those with mental illnesses, tend to place mood tracking as a secondary focus, with other functions such as medication management as the main emphasis. Since in this study we are interested in apps designed specifically for mood tracking, many apps that aim for specific mental health management were excluded. Second, mood tracking apps that focus on a particular population tend to have fewer users, which makes them less likely to have over 25 ratings than mood tracking apps for the general population. Thus, all but one of the apps included in our review are designed for a general population. For several of the apps, we included both Android and iOS versions (e.g., iMoodJournal). However, for five of them, one of the two versions did not meet the criterion of over 25 ratings, and thus they were not included in the analysis. These apps are marked with an * in Table 2.

App feature analysis

After iteratively coding features using the personal informatics stage model, we categorized the features into four stages in Table 1. For the Preparation stage, we included features that provide information to prepare users for tracking their moods, such as instructions, explanations, and other resources about the app itself or the type of mood tracking introduced in the app. The Collection stage consists of app features that support recording mood using different methods, and setting reminders for logging mood in the future. For the Reflection stage, the most common app feature is the data visualization function, which comes in various styles. Finally, the Action stage mainly includes 1) a recommendation feature in which an app provides any recommendations or resources for further actions based on the mood recorded by users, and 2) a sharing feature that allows users to share or export their mood data. We did not include the Integration stage in this analysis because all of the selected apps handled this process automatically.

We analyzed the features of each application, including their functionalities and user interfaces. In Table 2, we present

The features in each app that correspond to four stages of mood tracking: Preparation, Collection, Reflection, and Action.

For the Preparation Stage, we found that only a few (N=8) applications provided substantial information about how to track mood, or about how tracking mood can help manage and promote well-being. Other apps provided little or no such information. However, even for apps that do provide features for the Preparation stage, such information is often very limited, and usually only appears when users first launch the app. Often, this information is not shown again after the first time the app is launched.

For the Collection Stage, all apps allow users to record their mood. We have found a diverse set of tracking interfaces, including 1) pre-defined text, i.e., text provided by the app that the users can select, such as ‘optimistic’ or ‘tired’, 2) free text, i.e., text that users can type themselves, 3) colors, i.e., choosing a color to represent the current mood, 4) pictures, either taking a picture or choosing one on the app to illustrate the current mood, 5) recorded audio, 6) emojis, i.e., picking an emoji or similar image to represent the current mood, and 7) ratings, e.g., 21 apps allow users to select the intensity of a particular mood. For instance, MoodPanda users could rate their happiness on a scale from 0 to 10. A few apps also support users to add notes to their mood. Notes could include contextual information, or a more detailed description of the mood. As for reminders, about one third of the apps do not include features for reminding users to enter data. Figure 1 presents screenshots of apps with different tracking interfaces.

**Figure 1:** Example screenshots of the Collection stage illustrating mood collection interfaces

For the Reflection Stage, we found that most apps (N = 29) provide mood visualization, such as bar and pie graphs. Other visualization modalities include lists, line graphs, calendar view, map view, and mood meter. For instance, pie charts and meters can help users get an overall view of their moods; calendar view and line graphs can facilitate users to find patterns in time, and map view can assist learning association between mood and physical locations. Many apps provide visualization support in one or multiple modalities for reflection.

For the Action Stage, only 7 of the 32 apps we analyzed provide features to support future actions, including recommendations for handling depression, contact information for a support hotline, strategies to avoid triggers, handle stress, and improve mood, and social features which help users look for support. Further, 25 apps have sharing features that allow users to send their mood data to their social networks for additional support, or to export the data in free text or spreadsheet format.
**App review analysis**

After the feature analysis, we investigated consumers’ reviews of the mobile apps. In total, we obtained an initial data set of 13,736 reviews. After excluding reviews not written in English or shorter than 20 characters, 8,584 reviews remained. We then randomly selected 1,000 reviews for analysis. From the app reviews extracted from the app stores, our analysis revealed consumer experience in the following aspects: consumers’ characteristics and goals in using the apps, their current app usage, and challenges they face. We summarize the findings in Table 3.

**Table 3:** Summary of main findings from consumer reviews

**Motivations of using mood tracking apps.** Users reported that their goals for using mood tracking consist mainly of learning about their mood to find strategies to improve, cope with stress, and manage mental illnesses. For instance, users were often interested in finding patterns in their mood data to understand influencing factors, and those with mental illnesses utilized mood tracking to monitor their symptoms.

“This app is great for keeping me in check and knowing what things contribute to my emotional state. It also makes me stop and think about my day and how I’ve felt! Which is a great factor in being able to turn a bad day around. [...]” (Diary - Mood Tracker, Android).

“I adopted this app as a core component of my self-quantification and improvement effort. It has proven incredibly valuable in helping me analyze patterns and manage my approach to stress and increasing happiness.” (Happiness, iOS).

By monitoring and learning about their own emotions, users reported feeling more in control of their mood, making informed decisions with the goal to become happier, and becoming more confident and positive in their emotional well-being.

Besides the general population, we found that users with mental illnesses also used mood tracking apps, even though the apps we selected were mainly designed for the general population. Users reported having a mental illness in approximately 10% of the analyzed reviews. The most common conditions mentioned in the app reviews were depression, bipolar disorder, and anxiety. In addition to the common mental illnesses, borderline personality disorder, obsessive compulsive disorder, attention-deficit/hyperactivity disorder, posttraumatic stress disorder, psychosis, and schizophrenia, were also cited as diseases that made users feel the need to track their mood.

“I have major depressive disorder and sometimes it is hard for me to keep track of how I feel one day to the next, especially when going to therapy. I actually heard about this app through some people on tumblr and I’m glad I tried it out. Wonderful app. [...]” (Diary - Mood Tracker, Android).

“As someone who suffers chronic physical and mental illnesses, this app is perfect to find trends in what is making me ill. [...]” (Diary - Mood Tracker, Android).

In the above review, users with mental illness also want to use mood monitoring apps because they might have other issues to track at the same time. In such cases, they might choose the app designed for the general population instead of those specifically designed for mental diseases.

Thus, user reviews indicate that the general population mainly uses the apps to learn about their mood patterns, better
manage their emotions, and make informed decisions to enhance their emotional well-being. Meanwhile, some users with mental illnesses also use the apps to monitor their mood. Some of them chose these apps instead of disease-specific apps for more flexibility and monitoring other chronic conditions together.

**Current usage.** We found that many users value the ability to register their mood frequently and add explanations to support reflection. Some users also share their mood data with therapists and psychiatrists. Most reviews that mentioned tracking frequency reported tracking daily, or multiple times per day. The reviews also showed that users appreciated the ability to present and share the visualized mood data with physicians, counselors, or therapists so they could monitor symptoms, or to support a possible diagnosis. A few reviews also mentioned that the app had been recommended to them by a healthcare provider. In a few cases, users with mental diseases tracked their mood alongside a family member, so both could monitor the occurrence of symptoms. These findings suggest that users collaborate with healthcare providers, caregivers, or relatives during the entire mood tracking process, or during the Reflection stage.

“[...] I have a mood disorder and the graphs make a great visual aid for sharing mood fluctuations with my doctor. [...]” (iMoodJournal, iOS).

“[...] [The app] was recommended by my therapist and I will recommend it to everyone I know. [...]” (iMoodJournal, iOS).

Based on the review, it seems that consumers could extend the logged mood data for individual usage to sharing with others. They reported leveraging mood tracking data to communicate with their healthcare providers, family members, and caregivers.

**Desired features of mood tracking apps.** In many reviews, users asked for additional features. The most commonly requested features were the capability to add personalized mood options, process logged data (e.g., order, search by mood/location/time), and update privacy settings (e.g., use a password to limit other people’s access to the data).

Also, while those who reported having a mental illness predominantly reported having positive experiences with the apps, they would often ask for specific features for their particular conditions. For instance, apps may assume that very positive emotions are desirable, but that might not be the case for people with bipolar disorder. For them, being too happy or optimistic might signify a manic episode. Users with mental illness also expected features such as tracking other symptoms or tracking medicine.

“[...] I’d hope to soon be able to sort my emotions by physical location. [...]” (Moodnotes, iOS).

From the consumer review above, it seems that users desire features that help them associate mood data with contextual information, such as location, to better manage their emotional well-being and their health conditions. For users who suffer from mental illnesses, sometimes they hope to have more options for mood and personalize the input.

“[...] The ability to leave notes is great and makes up a little for the lack of variety in mood choices. I also suffer from bipolar and add and find the mood choices way too simplistic when I can feel many different shades of very irritable, beyond happy into excitable and beyond that into a bit manic which might be the top end of the mood spectrum but is completely not nice. [...]” (iMoodJournal, iOS).

“[...] I suffer from a condition that makes me feel things rather intensely and only having five possible emotions to track seems lacking. However, you can add tons of activities and skills.” (Diary - Mood Tracker, Android)

**Discussion**

We found that mood tracking apps have many features supporting the Collection and Reflection stages of self-tracking, such as diverse forms of data collection and visualization. But the analysis revealed a lack of support for the Preparation and Action stages. Through analyzing app reviews, we found that users seek to learn about their mood patterns and improve them, and to manage emotional distress and mental illnesses. Many users pursue these goals by collecting data frequently, registering contextual information through notes, and sharing their data with healthcare providers. Still, they wish for additional features, such as the ability to personalize mood options, process their data for analysis, secure data to preserve privacy, and features specific for particular conditions.
Design app features to support Preparation, Collection, Reflection, and Action. While we found that most apps offer several different kinds of tracking options (Collection) and data visualization (Reflection), support for Action is mainly focused on sharing with social networks or exporting data. Most apps did not provide appropriate features for supporting the Preparation stage. The review analysis also indicates that apps could better support different types of users (i.e., the general population and users with mental conditions) and help them decide whether the mood tracking apps are well suited for them. Because being knowledgeable about self-tracking could help users achieve better results, it is likely that the lack of support for Preparation and Action of tracking constitutes a barrier to the effective use of mood tracking apps.

Our findings indicate that users’ experiences and results could be improved by extending the support for the Preparation and Action stages of mood tracking. Providing users with more information about tracking could help them to better prepare by setting concrete goals, better plan their data collection, and gain more insights about their mood patterns. Presenting them with advice or guidelines about how to handle crises and effectively improve their overall emotional wellness based on their mood data could also improve outcomes by helping users to take appropriate action for their situation and goals. We did not observe a substantial number of requests for these features from the user reviews, which might partially explain why they are seldom present. But supporting the Preparation and Action stages better is likely to help users to become more knowledgeable about the benefits and limitations of self-tracking, and maximize how much they benefit from this practice.

Consider both the general population and users with mental conditions. The majority of the apps analyzed were designed for the general population. There is limited previous work on the benefits of mood tracking for those who do not have mental conditions, but our results show that there is substantial interest in mood tracking from the general public. Our study shows users desire to manage and improve their mood despite not having mental illnesses. Given the fast-paced and busy lifestyles in industrialized societies, mood management is an important area that could be further supported by technology. Our study points to the motivations, current preferred features and future desired features of mood tracking apps, and provides valuable insights for enhancing wellness interventions and features supporting self-knowledge and awareness.

While these popular mood tracking apps may not support the integrated needs of disease management, we found users with many different mental illnesses utilized these apps for their self-management. The diversity of conditions users reported illustrates that mood tracking could assist in the self-management of several mental illnesses. While a recent analysis of available health apps found that many conditions have few or no specific apps available, our results indicate that individuals with these conditions are utilizing apps designed for other populations. Since individuals with mental conditions might have particular needs, even those who have other options (i.e., disease-specific apps) may choose to use apps intended for the general public, due to preferring their design or features. In order to use non-disease specific apps, this population requires more flexible features to be able to track specific aspects related to their illness, such as symptoms related to manic episodes. For these users, receiving support for the Preparation and Action stages is crucial, since such support could help them to track their mood more efficiently and effectively, and to decide on how to act based on their symptoms. Based on this finding, we believe that mood tracking should be investigated as a strategy to support a wide range of mental illnesses through offering flexible and personalized mood tracking options. More effort towards investigating this population’s needs and how effective mood tracking can be for individuals with each illness, could help with the development of more appropriate tools for supporting the health management needs of people with mental illnesses.

Support both individual reflection and data sharing. The app feature analysis suggests that most apps allow users to share their mood data with others. We found from consumer reviews that users share their mood data with their physicians, therapists, and counselors. Users who share the reviews with healthcare professionals are likely to be suffering from mental conditions or mental distress. Sharing mood tracking data with healthcare professionals indicates that these apps are being used not only for self-management, but also for communicating symptoms and collaborating with healthcare providers. The apps provide ways to export data and thus make it easier to share. Similar to other kinds of patient-generated data, it is likely that the kind of data visualization that is appropriate for patients might not be preferred by healthcare providers. Thus, more research is needed to investigate mood tracking apps that can facilitate data sharing between patients and healthcare providers. Further, it is important to investigate how to support
sharing data with family members, caregivers, and friends, while protecting users’ sensitive information. Since family members, caregivers, and healthcare providers might have different motivations and information needs, it might be worthwhile to consider different options in different kinds of data and visualization for shared data.

Implications for clinical practice. The outcomes of this study indicate that mood tracking tools are being used by many people, including people who have mental illnesses. Our data indicate that apps should improve their support of preparation and action activities, but they also can offer benefits to users by helping them to increase awareness of their mood patterns. Health care providers may assist patients in choosing adequate mood tracking apps and using them effectively, if they are informed about which options would match patients’ needs. Providing patients with information on mood tracking could compensate for the limited support for preparation and action activities from the apps.

Analyzing app reviews can reveal valuable insights about real users’ experience, but there are associated limitations. First, since not every user is expected to write reviews, there might be selection bias of the user opinions we can access. Similarly, we are not able to estimate the distribution of user groups, e.g., the general population and those with mental conditions. Since not every user who wrote reviews choose to disclose their mental conditions, we cannot assume that they do not suffer from any conditions if illnesses are not mentioned in the reviews. Additionally, even though we assume that the reviews could reflect consumers’ real experiences, it is difficult to determine how long they have used the app and whether they have abandoned the app.

Conclusion

A qualitative analysis on consumers’ reviews of mood tracking apps showed that both the general population and consumers with mental conditions used the apps. The general population mainly used the apps to learn about their mood patterns and cope with stress, while users with various mental conditions also used the apps to monitor their symptoms. They not only tracked the data for themselves, but also used the data to communicate with their healthcare providers and share with family members.

Abstract

Knowledge Organization Systems (KOS) play a key role in enriching biomedical information in order to make it machine-understandable and shareable. This is done by annotating medical documents, or more specifically, associating concept labels from KOS with pieces of digital information, e.g., images or texts. However, the dynamic nature of KOS may impact the annotations, thus creating a mismatch between the evolved concept and the associated information. To solve this problem, methods to maintain the quality of the annotations are required. In this paper, we define a framework based on rules, background knowledge and change patterns to drive the annotation adaption process. We evaluate experimentally the proposed approach in realistic cases-studies and demonstrate the overall performance of our approach in different KOS considering the precision, recall, F1-score and AUC value of the system.

Introduction

In order to support various tasks in medical information systems such as retrieving, sharing and exchanging information, the data stored within these systems are usually annotated with concept codes from standard Knowledge Organization Systems¹ (KOS). These annotations make the semantics of the data explicit for machines in order to automatize the above-mentioned tasks. However, KOS evolve over time and their elements may be modified, which, in turn, may affect the dependent annotations as shown in our previous work² and drastically impact the reliability of applications exploiting them. Methods and tools are therefore required to keep semantic annotations updated as KOS evolves. The idea is to avoid a complete re-annotation of the document, which is both time consuming and requires human intervention for validation purpose.

Over the past decade, several approaches have been developed to tackle this problem. For sake of clarity, we split this complex problem into two sub-problems: (1) how to detect the annotations impacted by the evolution of the KOS; and (2) how to update impacted annotations to keep them consistent with the new version of the KOS. Many existing approaches focus on the first sub-problem, proposing several different techniques such as logic rules³–⁵ or NLP processes to detect changes⁶,⁷ or even database versioning⁸,⁹. The second sub-problem is mainly addressed by removing the outdated annotations from the corpus⁷, or by adapting existing annotations. By applying the former approach, the user accepts loosing part of the existing knowledge. To avoid this, the latter approach can be adopted. Different adaptation methods are proposed and can be classified according to the techniques used. In⁹, the authors proposed a migration algorithm. Frost et. al.¹⁰ proposed a novel algorithm for optimizing gene set annotations using entropy minimization over variable clusters (EMVC). This filters annotations for each gene set to remove inconsistencies. In their work, Traverso Ribon et al. proposed the AnnEvol¹¹ framework to describe datasets of ontology-based annotated entities. These approaches usually focus on one kind of KOS (e.g. Gene Ontology), or on very expressive ontologies to use reasoning techniques³, and do not exploit information that can be acquired from the analysis of KOS evolution. In our previous work, we designed the DyKOSMap framework for maintaining valid the semantic mappings between evolving KOS¹². However, unlike mappings that formally connect concepts, semantic annotations refer to information of a different nature (e.g. text, images, video ...) that is less rich from a semantic point of view. In consequence, the approach that we proposed for mappings needs to be redesigned to address the semantic annotation maintenance problem.

To overcome the limitations of existing approaches mentioned above, our contribution consists of: (i) the definition of a set of rules following a rigorous analysis of the evolution and adaptation of a set of annotations over a 10-year period² (ii) the combination of these rules with two other techniques to improve the quality of the maintenance process: The first technique relies on the use of background knowledge (BK)¹³ while the second exploits semantic change patterns
Table 1: Example of an evolving annotation, extracted from our silver standard.

(SCP)\textsuperscript{14} that have shown great capabilities for the maintenance of ontology mappings\textsuperscript{12}. Moreover, we provide an experimental assessment of our framework by maintaining a corpus of documents annotated with ICD-9-CM, MeSH, NCIt and SNOMEDCT.

The remainder of the paper is structured as follows: The following section presents our method for adapting semantic annotations. Then, we introduce the experimental evaluation of our approach and the results we obtained at validation time. Finally, we discuss the results and conclude our paper.

Semantic Annotation Adaptation

In this section we describe our rule-based approach for adapting outdated semantic annotations and the material to evaluate it. We represent annotations following the model of the W3C Web Annotation Data Model\textsuperscript{1}. We included some modifications, e.g., a property to link the evolved annotation to its past version, the KOS change which impacted the annotation and other properties\textsuperscript{2}. To illustrate how an annotation is represented in our system, Table 1 contains the original annotation (from 2009) in the first line and the evolved annotation (from 2010) in the second line.

In our analysis, we used the following features: the name and version of the KOS, the reference of the document used as a resource, the concept code, the annotated text followed by the start and end offset, i.e., the position in the document where this annotation can be found, and the prefix and suffix, i.e., the information that comes before and after the annotation. However, if available, more metadata can be included, respecting our annotation form\textsuperscript{2}. The illustrative example shows one annotation produced with the 2009AA MeSH version using the PubMed document 232\textsuperscript{2} and the concept D019684. The annotated text is “Magnoliophyta”, and this can be found in the position [4587,4600]. We set up the system to have four words as a prefix “during the evolution of” and a suffix “(angiosperms) [5]. typical”. We can observe that the concept label used to annotate the text changed from 2009AA to 2010AA.

Our maintenance process relies on the combined use of seven rules, background knowledge and semantic change patterns. The rules proposed derive from our analysis of the evolution of annotations impacted by changes in the underlying terminology\textsuperscript{2}. The rules are part of the implementation of our global framework\textsuperscript{15}. The decision to execute a rule depends on several criteria, but instead of checking all annotations, a first filter is applied: only annotations associated to concepts that have changed (computed with COnto-Diff\textsuperscript{16}) are checked. Unlike rules for mapping maintenance\textsuperscript{12}, the proposed annotation maintenance rules consider many other features used to characterize semantic annotation\textsuperscript{2}. We based our approach on the guideline associated with semantic annotation\textsuperscript{17}. The criteria that we used to guide us during the annotation process also inspired us to define the sequence and conditions that our rules have to be applied.

The seven proposed rules are listed in Table 2. Each column represents one feature: the original concept code and the KOS version ($CP_{v0}$), annotated text ($Annot_{v0}$), a prefix ($Prefix_{v0}$), and a suffix ($Suffix_{v0}$). We also added one column to show the changes observed ($Changed_{v1}$) and another to indicate the rule executed for the presented situation (one rule by line). The proposed rules are:

1https://github.com/anno4j/anno4j
2https://www.ncbi.nlm.nih.gov/pmc/articles/PMC2631504/
1. **MergeAnnot**: This rule will be applied when two parts of a document, annotated with different concepts, can be put together and annotated with one (more specific) new concept only. For instance, in 2004AA, the texts “pregnancy” and “hypertension” were annotated with the concept codes D011247 and D006973, respectively. In 2005AA, text containing both terms, i.e., “pregnancy-induced hypertension” was annotated with the new concept D046110, see Table 2.

2. **IncreaseAnnot**: This rule increases the amount of information that can be annotated after the evolution of the underlying KOS. To do this, we compare the new label or attribute values of the candidate concept with the information surrounding the initial annotation (i.e., we take into account the prefix and suffix of the annotated text). Concretely, this action modifies the offset value in the annotation model and (if needed) the concept ID, e.g., \{D002403, cathepsin\} ↔ \{D056668, cathepsin l\}, see the second example on Table 2.

3. **ResurrectAnnot**: In some cases, one concept can be temporarily deleted from a KOS, leading to the deletion of the associated annotation. For instance, the annotation *chemiluminescence* in Table 2 was removed by a change in MeSH 2005AA. This rule allows the annotation to be re-activated when the concept is re-integrated to the KOS, e.g., the concept D017083 in MeSH 2006AA.

4. **PluralAnnot**: This rule verifies whether the change in the underlying concept or attribute value is due to a plural or singular (agglutination ↔ agglutinations). In this case, the change in the terminology does not imply a change in the impacted annotations since the semantics of the concept are not altered. Note that plurals are language-dependent rules and we are evaluating only for English KOS.

5. **ChangeConceptAnnot**: This rule changes the concept ID of the annotation due to the evolution of the concept. This situation arises when the label or the attribute value of the concept, used to create the annotation, is moved to another concept or used to create a new concept. For instance, concept D003704 changed to D057174 (referring to *Semantic dementia*) in MeSH 2009AA/2010AA.

6. **SplitAnnot**: This rule splits an existing annotation if the evolution of the underlying concept leads to the creation of two more precise annotations. For instance, the text “diabetic foot ulcers”, annotated in 2005AA with the MeSH code D017719, was split into two other annotations in 2006AA: D017719 (diabetic foot) and D016523 (foot ulcers), see Table 2.

7. **SuperClassAnnot**: This rule changes the concept ID to the superClass ID since no concept can be found to precisely maintain the annotation. It will also change the relation (i.e., “Equivalent” → “Is A”) between the concept and the annotation. For instance, after checking whether any of the previous rules were executed with the annotation *infective agents*, the last example in Table 2, instead of deleting the annotation, we propose to using superClass to annotate the text. Thus, *infective agents* is a kind of *other organism groupings*. Note that it is only possible if the formalism used to annotate the text follows our proposed formalism².

The sequence in which the rules are executed is important to assure the quality of the modified annotations. Based on the propositions of the annotation guidelines¹⁷, we established the following sequence: MergeAnnot, IncreaseAnnot, ResurrectAnnot, PluralAnnot, ChangeConceptAnnot, SplitAnnot, SuperClassAnnot. We ranked first the rules that increase the information of an annotation (i.e., MergeAnnot and IncreaseAnnot), as suggested in the guideline “Annotate the most specific concept that correctly describes the disease mention”. The next rules (ResurrectAnnot, PluralAnnot and ChangeConceptAnnot) are mainly related to the structure of the KOS and text. We started by ResurrectAnnot because changing the concept ID (ChangeConceptAnnot) would increase the complexity in identifying the restoration of the concept. The PluralAnnot rule is an exception, because it does not affect the other rules and can be placed anywhere in the sequence. The SplitAnnot was placed close to the end of our process due to the rare cases where it occurs as mentioned by Doğan et. al.¹⁷. It respects the following recommendation: “Annotate a disease mention using multiple concepts to logically describe the disease mention, using the “+” concatenator”. Finally, the SuperClassAnnot was positioned at the end of our process as an alternative to the removal of the annotation.

The precision of rules has some limitations. We observed that some exceptions could sensibly increase the complexity of the rules (and the time required to execute them). Thus, we decided to evaluate other potentially complementary
Table 2: Example of annotations computed by our rules. \((CP_{v0})\) concept code in specific year, \((Annot_{v0})\) annotated text, \((Prefix_{v0})\) prefix, \((Suffix_{v0})\) suffix, \(Changed_{v1}\) result of applied rule.

methods in order to improve the quality of our outcomes. In this sense, we selected two other methods: background knowledge and semantic change patterns. Details of each method can be found in \cite{13} and \cite{15}, respectively. We briefly introduce the main aspects of these two methods below:

**Background Knowledge (BK)**

The main idea behind BK is to use information inferred from external ontologies in order to discover the semantic relation between two successive versions of a concept \cite{13}. For instance, the evolution of the label “Magnoliophyta” to “Angiosperms” cannot be characterized only by considering the syntactic aspect. However, external “sources of knowledge” can tell us that these two terms are synonyms. We used the mappings between the concepts from different terminologies to determine the relation between these concepts. In our case, we used the mappings contained in Biportal \cite{18}. However, this approach can be extended to any external resource.

The BK algorithm (see algorithm 1) presents an overview of the whole process. Fig. 1 helps to illustrate how the algorithm works. The input of the algorithm is the concept ID ($C_s$), label ($L_s$), KOS target ($KOS_t$), and KOS source ($KOS_s$), e.g., (D019684, Magnoliophyta, MESH, \{SNOMEDCT, ICD-9-CM, NCIT\}). After initializing the variables (lines 1 to 2), our method queries external sources using the impacted annotation (line 3) label and stores the resulting concepts ($Request$). For instance, the concept 420928000, from SNOMEDCT, is one candidate. Only concepts candidates belonging to the source KOS ($KOS_s$) are kept (lines 4-5). Then, for each concept from $Request$, the mappings are collected (line 6). Only mappings to the target KOS ($KOS_t$) are kept (lines 7-10), they are the gray boxes in Fig. 1. From all candidates that satisfy the previous conditions, only the best candidate is selected to maintain our annotation (lines 11-13). The selection criteria is based on the semantic similarity (i.e., Tversky similarity) between the concept source and the concept target, i.e., ($C_s$ and $C_t$) from MESH.

**Algorithm 1:** Background Knowledge to find the link between 2 concepts

| Input: | Concept source $C_s$; Label $L_s$; Ontology source $KOS_s$; Ontology Target $KOS_t$ |
| Output: | Concept Target $C_t$ |
| MappingSet ← $\emptyset$ |
| Result ← $\emptyset$ |
| $Request ← getConceptsFromBK(L_s)$ |
| forall $cp ∈ Request$ do |
| | if ($cp ∈ KOS_s$) == TRUE then |
| | | MappingSet ← getMappings($cp$) |
| forall mapping ∈ MappingSet do |
| | target ← getConceptTarget($mapping$) |
| | if ($target ∈ KOS_t$) == TRUE then |
| | | Result ← target |
| forall obj ∈ Result do |
| | calSemanticDistance($C_s$, obj) |
| $C_t ← getHighSimilarity(Result)$ |
| return $C_t$ |

**Semantic Change Pattern**

Change Patterns are morphosyntactic modifications observed in attribute values of a concept, using linguistic-based features to identify the correlation between concepts over time. This technique has already been explored in the context of ontology mapping adaptation \cite{14} and we adapted it to the maintenance of annotations \cite{15}. It consists of a set of rules that allow the identification of the impact of evolving an ontology on the semantics of the concept.

For instance, the annotation, “Physiologic processes” produced using MeSH 2008AA, was impacted in 2009AA. This
Figure 1: Use of BioPortal as Background Knowledge

is due to a change in the attribute value in the definition of concept D010829 leading to “Physiological Phenomena”. The rules proposed in\textsuperscript{14} will determine which class of change it belongs to: \textit{total copy}, \textit{total transfer}, \textit{partial copy}, \textit{partial transfer}. We can conclude, for instance, that if changes in the ontology lead to a total transfer of information from one concept to a new one, than the annotation will probably change the source (or target) concept to this new one too. This is a simplification of inferences that can be used. To better understand the context and the complexity behind SCP, we advise reading\textsuperscript{14}.

Experimental Assessment

In this section, we introduce the method and material we have used to evaluate our approach. The experiments we have conducted consist of applying our approach to a set of annotated documents and comparing it to a corpus of reference representing an evolved version of the initial set of documents.

Material

Our annotation maintenance process takes as its input:

- a set of outdated annotations,
- the old and new OWL versions of the KOS used to generate the annotation.

In our experiments we have used: International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM), Medical Subject Headings (MeSH), National Cancer Institute Thesaurus (NCIt) and Systematized Nomenclature of Medicine - Clinical Terms (SNOMEDCT). We used versions 2009AA and 2010AA downloaded from the UMLS and transformed into OWL files. These KOS follow the formality expressed in the UMLS metathesaurus\textsuperscript{3}, e.g., \textit{(Concept A rdfs:superClassOf Concept B)} ; \textit{(Concept A skos:prefLabel term 1)}, etc. We used COnto-Diff\textsuperscript{10} to identify the changes in the new version of the KOS since these changes are strongly correlated with the validity of annotations\textsuperscript{2}.

Silver Standard

Since no annotation baseline generated with sequential ontologies versions exists, we had to build our own corpus of reference using the annotations produced in\textsuperscript{2} as a basic resource. To do this, we randomly selected 500 annotations generated with the 2009AA version of the four KOS (125 annotations from each KOS) and asked three experts to manually validate/correct the evolution of the 500 selected annotations, according to the 2010AA version of the corresponding KOS. Each expert validated 1/3 of the annotations and no discussions between them was organized. The consolidated

\textsuperscript{3}https://www.ncbi.nlm.nih.gov/books/NBK9685/
outcomes compose the silver standard, which can be downloaded from [http://www.elisa-project.lu/](http://www.elisa-project.lu/), look into menu publications/downloads. We adopt the term "silver" to indicate that our reference is based on only one viewpoint.

To measure the effectiveness of the proposed approach, we used classic well-known metrics from the literature, such as, precision, recall, F1-score, ROC curve, accuracy, false/true positives/negatives. For the sake of readability, we will present only three metrics in the table. But, we used all six metrics to investigate/understand two characteristics of our method: i) the capacity of our framework to detect impacted annotations after changing a KOS concept; and ii) the ability to correctly evolve those impacted annotations into consistent ones. In this case, consistency means equivalency with the silver standard. We measured the efficiency of the rules alone, the BK alone, and the SCP alone and the efficiency of the combined techniques in order to determine whether they complement each other.

### Results

When applying the three annotation maintenance methods (BK, SCP, Rules) to our dataset we can observe a significant difference in the results (based on the six criteria used). For instance, as shown in Table 3, all three methods can provide good precision, but there is a significant variation [0, 0.98] regarding the recall. In the first line of Table 3, we present the precision, recall, and F1-Score resulting from applying the BK method to four different subsets of our initial dataset (ICD-9-CM, MeSH, NCIt, and SNOMEDCT). We also evaluate the consequence of combining the methods (2-by-2, and all together). For instance, the fourth line of the table presents the results of combining BK and Rules methods, while the seventh line shows the results of combining all three methods.

The goal of this first set of experiments was to evaluate whether the methods (or a combination of them) provides satisfactory quality (in terms of F1-Score) to determine whether an impacted annotation will evolve or not. Note that we are not yet evaluating whether the annotation evolved correctly (this is part of the second evaluation step). A quick analysis shows that all methods can accurately identify some of the evolving annotation, but not all. From a practical point of view, whether an error of 2% is acceptable for the domain, then KOS engineers can trust our best method to identify annotations that will change (i.e., the minimal observed precision was 98%). However, the recall can be significantly different according to the dataset and the method adopted. We detail the reasons for this in next section. We would like to highlight that our Rules method had an impressive performance, obtaining in some cases a F1-Score of 99%.

The second evaluation process consists of applying methods to select which adaptation actions can make the annotation evolve correctly, and compare the outcomes with the silver standard. The goal is to measure how precise our recommendations are. Table 4 describes the performance of each method regarding the four different datasets. Each experiment is represented by an Area Under the Curve (AUC) value, giving the probability that a randomly selected instance will correctly be adapted by our method19.

The AUC values of the analyzed methods vary according to the dataset. A quick analysis in Table 4 shows that combining all methods provides slightly better results than applying only one of them. Furthermore, SCP shows the

### Table 3: Precision (P), Recall (R) and F1-Score (F1) of impacted annotations computed using three different methods (BK, SCP, Rules) and the combination of them. The red and orange colors indicate low and medium recall, respectively.

lowest AUC values of all heuristics. We also verified that the AUC has significant differences between the KOS, like those between ICD-9-CM and NCIt. Detailed explanations on these observations are provided in the next section.

Discussions

The analysis of annotation evolution in the healthcare domain is an understudied topic. As explained in the introduction section, several works propose the automatic detection of inconsistent annotations, but few of them address the automatic correction of inconsistent annotations. The work presented in this paper shows that some annotations can be preserved/adapted after the evolution of the KOS used to generate the annotations. Three methods were proposed: Background Knowledge, Semantic Change Patterns, and Domain Specific Rules. The outcomes presented in the results section demonstrate that we can obtain high AUC by applying these methods together in the automatic maintenance of annotations or to support domain experts in this activity.

When analyzing each method, we observed that BK contributes to the precision of the annotation changes. The main characteristic of BK is that it depends on the richness of information in other sources (e.g., ontologies with overlapping concepts). Furthermore, BK can provide unaligned mappings to past KOS versions leading to another phase to filter inconsistent results. This limitation of the method generates a low recall (but good precision) of results. We estimate that it can be an interesting complementary method for the maintenance process. Another aspect that can be deduced from the experiments is the dependency of the BK method on the expressivity and consistency of the KOS. For example, MESH D002544 has as a synonym the concept labels that are considered siblings in other KOS (e.g., “Cerebral infarct left hemisphere” SNOMEDCT 362323007 and “Cerebral infarct right hemisphere” SNOMEDCT 362322002), leading to loose information when the system follows the KOS mappings that cross MeSH. We also observed that SNOMEDCT and ICD-9-CM allow equal “labels of concepts” (e.g., in SNOMEDCT the concept “diverticulosis” has the following codes 31113003, 397881000, and 68047000), which can lead the system to select the wrong concept to replace the impacted annotations, and necessitating an additional disambiguation phase. Another limitation of BK is that we can only find the last version of KOS in the Bioportal (i.e., from 2016), but our experiments use documents annotated with the version 2009AA and 2010AA. Versionning is an aspect that is not yet integrated to Bioportal, but it deserves to be considered in future.

The analysis of SCP also shows a good precision and low recall. The reason here is that SCP considers only change between concepts that are in the same neighbourhood (i.e., siblings, super-, and sub-concepts). Thus, changes that move the concept to other branches of the KOS are not included, leading to an increased number of false negatives. For SNOMEDCT, Table 4, we did not observe any cases with SCP in our dataset. Since, the data used was randomly selected, we consider that it was a coincidence. We did our analysis based on the results coming from the other KOS. However, this heuristic is able to cover cases where the Rules or BK do not work. For instance, the annotation “ubiquitin carboxyl-terminal hydrolase” NCIt C21490 correctly evolved to “ubiquitin carboxyl-terminal hydrolase BAP1”. Thus, the AUC value to NCIt in Table 4 is higher in Rules & SCP than that compared to BK and its combinations (lines 1, 4, and 5).

Domain-specific rules are defined to describe frequent patterns of changes, and it is expected to generate outcomes from them with good precision and recall. This was the case for the rules proposed in our experiments. However,
our rules do not cover all annotation evolution cases perfectly; some ambiguities are still observed. The proposed rules are not very precise when the annotated text and the concept label (or synonyms) do not have an exact match. For instance, the text “dysarthria” was annotated in 2009AA with the concept 784.5 (Other speech disturbance); in 2010AA, a new sub-concept 784.51 (“dysarthria”) was created. The rules were unable to determine that the specialized concept was more appropriated to the annotation. This evolution was correctly proposed by the BK method. Such cases of misclassification are more frequent in NCIt because we observed fewer annotations with an exact match and a lower number of mappings from/to this KOS in Biportal.

Another aspect to highlight, is that depending on the context in which the maintenance methods were used (e.g., high expressive KOS), there are considerable differences in the sets of results. We also observed that a combination of methods can be used for a more complete set of evolution situations, as in following:

- SCP and BK methods show low complementary results to identify whether the KOS evolution impacts the annotations, but an improvement was observed by combining the methods to identify the correct evolution of the annotation.
- On one hand, Rules increase the amount of corrected annotations of all BK and SCP analyzed cases. On the other hand, BK and SCP have a minimum effect on the rules for the first set of experiments and demonstrate the ability to improve the identification of correct evolution of the annotation (second set of experiments).
- Compared to the pairwise combination of the methods (BK & Rules, SCP & Rules), applying the three methods together improves (or at least keeps the same) the AUC of the correct evolution of the impacted annotations (second set of experiments).

Conclusion

The work presented in this paper shows the possibility of having annotation maintenance tools that can keep tracking KOS evolution and measure the impact that it will have on the set of annotated documents. Moreover, it also demonstrates that automatic correction/adaptation of annotations can reach a reasonable reliability rate. But, it is important to highlight that the role of human beings is still determinant to assure the quality of the annotations in critical scenarios, as observed in the biomedical domain. Our approach contributes to a more generic objective that intends to define methods and formalism to improve the annotation task in order to better support the annotation maintenance. In previous work, we evaluated the annotation formalism and proposed some extensions to close the identified gaps. In future work, we will evaluate the performance of our approach in a larger temporal window and search for methods that can generate additional rules from the data.

Abstract

Free-text reports in electronic health records (EHRs) contain medically significant information - signs, symptoms, findings, diagnoses - recorded by clinicians during patient encounters. These reports contain rich clinical information which can be leveraged for surveillance of disease and occurrence of adverse events. In order to gain meaningful knowledge from these text reports to support surveillance efforts, information must first be converted into a structured, computable format. Traditional methods rely on manual review of charts, which can be costly and inefficient. Natural language processing (NLP) methods offer an efficient, alternative approach to extracting the information and can achieve a similar level of accuracy. We developed an NLP system to automatically identify mentions of surgical site infections in radiology reports and classify reports containing evidence of surgical site infections leveraging these mentions. We evaluated our system using a reference standard of reports annotated by domain experts, administrative data generated for each patient encounter, and a machine learning-based approach.

Introduction

Health care-associated infections (HAIs), such as surgical site infections (SSIs), affect one in every twenty hospitalized patients and account for $10 billion dollars in potentially preventable health care expenditures annually¹. Identification and reporting of HAI after selected procedures is a required hospital quality measure by several federal agencies. In addition, detection of HAIs in a timely manner may alter treatment courses, reducing hospital costs and improving patient care.

Information indicating an HAI may be recorded in a variety of locations in the electronic health record (EHR): physician notes, radiology reports, and microbiology reports. One common method of documenting HAIs is using administrative data such as International Classification of Diseases (ICD). Due to the lack of specificity in administrative billing codes and timing of their assignment, these codes cannot reliably be used to identify HAIs in an accurate and timely manner. Furthermore, administrative data are often insufficient and incomplete due to the underutilization of structured data fields, lack of standardization, and unknown quality of clinical data². Relevant information may instead be documented in free-text reports and text fields of the EHR. However, these reports are unstructured and the information contained within them must be extracted into a structured, computable format in order to utilize them. The traditional method of extraction is manual chart review, such as in the National Surgical Quality Improvement Program (SQIP). Specifically, these programs leverage trained surgical case reviewers to manually extract data from EHRs to detect and to report the development of HAIs³. However, manual abstraction is expensive, labor-intensive, and time-consuming. More efficient methods must be considered to extract this information.

Natural language processing (NLP) systems can be developed to automatically extract HAI information from textual data as an efficient and effective method of HAI detection. Melton et al. trained the NLP system MedLEE to identify adverse events (AEs) from discharge summaries⁴. MedLEE uses grammatical rules to identify concepts and their semantic context, which are then mapped to controlled vocabularies⁵. MedLEE outperformed manual review for AEs, but their study included only one postoperative HAI (wound infection), which the system achieved a low precision (0.34) for detecting wound infections. Their overall recall (0.28) and precision (0.45) were fairly low, while their specificity was quite high (0.98). Penz et al. combined MedLEE and phrase-matching techniques that utilize regular
expressions to identify AEs related to the placement of central venous catheters. By combining these two methods, they achieved good recall (0.72), specificity (0.80), and precision (0.64). False positives occurred due to indications of risk, in which the doctors discussed the hypothetical risks of a catheter placement. Some mentions were also missed due to misspellings in the text. The authors compared the NLP performance to that of ICD-9 and CPT codes. They concluded that NLP techniques are far more sensitive than using administrative data, which captured less than 11.5% of all central line placements.

Several studies have specifically focused on the effectiveness of NLP at detecting surgical AEs. FitzHenry et al. applied NLP methods to surveil for the presence multiple surgical complications, including pneumonia, wound infection, and urinary tract infections. They achieved moderate to high performance for detecting each type of complication measured: pneumonia (recall: 0.90 and specificity: 0.80); wound infection (recall: 0.63 and specificity: 0.77); and urinary tract infections (recall: 0.80 and specificity: 0.95). Similarly, Murff et al. compared the performance of NLP techniques in the detection of surgical AEs to the performance of using patient safety indicators. The NLP system performance ranged from moderate to high for detecting pneumonia (recall: 0.64 and specificity: 0.95) and sepsis (recall: 0.89 and specificity: 0.94). Their system had a higher recall and lower specificity than administrative data. Both of these studies were conducted in Veteran Affairs (VA) centers and used a gold standard of manual review performed by a VA-SQIP nurse.

The main limitation of these studies is the lack of additional clinically relevant information (such as anatomic location) in development of these detection systems. The goal of this study was to evaluate the performance of an NLP algorithm in the extraction of evidence of intra-abdominal surgical site infections that specifies the anatomic locations of these SSIs. The overall hypothesis is that NLP methods will achieve a level of accuracy equal to or greater than that of manual chart review and greater than that of administrative data. Our objective was (1) to develop a knowledge base that supports deep semantic extraction of evidence of intra-abdominal surgical site infection mentions and their anatomic locations and (2) to test a knowledge base-powered NLP algorithm's ability to make report-level predictions of whether evidence of an intra-abdominal surgical site infection is present. We evaluated our NLP algorithm's performance using a reference standard of expert-annotated text and compared its performance against other baseline approaches such as administrative data and machine learning.

Methods

The overall approach for this study included four steps: (1) identifying surgical patients and collecting their associated EHR data; (2) annotating text data and developing a knowledge base; (3) detecting mentions of SSIs and classifying reports for the presence of a SSI; and (4) evaluating automated methods against the reference standard annotations for SSIs. Institutional review board approval (IRB) was obtained.

Patient Identification and Dataset Extraction

We identified a cohort of patients undergoing gastrointestinal surgery from MIMIC-III Critical Care Database and collected their de-identified EHR data. Specifically, we collected administrative information (admission date, procedure date, ICD-9 diagnosis codes, and Current Procedural Terminology (CPT) codes). We limited the study to patients undergoing gastrointestinal surgery covering topics of esophageal, gastric, small intestine, large intestine, liver, pancreas, abdominal wall, ovarian, uterus, kidney procedures based on 28 CPT codes (e.g., CPT 49000=Under Incision Procedures on the Abdomen, Peritoneum, and Omentum). We limited our review and process to only include computed tomography (CT) reports due to their standardized structure and reliable reporting of findings. From this cohort, all the CT reports within 30 days after the surgical procedure were collected for our dataset.
Annotation Study

We conducted an annotation study using our development dataset to generate a reference standard of mention-level and report-level classifications using the full dataset. Two domain experts, a surgeon (author BB) and a surgical resident (author DS), annotated these reports using the annotation tool, the extensible Human Oracle Suite of Tools (eHOST)10. In these reports, evidence for a SSI is commonly described by phrases such as “fluid collection” or “abscess”51. To confirm the mentions (subsequently referred to as “fluid collections”) we were referencing findings related to the gastrointestinal tract surgery, we limited our search to detecting mentions co-occurring in the same sentence with descriptions of a gastrointestinal anatomic location such as “liver” or “abdomen”. The annotators annotated sentences containing mentions of fluid collection as one of the following classes: positive evidence of fluid collection; negated evidence of fluid collection; indication for exam; and annotated mentions of anatomic location within these sentences marked as positive evidence of fluid collection (Table 1). After annotation was complete, we then randomly split our dataset into development set (n=565 documents for 409 patients) and test set (n=100 documents for 96 patients).

Mention Detection

To automatically identify and classify evidence of surgical site infection from each report according to our annotation schema, we developed an NLP system called SSI-Detect. We created a module called Fluid Collection Finder (fcFinder) that targets and classifies fluid collections*. fcFinder leverages the pyConText library, an adaptation of the ConText algorithm. ConText utilizes trigger terms and termination points to extract and associate contextual features such as negation, temporality and experiencer to targeted terms12. Specifically, pyConText extends the ConText algorithm by leveraging NetworkX digraphs to relate targets with modifiers and supports report-level classification13. pyConText has been adapted to support several use cases: to identify pulmonary embolisms, to classify cancer history, and to flag reports with significant carotid stenosis findings13-15. Using the development set, we created a knowledge base lexicon of 46 fluid collection targets and 128 anatomic location modifiers*. fcFinder utilizes this knowledge base to implement the pyConText algorithm and identify relationships between contextual and anatomical modifiers and fluid collection targets. After creating these relationships, fcFinder applies rules to classify each sentence containing a mention of a fluid collection finding as being positive evidence of fluid collection, negated evidence of fluid collection, or indication for exam. Figure 1 depicts an example pyConText markup sentence with a target and its associated modifiers of negation and anatomic location.
Figure 1. An example of negated evidence of fluid collection. The target, “abscess”, is modified by “no evidence”, a forward-direction negation modifier, and “abdomen”, a bidirectional anatomic modifier.

Evaluation

We computed the performance of fcFinder by comparing the mention-level findings of positive evidence, negative evidence, and indication with the annotated reference standard. Definitive, historical, and probable evidence were all considered positive evidence mentions and could be matched with one another. Two findings were considered a match if their spans overlapped and they had the same class. We defined a true positive (TP) as a correctly identified mention, a false positive (FP) as a spuriously flagged mention, and a false negative (FN) as a missed mention. We evaluated fcFinder’s performance overall and within each class using F1-score (Eq. 1), recall (Eq. 2), and precision (Eq. 3).

\[
\text{(Eq. 1) } F1 = \frac{2TP}{2TP + FP + FN} \quad \text{(Eq. 2) } \text{Precision} = \frac{TP}{TP + FP} \quad \text{(Eq. 3) } \text{Recall} = \frac{TP}{TP + FN}
\]

Report Classification

Using the mention-level annotations created by fcFinder, we classified a report as either fluid collection-present or fluid collection-not present using a python module called fcClassifier. If a report contained at least one positive mention-level annotation, the report was labeled as fluid collection-present. If it contained only negative or indication findings, or no findings at all, then it was labeled as fluid collection-not present. Additionally, we assessed fcClassifier’s performance using three configurations: 1) without context; 2) without anatomy; and 3) with all modifiers. First, we implemented fcClassifier without context using only the targets without any linguistic (negation, historicity, indication) or semantic (anatomy) modifiers. This could essentially be considered a keyword search. We then tested fcClassifier using linguistic modifiers, but no semantic modifiers. This allowed us to evaluate the importance of excluding negated mentions of fluid collection and of requiring the use of anatomic location in order to accurately classify reports. Finally, we tested fcClassifier using both linguistic and semantic modifiers.

Baselines

We generated two baseline approaches for classifying each report comparison against fcClassifier: 1) ICD-9 codes and 2) n-grams. First, we developed a simple ICD-9 classifier that predicts fluid collection-present for each report from a patient encounter encoded with ICD-9 code 998.53. For any report from a patient without this ICD-9 code, it predicts fluid collection-not present. We then experimented with several machine learning models utilizing n-grams (1-4 window word features) from the development set, excluding words occurring in an English stopwords list and word features occurring less than twice. To reduce the likelihood of overfitting, we applied the following feature selection strategy. We determined an upper bound threshold of n features to consider approximated using the square root of total training reports as 25 features. We ranked the informativeness of these 25 features by p-value using Chi-square with 5-fold cross-validation. We evaluated each classifier’s performance at intervals of 5 features (5, 10, 15, 20, 25 features) and selected the highest performing classifier according to F1-score with the fewest number of features. We experimented using several machine learning classification models, including a naive bayes, random forest classifier, and linear support vector machine (SVM). For this study, we applied the most predictive classifier,
the linear SVM, leveraging the 15 highest-ranked word features to the test set. In Table 2, we compared these n-gram features to fcFinder’s knowledge base and determined some terms are shared with our rule-based approach, giving us confidence this could be a reasonable baseline approach.

Table 2. 15 top-ranked features for n-gram classifier. **Bolded**=shared terms with fcFinder’s knowledge base.

| Collection, fluid, fluid collection, hematoma, cm, drain, collections, drainage, fluid collections, subcapsular, pigtail, catheter, rim, noted, extravasation |

**Evaluation**

We compared the performance of each baseline approach as well as fcClassifier and its various configurations against the testing set reference standard using accuracy (Eq. 4), F1-score, recall, and precision. We defined true positives (TP) as correctly classified reports as fluid collection-present and true negatives (TN) as correctly classified reports as fluid collection-not present. Specifically, we aimed to determine how well each approach could predict a report as fluid collection-present or fluid collection-not present in the test set. We assessed whether the differences in performance between the fcClassifier using all modifiers and all other approaches were statistically different using McNemar’s test.

(Eq. 4) \[ \text{Accuracy} = \frac{TP + TN}{\text{All reports}} \]

**Results**

**Annotation Study**

We calculated the inter-annotator agreement between annotators over 4 batches. There were a total of 249 mention-level annotations in the test set (Table 3). The most prevalent mention-level annotations were positive evidence of fluid collection (57%; 142 of 249 annotations) followed by indication for exam (32%; 80 of 240 annotations). The most prevalent report-level classifications were fluid collection-not present (69%). F1-scores were high and consistent for mention-level classes ranging from 0.88 to 0.89 and near excellent for report-level classification (0.96).

Table 3. Inter-annotator Agreement in Test Set using F1-score (surrogate for Cohen’s Kappa).

**Mention Detection**

We evaluated fcFinder’s ability to identify and classify mentions of fluid collection from a reference standard using F1-score, recall, and precision (Table 4). Results were comparable between the development and test datasets (not shown). The algorithm performed with high F1-scores ranging from 0.87 to 0.90 for each category. Recall and precision was comparable (+/-2 points) for overall and for evidence of fluid collection. Recall was notably lower (-18 points) than precision for indication for exam. In contrast, recall was higher (+9 points) than precision for negated evidence of fluid collection.

**Table 4.** Mention-level comparison of fcFinder against the reference standard in the test test. **Bolded**=highest score for each metric.

</table>

**Report Classification**

The prevalence of fluid collections in the development set (fluid collection-present: 42% and not present: 58%) was slightly skewed to positive cases compared to the test set (fluid collection-present: 31% and not present: 69%). We evaluated fcClassifier's ability to classify reports containing positive mentions of fluid collection compared to two baseline approaches: ICD-9 codes and n-grams (Table 4). ICD-9 codes achieved moderate performance (F1: 0.48; recall: 0.45). The use of targets without context for report classification resulted in improvement in classification (F1: 0.66; recall: 1.0). However, this improvement in recall results in a reduction of precision (0.49). fcClassifier without anatomic references improves precision (0.64) without sacrificing recall (1.0). fcClassifier with anatomic references performs with the highest F1 (0.88) and precision (0.82) with high recall (0.93). A comparison of each baseline to fcClassifier using McNemar’s test suggests this improvement is not by chance alone.

Discussion

We developed an NLP algorithm called fcFinder to automatically detect fluid collections from radiology reports. Our system utilized lexical and semantic features to determine the context of mentions of fluid collections. Based on the mention-level findings, we then classified reports as either fluid collection-present or not present. Our system performed well at both the mention and report levels, outperforming all compared methods.

Error Analysis

We examined instances where incorrect mention level-annotations caused misclassification of reports. Most instances of misclassification were caused by terms that were missing in our lexicon. The errors made by the system can be grouped into the following categories:

- **False positive target**: Our lexicon included the literal “collectin”, which was meant to match misspellings of “collection”, but also matched “fluid collecting”, which is not equivalent to a fluid collection. This resulted in an incorrect positive evidence of fluid collection annotation, which caused the document to be incorrectly classified as fluid collection-present.

- **Missing anatomic location modifier**: We did not have the literal “postoperative site” in our lexicon, resulting in a false classification of fluid collection-not present. We also deliberately excluded the literal “subcutaneous” as an anatomic modifier, due to its lack of specificity, but it was once used by the annotators, leading to another false negative classification.

- **Missing pseudoliteral**: Our lexicon included a number of “pseudoliteral” terms that would explicitly exclude phrases that could lead to false positives, such as “collection of gas” or “subpleural collection”. One report was incorrectly classified because “collection of intraluminal gas” was not included in our lexicon of pseudoliterals. A similar error was caused by the phrase “pockets of gas”.

- **Abbreviation**: A number of mistakes were made due to clinicians' use of a question mark, “?”, as an abbreviation for indication for exam. This was not included in our lexicon and several phrases such as “?absecess” were not annotated as indication for exam. This is an example of one of the biggest challenges facing clinical NLP, which is the informal and inconsistent nature of clinical text.

- **Reference standard problem**: A small number of mismatches were due to mistakes made by the annotators in the reference standard.

Key Findings

**Contextual Features**

Overall, fcFinder performed well with each mention-level class: positive evidence (F1: 0.91), negated evidence (F1: 0.91), and indication for exam (F1: 0.87). This allowed fcClassifier to achieve high results with report classification (accuracy: 0.95; F1: 0.88). fcClassifier's performance demonstrates the importance of linguistic and semantic context. ICD-9 codes, which provide information at a patient level and do not consider any information that is contained within a report, performed much worse at report classification (F1: 0.48). Searching for target concepts without taking into account any context resulted in a perfect recall (1.0), but a very low precision (0.49). When utilizing linguistic and semantic context, fcClassifier maintained a high recall (0.93) while achieving a much higher precision (0.82). This high precision could enable a more accurate selection of reports for review, greatly reducing the amount of work needed to evaluate and detect surgical site infections. This demonstrates the value of including contextual features when extracting information from clinical reports.
Anatomic Location Modifiers

Our intention was to identify only reports that contained fluid collections in the site of recent gastrointestinal surgeries. To do this, we developed a knowledge base of 128 anatomic location modifiers. The use of these modifiers enabled us to exclude reports that contained mentions of other collections, such as pleural or sternal collections, but no gastrointestinal fluid collections. The importance of anatomical designation is shown by the decrease in overall classification performance (~9 points) when anatomic modifiers were excluded from the criteria for mention-level findings. The significant increase in both recall and precision using anatomic modifiers is a valuable contribution towards the effective and efficient identification of surgical site infections. This knowledge base should be expanded to other anatomic regions if utilized in other settings.

N-gram Classifier

The best-performing baseline model was the n-gram SVM classifier (F1: 0.76). Despite not using any contextual features, this model achieved fairly high accuracy (0.86) and precision (0.81), and reasonable F1 (0.76) and recall (0.71). While the SVM's precision was comparable to fcClassifier's (0.81 vs. 0.82), its recall was much lower (0.71 vs. 0.93). Given the top 15 word features used by the n-gram model, we can conclude that the model does not take into account any linguistic (negation, historicity) or semantic (anatomic locations) context. However, the presence of procedural terms (“drainage”, “catheter”, “drain”) suggests the model includes situational context from the narrative, namely the treatment of fluid collection, which might be equally useful for asserting the presence of fluid collection. Future work could combine situational with linguistic and semantic context. Additionally, a system that utilizes structured data, such as ICD-9 codes, in combination with NLP could achieve even better results than those we report here.

Value of Rule-based Methods

This study demonstrates the potential of rule-based NLP to offer a semantically rich and detailed narrative of patient care. Techniques such as administrative data and machine learning offer very little detail beyond binary classification of a report. Rule-based NLP methods, such as those utilized by fcFinder, can extract much more detailed information. Here we showed the value of leveraging both linguistic and anatomic location modifiers to restrict SSI findings to a particular anatomic region. Similar methods can also model the administration and effectiveness of treatment in conjunction with the change of severity and course of a disease over time, without requiring much extra effort in developing new models to address each new question. This can offer a much more detailed and specific review of patient care, and can also enable a generalized approach to evaluating quality of treatment.

Comparison to Other Works

By conventional standards, our system achieved acceptable results. No other study has specifically aimed to extract mentions of fluid collection as evidence of SSI, but previously studies have successfully extracted other evidence of SSIs. Melton et al.’s algorithm, which utilized MedLEE, achieved a detected postoperative wound infection with a precision of 0.34. The algorithm implemented by FitzHenry et al. to detect wound infection achieved a recall of 0.63 and specificity of 0.77. Murff et al. report a recall of 0.89 and specificity of 0.94 in the detection of sepsis. We achieved a recall of 0.92 and precision of 0.90 in the detection of positive mentions of fluid collection. Our algorithm introduces the novel technique of connecting targets with anatomic location modifiers. This technique contributed to our overall performance and was a unique method of using NLP to detect a surgical AE. While some studies have evaluated the extraction of anatomic site of a condition, to our knowledge, no studies have done so in connection to surgical site infections or other surgical adverse events.

Limitations and Future Work

There are several limitations to our study. We used reports from the MIMIC-III Critical Care Database. These reports were written for surgical patients in intensive care. Because of the severity the patient’s condition, the prevalence of surgical site infections is higher than what we would expect to see in the general population. Reports
were then more likely to contain mentions of our targets, fluid collection. This may not directly generalize to the general population, where we would expect the prevalence of surgical site infection to be ~8-10% of patients. In this testing sample, 31% of notes were found to have fluid collections-present. However, the MIMIC-III dataset is openly available and the work that we have done with it can be reproduced and compared against. Furthermore, in the future, we will apply these methods to a more general population which could more broadly validate the results of this study.

Another limitation is the focused scope of this project. We looked only at radiology reports, specifically including only CT reports because of their relatively consistent structure and content. We focused on one specific anatomic region, and our targets included a relatively small lexicon of a single clinical concept, fluid collection, as evidence of surgical site infection. The CDC lists three additional criteria for defining an organ/space surgical site infection: purulent drainage from a drain, organisms found in a culture, and diagnosis of a surgical site infection by a surgeon or attending physician18.

Despite the relatively narrow focus of this project, it has proven the utility of a number of system features that can be applied in future studies and future implementations of SSI-Detect. In particular, this study has shown how a knowledge base of anatomic modifiers combined with NLP contextual tools results in a much higher precision and much richer semantic detail. This study is the first step in a larger framework of applying NLP methods to identify surgical adverse events. Future work should focus on expanding the knowledge base which we developed for this study, improving the performance of our system on non-enriched text, conducting a data analysis across various report types to test the generalizability of our methods, and expanding these methods to address other anatomic regions and clinical problems.

Conclusions

The automated detection of adverse surgical event has the potential to revolutionize how providers and hospitals detect and report quality measures. Currently, these efforts rely on manual chart review which limit the scalability and generalizability of quality measurement activities. In addition, leveraging automated detection into clinical decision support services may lead to better surveillance and the potential to improve patient care. We executed automated detection of evidence of intra-abdominal surgical site infections using a rule-based NLP system that achieved accuracy similar to manual chart review. In addition, this system outperformed other approaches using administrative data or SVM machine learning techniques. Future work in this field will seek to broaden our NLP approach and leverage addition types of structured and unstructured healthcare data to the detection of postoperative adverse events.

Abstract

Opioid analgesics, as commonly prescribed medications used for relieving pain in patients, are especially prevalent in US these years. However, an increasing amount of opioid misuse and abuse have caused lots of consequences. Researchers and clinicians have attempted to discover the factors leading to opioid long-term use, dependence, and abuse, but only limited incidents are understood from previous works. Motivated by recent successes of deep learning and the abundant amount of electronic health records, we apply state-of-the-art deep and recurrent neural network models on a dataset of more than one hundred thousand opioid users. Our models are shown to achieve robust and superior results on classifying opioid users, and are able to extract key factors for different opioid user groups. This work is also a good demonstration on adopting novel deep learning methods for real-world health care problems.

1 Introduction

Opioid analgesics are effective, commonly prescribed medications used for management of both acute and chronic pain in patients with many different medical conditions and following many medical procedures\(^1,2\). Prescription of opioids in the United States is high, and between 2011 and 2012, nearly 7% of the adult population was estimated to have taken an opioid in the last thirty days\(^3,4\). However, as reported in several previous studies, these medications do not effectively control pain in all patients\(^5,6,7\), and many patients are at high risk of adverse effects due to these medications\(^7,8\). A meta-analysis of randomized trials found that 80% of patients treated with opioids for chronic, non-cancer pain experienced at least one adverse event, with symptoms ranging from mild nausea to life-threatening respiratory depression\(^8\). In addition, the US is experiencing an opioid epidemic. Specifically, opioids are increasingly misused and diverted from their intended recipients, and abuse and overdoses have risen alarmingly in the last ten years\(^9\). The rate for drug overdose deaths, driven largely by opioid overdose, increased approximately 140% from 2000 to 2014\(^10\). In 2017, one of the largest pharmaceutical distributors in US was fined a record $150 million for failing to report suspicious orders linked to the opioid addiction epidemic\(^11\). Indeed, prompt and proper actions need to be taken to achieve a balanced opioid usage strategies, stem the tide of this public health epidemic, and prevent further devastating consequences.

The factors that contribute to opioid use – particularly the patient factors that contribute to long-term, chronic use of these medications and/or dependence or abuse of these drugs are poorly understood. Previous work found significant increases in incident opioid prescriptions for chronic, non-malignant pain between 1997 and 2005 in the Kaiser Permanente and Group Health populations\(^12\). Additionally, the proportion of the population receiving long-term therapy nearly doubled in the same time frame. The most common indications for long-term use in this study were chronic back pain, extremity pain, and osteoarthritis. Apart from these data, however, little is known about who receives opioid analgesic prescriptions in an average community. Additionally, with the exception of a few studies exploring the role of mental illness, depression, or previous patterns of substance abuse\(^13,14,15\), patient characteristics that might contribute to these adverse outcomes have not been described.

The rapid growth in electronic health record (EHR) adoption provides a wealth of patient information that could help identify patients at high risk of long-term opioid use or dependence. If one predictive or classifying model can leverage such data for analysing opioid usage and/or dependence, that is, the model has the ability to identify patients likely to benefit from or get addicted to these medications and target therapy more appropriately to them, we can expect those models to be able to extract the knowledge of the clinical characteristics associated with the progression of a short-term to an episodic or long-term opioid prescribing pattern and aid in the identification of at-risk patients and provide the basis for developing targeted clinical interventions. In the era of data explosion, however, more powerful data-driven learning models are in urgent demand in order to fully utilize the large amount of EHR data, identify meaningful features for opioid dependence or abuse, provide precise information for clinicians to make early decisions, and ultimately contribute to better personalized health care quality.
In this paper, we utilized state-of-the-art deep learning models on a much larger data set for opioid usage prediction and factor investigation tasks. Deep learning models have brought lots of significant successes including but not limited to recognizing and distinguishing thousands of human faces at a time\textsuperscript{16,17}, understanding, translating, and generating human languages\textsuperscript{18,19}, and mastering games and beating top human professional players\textsuperscript{20}. Deep learning is also revolutionizing the health care domain with the focuses on a variety of important and challenging tasks, such as computational phenotyping\textsuperscript{21,22}, predictive modeling\textsuperscript{23,24} and medical imaging analyzing\textsuperscript{25,26}. It is well known that deep learning solutions equipped with ample computational resources and large-scale datasets are able to go far beyond traditional statistical methods and shed light on intriguing real-world applications in health care. In this paper, we demonstrated our proposed deep learning solutions for identifying opioid user groups and showed that they provided superior classification results and outperformed other widely used learning baseline methods. We validated important factors and risk factors identified by deep learning models with previous clinical studies. Our work also provided a practical example on properly adopting novel deep learning methods for real-world health care problems leveraging large-scale EHR data.

2 Data and Task Descriptions

In this work, we took a cohort of 142,377 patients from the Rochester Epidemiology Project (REP)\textsuperscript{27}. The total number of people identified by REP, as shown in previous work\textsuperscript{28}, cover about 98.7% of the population that reside in Olmsted County by the US Census. Thus, this large-scale dataset is well-representative for this population-based study and suitable for powerful and complex deep learning models.

Cohort Selection

First, all outpatient drug prescriptions were obtained from Mayo Clinic and the Olmsted Medical Center from January 1, 2003 through March 31, 2016 for patients who authorized the use of their medical records for research purposes. The drug prescriptions were standardized using the 2016 version of RxNorm\textsuperscript{29}. We kept the records for all patients who received at least one opioid analgesic prescription between July 1, 2013 and March 31, 2016 and did not have any opioid prescriptions 6 months prior to their first prescriptions within the study period. The analgesic prescriptions were determined by the RxNorm Code, with either National Drug File Reference Terminology (NDF-RT) code C8834 (Opioid Analgesics) or ingredient code 10689 (Tramadol) and 352362 (Acetaminophen/Tramadol). In order to remove incorrectly duplicated and modified prescription records, only the last prescription would be kept if same drug prescriptions were made for one patient within 30 minutes. A cohort of $N = 102,166$ patients was created after these data cleaning and selection steps.

Group Identification

All patients were classified into three groups, namely \textit{short-term} users (ST), \textit{long-term} users (LT), and \textit{opioid-dependent} users (OD). ST and LT groups were defined by the CONSORT study\textsuperscript{30} and the same as in our previous work\textsuperscript{31}. Episodes of opioid prescription lasting longer than 90 days and with 120 or more total days supply or 10 or more prescriptions were classified as long-term ($N_{LT} = 21,570$), while others were classified as short-term ($N_{ST} = 80,596$). $N_{OD} = 749$ opioid-dependent patients were further identified by the diagnosis of “opioid dependence” from their problem lists. It is noting that the relatively low identification rate might be due to the fact that only part of dependent patients got explicit diagnosis in the problem lists by doctors. All identified dependent users were validated by clinicians. Table 1 shows detailed data characteristics of each patient group, which also match the finding in our previous related study on a smaller dataset\textsuperscript{31}. Two classification tasks were considered in our experiments: 1) whether the patient will become a long-term opioid user or just a short-term opioid user (Task \textit{ST-LT}), and 2) whether a long-term opioid user is an opioid-dependent patient or not (Task \textit{LT-OD}).

3 Methodology

In this section, we first describe our feature extraction and temporal data processing steps. Next, two deep learning models deployed in our study are presented: A deep feed-forward neural network model with multiple hidden layers, and a recurrent neural network model with Long Short-Term Memory which can better model time series data. Several ways used to improve the model performance and obtain important features are discussed, followed by the descriptions of some machine learning baselines. In the following part, we use bold capital letter (e.g., $W$) to refer to matrix variable, bold lowercase letter (e.g., $b$) for vector variable, and unbold letter (e.g., $l$, $D$) for scalar, if not specified.
Table 1: Data characteristics of different patient groups.

Feature Extraction We retrieved structured EHR data of the chosen patients from REP historic sources, Olmsted Medical Clinic and Hospital, Mayo and Mayo Clinic Health System between January 1, 2003 and March 31, 2016. We extracted code records with time stamps and other information from three chart tables: diagnoses (DX), procedures (PR), and prescriptions (RX). The details are shown in Table 2. Instead of taking raw records in these tables, we mapped all the codes to a higher level code space, for the following two reasons: First, coding systems used in Mayo were different and often change from time to time. For example, three different coding systems, ICD-9, ICD-10, and HICDA (Hospital International Classification of Diseases Adapted) were used for disease records in DX table. HICDA codes were used only before 2011, ICD-10 codes have not been in use until the year of 2015. This prevented us from taking one single raw code system and thus a consistent mapping of these conceptually-overlaid codes was required. Second, since there were tens of thousands of different raw codes in each table, the raw data tables were quite sparse and difficult to be examined in the feature level. Therefore, we mapped all DX and PR codes into categories in Clinical Classifications Software (CCS) and all RX codes into NDF-RT class. In PR table, we also recorded the corresponding quantity together alone with the code.

† Notice all patients included in OD group were also included in LT group.
† FOT refers to the time of the first opioid prescription for each patient.

Temporal Data Processing  We applied 1-of-K (one-hot) encoding\(^35\) on the extracted features and used either the temporal sum-pooling or segmentations of the encoded features to get numerical features from sparse categorical features simply yet effectively. The 1-of-K encoding converts each record line to a single binary vector of the same length, and temporal sum-pooling and segmentation step (i.e., sum-pooling in each temporal segment) further aggregates features along the temporal direction. For RX table, we used the length of days instead of 1 when applying 1-of-K encoding on prescription records to utilize the important quantitative effective length information for each prescription. For example, a prescription record with length of 4 days was converted into a vector like \([0,...,4,...,0]\). Our recurrent neural network models were able to handle time series data directly and capture temporal information. We computed the sum-pooling vector\(^36\) in each year and stacked them into a matrix, which we referred as yearly temporal segmentations. Since the medical records for patients might be of different length, the resulted matrices also had different length \(T_{\text{seg}}\), thus these matrices could not be directly used in other models including non-recurrent deep networks and other machine learning baselines. For those model we chose the sum-pooling along all time steps and thus obtained a vector with fixed length. The length was the sum of the numbers of all mapped features from three tables \((D = D_{DX} + D_{PR} + D_{RX} = 836)\) in our dataset. The prediction models took the obtained data as the input and provided predictive results. The entire pipeline is illustrated in Figure 1.

Figure 1: An illustration of the proposed pipeline from raw cohort data to final prediction. Left: DNN prediction model for data with temporal sum-pooling; Right: RNN prediction model for data with temporal segmentation.
Deep Feed-Forward Neural Network (DNN) Model A deep feed-forward neural network model (DNN) is composed with multiple non-linear transformation layers. The output of each layer is fed to the next layer as input. For a DNN model with $L$ layers (i.e., $L - 1$ hidden layers and one final output layer), the input vector for the $l$th layer is denoted as $x^{[l]} \in \mathbb{R}^{D^{[l]}}$, and rectified linear unit (ReLU) function is used as the non-linear transformation function for each hidden layer. The output of layer $l$ is

$$h^{[l]} = ReLU(W^{[l]}x^{[l]} + b^{[l]}),$$

which is also the input to the next layer $x^{[l+1]}$. Here $W^{[l]}$ and $b^{[l]}$ are parameters which can be learned via back-propagation during training. Notice that in our case we had input dimension $D^{[1]} = D$. We chose ReLU function because 1) it is shown to not suffer from gradient vanishing problem during training compared with other non-linear transformations such as sigmoid and tanh functions, and 2) our model investigation step requires it. To conduct binary classification tasks, we applied sigmoid function $\sigma(x) = \frac{1}{1+\exp(-x)}$ in the last layer and set the output dimension to be 1. In other words, we had $W^{[L]} \in \mathbb{R}^{L^{[L]} \times 1}$ and $h^{[L]} = \sigma(W^{[L]}x^{[L]} + b^{[L]}) \in [0, 1]$. With this proposed DNN model structure, we could learn the weights by optimizing binary cross-entropy loss function during training, which is

$$\ell_{loss} = -\sum_{n=1}^{N}(y_n \log h^{[L]} + (1 - y_n) \log(1 - h^{[L]})),$$

where $y_n$ is the binary label for $n$th patient. In ST-LT prediction task, $y_n = 1/0$ indicates long-term/short-term opioid user. In LT-OD prediction task, $y_n = 1$ and $y_n = 0$ are for opioid-dependent and other patients, respectively.

Recurrent Neural Network (RNN) Model In order to handle sequential or temporal data of arbitrary length and capture temporal information from the data, recurrent neural network (RNN) models are widely used. Unlike feed-forward neural network models, RNN models perform the same operation at each step of the time sequence and feed the output to the next time step as part of the input. Thus, RNN models are able to memorize what they have seen before and benefit from shared model weights (parameters) for all time steps. In order to capture complex long temporal dependency and avoid vanishing gradient problems, some modified RNN models such as Long Short-Term Memory (LSTM) and Gated Recurrent Unit (GRU) have been proposed with state-of-the-art performance. Assume the input is a matrix $X \in \mathbb{R}^{T \times D}$, where $T$ is the number of temporal segments and varies for different patients, and $D$ is the feature dimension. The $t$th row $x_t \in \mathbb{R}^{D^{[l]}}$ of the matrix represents the encoding vector at time step $t$. We used LSTM in our RNN prediction model. At each time step $t$, LSTM takes the input at that time step $x_t$ and output at previous time step $h_{t-1}$ to update its inner cell state $c_t$ and produce the current output $h_t$, as follows:

$$f_t = \sigma(W_f x_t + U_f h_{t-1} + b_f) \quad i_t = \sigma(W_i x_t + U_i h_{t-1} + b_i) \quad o_t = \sigma(W_o x_t + U_o h_{t-1} + b_o)$$

$$c_t = f_t \odot c_{t-1} + i_t \odot \tanh(W_c x_t + U_c h_{t-1} + b_c) \quad h_t = o_t \odot \tanh(c_t)$$

Here $W_f, U_f, b_f$ are all model parameters, $\sigma()$ is the sigmoid function, $\tanh()$ is the tangent function, and $\odot$ refers to element-wise multiplication between two vectors. We set the initial values of $h_0$ and $c_0$ to be 0. For binary classification tasks we applied another sigmoid layer of dimension 1 on top of the last output $h_T$, i.e., $h^{top} = \sigma(W h_T + b) \in [0, 1]$, and trained the RNN model by optimizing the binary cross-entropy loss on the training dataset.

Implementation and Training Techniques We implemented our deep learning models with Python Theano and Keras libraries and all the models were reproducible. For both DNN and RNN models, we set the dimension of each hidden layer to be 256, which was chosen to have proper size and good performance. Several training techniques were designed or used to better handle our data. First, we applied an L-1 regularizer with coefficient $1 \cdot e^{-4}$ to make the model robust and able to select important features. Our preliminary experiments showed that L-1 provided more compact models with better or similar performance as L-2 or no regularizers. Second, dropout technique with rate $p_{dr} = 0.5$ was used for all layers to reduce overfitting and avoid harmful weight co-adaptations. This was implemented by randomly dropping out units by probability of $p_{dr}$ in the neural networks at training time and re-scaling all the weights by $W_{test} = p_{dr} W_{train}$ at test time. Third, we applied novel batch normalization on all non-recurrent layers. The basic idea is to normalize the activations of the previous layer such that the outputs keep mean of 0 and standard deviation of 1 in each mini-batch during training. The running averages computed on training dataset are used to normalize the outputs at test time. This strategy speeded up training process and improved
Investigating Important Features Deep learning models are often argued to be difficult to interpret and investigate, especially because of their complex structures and thousands of or even millions of parameters. Furthermore, carelessly attempting to check and visualize individual units in neural networks might lead to misleading conclusions. However, by checking the overall model weights and structures, it is still possible to identify important features extracted from the deep learning models and obtain rough quantitative evaluations. We designed the feature importance score \( I \) for such purpose. We first take the weight matrix in the first layer \( W^{[1]} \in \mathbb{R}^{D \times D} \) of a DNN model as an example, where each column \( u^{[1]}_d \) of \( W^{[1]} \) corresponds to the \( d \)th input feature. A simple way to quantify the feature importance is to take the summation of each column. The first importance score of \( d \)th input feature is formally defined as \( I_1(d) = \sum_{i=1}^{D} W^{[1]}[i, d] \), where \( W[i, d] \) is the number in \( i \)th row and \( d \)th column of \( W \). However, we only consider the first layer in this score, which is definitely insufficient for a deep models. To overcome this issue, we need to take weights in higher layers into consideration. Since ReLU function was used as transformation function in all the hidden layers, we multiplied weights in all layers and took the value at the corresponding index as the importance score. We also need to take care of the impact of batch normalization since it introduces different scales on parameters, so we apply batch normalization operation before we multiply the weight matrix for each layer. Thus, the second importance score can be defined formally as

\[
I_2 = W^{[1]} BN^{[1]} \cdot W^{[2]} BN^{[2]} \cdot \ldots \cdot W^{[L]} BN^{[L]} (1) \in \mathbb{R}^{1 \times D}
\]

where \( BN^{[l]} \) denotes the batch normalization operation for layer \( l \). This process can also be viewed as a simplified version of the original deep neural networks without non-linear transformations or bias vectors. In our experiments, \( I_2 \) was used for our DNN models. In order to validate the way of investigating important features and verify the selected features, we checked previous clinical studies and compared with features from our baseline models.

Other Machine Learning Baselines In order to evaluate the proposed deep models and validate the findings, we also compared some commonly used machine learning baselines in clinical research, including Logistic regression (LR), linear support vector machine with hinge loss (SVM), and random forest (RF). All the baselines are implemented in Python Scikit-learn package. We kept most of the default settings and hyperparameters which are shown to be effective in practice, but made several specific changes to better fit our tasks. In order to distinguish important features we introduce sparsity into the model coefficients, we also used L-1 penalty in LR and SVM, tuned the regularization strength \( C \) by searching from \( 1 \cdot e^{-4} \) to 10 and finally chose \( C = 0.1 \) in our experiments since it usually provided best prediction results. In RF, using more trees usually leads to better results, but also possibly makes the model computationally inefficient and overfitted to training samples, and the model size also will grow linearly to the number of trees. Since using more trees brought negligible performance improvement but drastically increased the model size in our preliminary experiments, we took the default setting (10 trees) so that the RF model had moderate size as others. As shown in Table 3, all the tested models had comparable sizes and thus the performance comparison was fair.

4 Results and Discussions

Classification Result Comparison As mentioned before, we conducted two classification tasks (ST-LT and LT-OD). All 102,166 patients were included in the 5-fold cross validation for ST-LT task. Only 3.47% long-term users

Table 3: Model size comparison when saved into binary files in disk. All deep learning models are serialized and saved in HDF5 files, and other models are saved in cPickle files.
Table 4: Long-term opioid patient prediction (ST-LT) results (mean ± 95% conﬁdence interval). In Setting A, we take
all the medical records before the date when the patient is marked as long-term user or Mar, 31, 2016, whichever is
earlier; Setting B is the same as Setting A except that we exclude all the opioid and non-opioid analgesics prescriptions;
In Setting C we take records made before the patient’s ﬁrst opioid prescription. Best results shown in bold.

RNN

are opioid dependent and thus the labels are quite imbalanced for LT-OD task. To get robust prediction and features,
we randomly generated 14 datasets with class ratio of 13 by downsampling the non-opioid-dependent patients. Each
generated dataset had records from 2 237 patients. We further introduced three different settings (A, B, C) to test
model performances in different simulated situations. The deﬁnitions of the settings are described in the caption
of Table 4. Setting A was the ideal case and the best prediction results could be achieved in this setting since all
possible information was taken into consideration. After we found the analgesics usage can be good indicators for our
prediction tasks and might hide other indicators, we designed Setting B which might impair the prediction performance
but help us ﬁnd some hidden but useful features. Setting C was the most practical case among the three and we took
it to demonstrate the early prediction capacity of our methods. For all the settings and tasks, classiﬁcation accuracy
‡ DNN-khl

refers to DNN models with k hidden layers and one output layer, k ∈ {1, 2, 3}.

531


(Acc.), area under the receiver operating characteristic curve score (AUC), precision (Prec.), recall (Rec.), and Cohen’s kappa coefficient (κ) are reported. Results for ST-LT and LT-OD tasks are shown in Table 4 and Table 5, respectively. First, deep models provided the best performance in terms of most evaluation metrics. The improvements on LT-OD were larger than ST-LT. Second, the RNN models which captured temporal information usually but not always beat standard DNN models. It obtained the best AUC score in 5 out of 6 settings. This implies that even loosely segmented time series contains useful temporal information. However, the superiority of RNN was shown to be less on LT-OD than ST-LT, and one possible reason is the lack of training samples on LT-OD.

Feature Analysis It is useful to get to know which features are more related to opioid use, or played more important roles in the prediction models. We take the DNN-3hl models in Setting A and show the top ten most important features ordered by the absolute value of importance score $Z_2$ in Table 6. Basically, features with positive/negative score can be interpreted as positively/negatively correlated to the prediction target (long-term use in ST-LT, and opioid dependence in LT-OD). The score should only be compared within the same model and the same task. For both tasks, “Opioid Analgesics” prescription is selected as the most important indicators. “Non-opioid Analgesics” is also an important factor for long-term opioid use but not very useful to distinguish opioid-dependent user from long-term user. Several disorders diagnoses, such as “substance-related disorders”, “anxiety disorders”, and “other mental health disorders” (e.g., interview, evaluation, and consultation), are all highly related to opioid dependence. These findings are consistent with previous studies and most of the top features are also selected by LR and RF baselines. In addition, the scores for top features in LT-OD task are closer than those in ST-LT. This indicates that in Setting A identifying opioid-dependent users is a more challenging task which requires the exploit of more different features. The fact that all models had higher evaluation score on ST-LT than LT-OD in Setting A (Table 4 and 5) also supported the same claim. As we only did preliminary investigations, more details and validations will be discovered in the following work.

Table 6: Most Important features for long-term opioid patient (ST-LT, left) and opioid-dependent patient (LT-OD, right) identified from DNN-3hl model.

5 Summary

In this paper, we applied deep learning models for opioid user group predictions on a large-scale real-world EHR dataset. The deep learning models were able to achieve superior classification performance and identify useful feature indicators for opioid-dependent and long-term users. Our work demonstrated how novel deep learning models can be utilized to obtain state-of-the-art performance in practical clinical studies. In our future work, we plan to further investigate important features extracted from deep models, and incorporate numerical and unstructured EHR data along with code records into deep learning prediction models. We also plan to explore more fancy deep learning models to capture the temporal dependencies and evolutions for medical records of opioid users.

Automated Metabolic Phenotyping of Cytochrome Polymorphisms Using PubMed Abstract Mining

Luoxin Chen, MA1, Carol Friedman, PhD1, Joseph Finkelstein, MD, PhD1
1Department of Biomedical Informatics, Columbia University, New York, NY, US

Abstract

Pharmacogenetics-related publications, which are increasing rapidly, provide important new pharmacogenetics knowledge. Automated approaches to extract information of new alleles and to identify their impact on metabolic phenotypes from publications are urgently needed to facilitate personalized medicine and improve clinical outcomes. Cytochrome polymorphisms, responsible for a wide variation of drug pharmacodynamics, individual efficacy and adverse effects, have significant potential for optimizing drug therapy. A few studies have addressed specialized efforts to automatically extract cytochrome polymorphisms and their characterizations regarding metabolic phenotypes from the literature. In this paper, we present a novel rule-based text-mining system to extract metabolic phenotypes of polymorphisms from PubMed abstracts with a focus on cytochrome P450. This system is promising as it achieved a precision of 85.71% in a preliminary proof-of-concept evaluation and is expected to automatically provide up-to-date metabolic information for cytochrome polymorphisms, which is critical to advance personalized medicine and improve clinical care.

Introduction

An overwhelming majority of medications are characterized by xenobiotics that are foreign chemical substances not normally produced by or expected to be present within human organisms. Hepatic enzymes are responsible for the metabolism of xenobiotics by first activating them, followed by conjugation of the active secondary metabolite and subsequent excretion in bile or urine. The most important group of enzymes involved in xenobiotic metabolism is hepatic microsomal cytochrome P450 (CYP or P450) since the majority of drugs are the substrates for these enzymes. CYP forms a family of about 20 cytochrome enzymes that have been confirmed to participate in xenobiotic metabolism in humans. Among these enzymes, CYP2D6, CYP2C9, CYP2C19, CYP2B6, CYP3A4 and CYP1A2 play the most critical role since they account for more than 90% of drugs metabolized by CYP.

Recent studies demonstrated that CYP enzymes are highly polymorphic and that cytochrome polymorphisms are responsible for a wide variation of drug pharmacodynamics, individual efficacy and the occurrence of adverse effects. Specifically, single nucleotide polymorphisms (SNP) of genes encoding CYP enzymes result in a spectrum of metabolic phenotypes responsible for individual drug responses. CYP phenotypes are divided into the extensive (or normal) metabolizers (EM) that demonstrate regular metabolic activity and the poor metabolizers (PM) that are characterized by low metabolic activity. Additional phenotype categorization includes intermediate metabolizers (IM) that have metabolic activity ranging between PM and EM, and rapid metabolizers (RM) that demonstrate higher metabolic activity than the EM.

Broad availability of relatively inexpensive testing of cytochrome polymorphisms can facilitate use of pharmacogenetics in clinical practice. Multiple studies demonstrated a significant potential of pharmacogenetics in optimizing drug therapy, reducing adverse effects and improving clinical outcomes. For example, it was shown that people with CYP2D6 genes having a rapid metabolizer phenotype should avoid codeine use because of increased toxicity, which in some cases may have lethal consequences. Lack of effectiveness of codeine was demonstrated in poor metabolizers of CYP2D6 for whom codeine had to be replaced by other medications not metabolized by CYP2D6. As polymorphisms of CYP2C19 affects the antiplatelet agent clopidogrel, patients undergoing percutaneous coronary intervention who are known to be poor metabolizers of CYP2C19 are required to consider alternate antiplatelet therapy to avoid the risk of bleeding complications. Cytochrome polymorphism in older adults with polypharmacy was shown to be an independent risk factor of frequent hospital readmissions.

During recent decades, we witnessed an explosion of publications in the area of pharmacogenetics. Information on newly discovered alleles and their potential impact on drug metabolism is constantly expanding. The majority of published information is available in PubMed, however optimal extraction and summarization of this information still represents a significant challenge. With PubMed growing at a double-exponential rate, more than two citations are added each minute. Since 2000, there was nearly a 600% increase in pharmacogenetics-related publications. Automated approaches to extract information concerning new alleles and to identify their impact on
metabolic phenotypes are urgently needed to further advance evidence-based personalized medicine. Extraction of pharmacogenetic knowledge from PubMed and other sources has been discussed in the recent literature. Various tools, including text mining and natural language processing (NLP) for broad aggregation of information related to genetic polymorphisms have been described. For example, Rubin et al developed an automatic system to obtain PubMed abstracts containing some pharmacogenetics knowledge, including gene products, drug effects, genetic variants, and the relationships among them, while Garten et al established Pharmpresso, a text-mining tool used for extracting pharmacogenomic concepts from the literature and determining gene-drug interactions. However, limited attention has been given to development of a specialized tool for targeted extraction of cytochrome polymorphisms and their characterization along the metabolic phenotype continuum. Introduction of such a tool can significantly enhance pharmacogenomics-driven clinical decision support tools for personalized medication optimization, reduce adverse effects and improve patient care.

The goal of this project is (1) to develop a system for automated metabolic phenotyping of cytochrome polymorphisms based on currently available information in PubMed abstracts; and (2) to estimate its precision in a preliminary proof-of-concept assessment.

Materials and Methods

Materials
This study was conducted using articles from PubMed and a genetic polymorphism reference released by EBM Consult. The articles used in this study consisted of the titles and abstracts associated with the variants of five cytochromes (CYP2C9, CYP1A2, CYP2C19, CYP2D6 and CYP3A4), which was obtained using our corpus generator. The genetic polymorphism reference tables from EBM Consult, which contains verified information about metabolic functions of the five cytochrome polymorphisms, was employed as a gold standard to evaluate the efficacy of our system. The article set was divided into a training set and test set. The training set was used for development only, and contained articles relevant to CYP2C9, while the articles from the remaining four cytochromes constituted the test set, and was used for evaluation.

Method

Overview

An overview of our system is shown in Figure 1, and a more detailed explanation is provided below. The system consists of four components: 1) the corpus generator, which performs PubMed queries via the Entrez Programming Utilities (E-utilities) to obtain titles and abstracts of articles that potentially contain gene variants, 2) the gene variant extractor, which applies regular expressions to recognize and extract gene variants from the articles obtained by the corpus generator, 3) the signal word fetcher, which performs stemming on the words in the articles obtained by the corpus generator and matches the stemmed terms with a predefined dictionary to fetch a set of words that denote the metabolic phenotypes (i.e. rapid metabolizer, intermediate metabolizer, poor metabolizer and normal metabolizer), and 4) the scorer, which determines the closest gene variant-signal word pairs as evidence of normal or aberrant metabolic functions, and then specifies the type of metabolic function with the highest score as the predicted result.

Figure 1. Overview
Corpus Generator

The first component of this system is the corpus generator, which aims to obtain a relevant corpus of PubMed abstracts related to polymorphisms. A query was designed for each cytochrome to select related articles via the Application Program Interface (API) of National Library of Medicine, Entrez Programming Utilities \(^{19}\). Basically, to acquire relevant evidence for variants of a specific gene, articles discussing the specific gene are initially retrieved, where the articles are restricted using the criteria that they are written in English, concern humans, and are not review articles. Review articles are excluded for two reasons. First, review articles are not original articles but collections of information that were reported in other original articles. Hence, review articles would not provide any new information even if they were included. Moreover, using review articles would introduce bias in our study since the information in those articles would be counted twice.

Therefore, this query contains 5 features, consisting of the gene name, the MeSH tags English, human, the negation of the MeSH tag animal (to ensure that the article was mainly about humans), and the negation of the publication tag review. An example query for CYP2C9 is shown below:

\[
\text{CYP2C9 AND Human NOT Animal AND Eng[LA] NOT review[PT]}
\]

Once this type of query returns the PubMed identifiers (PMIDs) of relevant articles, the E-utilities library is then used to download the citations of those articles from the MEDLINE database.

However, the articles returned from the above query were published by a very broad set of journals, where some journals are less relevant to pharmacology or pharmacogenomics. To determine a list of the more relevant journals, we used E-utilities to search for the broad subject term Pharmacology or Genetics from the NLM Catalog \(^{20}\) and then filtered out articles published in journals that were not on this list. The simple query used to obtain this list from the Catalog was:

\[
\text{pharmacology[Broad Subject Term] OR genetics[Broad Subject Term]}
\]

Gene Variant Extractor

After obtaining articles relevant to this task, the gene variant extractor recognizes and extracts gene variant mentions from their abstracts and titles. The gene names and their variants follow specific conventions most of the time. For example, the cytochrome p-450 family genes are usually written as CYP+number+letter+number, and then use ‘*’ at the end of the name followed by an integer to indicate a variant. This convention enables the use of regular expressions to identify the gene variants. By reviewing articles and analyzing features in our training set, we developed a regular expression to specify gene variants of the CYP gene family, as follows:

\[
\W?(\text{CYP}).*(\d+[a-zA-z]\d+)\D?.*(\*\d+).\D?
\]

Although the regular expressions above could recognize valid gene variants in text, a practical problem arose when processing the text. For example, gene variants in articles could be written in an abbreviated way as “… CYP2C9*3 (I359L), *13 (L90P), *26 (T130R), *28 (Q214L), *30 (A477T) …” or “CYP2C9 *33 and *34”. Although the regular expression works for an individual variant, in these cases it could not recognize all the variants of the same gene because of the repetition of the different variants of the gene. In order to solve this problem, we noted that the gene name and variants form a tree structure in text, where the gene name is the parent and all variants are its children, as shown in Figure 2. Each child with its parent could constitute of the comprehensive name of a gene variant (see Figure 2 below).

![Figure 2. The tree structure of gene variant names](image-url)
Using this property, we designed two regular expressions to match the name of gene and indication of variant respectively, drew the tree structure for each gene by tracking the index of each matched gene name or variant, and acquired all the gene variants mentioned in the text from the tree structure alternatively.

The two regular expressions for this is shown below:

Gene name: \W?(CYP).*(\d+[a-zA-z]\d+).D?

Variants: (\*d+).D?

**Signal Word Fetcher**

The metabolic functions of gene variants are usually indicated through a limited set of special key words, such as *poor* or *rapid*, which indicate the metabolic phenotypes specified as signal words in the articles. A signal word fetcher was designed to obtain signal words based on a predefined dictionary of signal words, which was established using the training set in the following steps. First, a Porter stemmer was used to stem the words in text (abstracts and titles). After getting the stemmed text, the Complex Sentiment Analysis tool of TAPoR was applied on the stemmed text to analyze the frequency of words which could show positive indication or negative indication in a predefined vocabulary within the tool. The most frequent words in the predefined vocabulary were manually reviewed and selected as signal words, which were included in the dictionary. Specifically, those signal words were manually divided into four categories, in order to meet the general classification of metabolic functions, consisting of “normal”, “rapid”, “intermediate” and “poor”. Some signal words for each category are shown in the table below:

<table>
<thead>
<tr>
<th>Category</th>
<th>Some signal words</th>
</tr>
</thead>
<tbody>
<tr>
<td>Normal</td>
<td>wild, normal, extensive</td>
</tr>
<tr>
<td>Rapid</td>
<td>rapid, ultrarapid, increase, accelerate, induce, prompt</td>
</tr>
<tr>
<td>Intermediate</td>
<td>impair, inhibit, decrease, reduce, slow, inactive</td>
</tr>
<tr>
<td>Poor</td>
<td>poor, absent</td>
</tr>
</tbody>
</table>

Using the pre-defined dictionary that was established, the system uses the same Porter stemmer to preprocess the text in the test set and identify signal words by a string matching method.

**Scorer**

The last component, the scorer, uses the gene variants and signal words extracted by the gene variant extractor and signal word fetcher to predict the metabolic phenotypes for each variant. The criteria use the closest gene variant-signal word pairs in the text as evidence for scoring. Assume \( P_{t,j} \) is the score representing that gene variant \( i \) belongs to category \( j \), where \( j \) can be “normal”, “rapid”, “intermediate” and “poor” as mentioned above, where the scores could be computed using the formula below:

\[
P_{t,j} = \sum_{k \text{ is a signal word in category } j} \text{ number of pairs } (i, k)
\]

Once the scores are calculated, they are organized into a table with scores for specifying each variant to each category of metabolism, where the category with the highest score is chosen as the predicted result for each gene variant. For example, CYP2C19 *5, which had 0 points for “normal”, 3 points for “rapid”, 8 points for “intermediate” and 9 points for “poor”, was assigned to “poor” category because of the highest score. If there is a tie among some categories of a variant, all these categories are assigned to it as potential candidates. However, when evaluating the results, a gene variant with multiple categories is considered to be an incorrect prediction.

**Evaluation Design**

The evaluation test set for this task consisted of 4 cytochromes (CYP1A2, CYP2C19, CYP2D6 and CYP3A4), whose variants have been well studied and the types of metabolic functions have been established by EBM Consult.
For each cytochrome, we applied the system we developed to obtain relevant articles related to the cytochrome and to acquire the predicted metabolic functioning for all its variants. The predicted results were compared and evaluated using the reference released by EBM Consult. Note that the reference table is incomplete, and only the variants recorded in the reference table were used for evaluation. The precision of the predictions was calculated using the formula below:

\[
\text{Precision} = \frac{\text{number of correct predictions}}{\text{number of total predictions}}
\]

As stated in the Scorer subsection above, each tie involving multiple categories was counted as a false positive. Sensitivity was not directly computed or reported in the results section for several reasons, which are described in the discussion section. In addition, we did not consider variants which we obtained that were not in the reference table as false positives. The reasons are also explained below.

Results

The entire system was developed using the Anaconda of Python 2.7 version with useful packages/tools including regular expressions (“re”), Natural Language Toolkit (“NLTK”) and Complex Sentiment Analysis tool of TAPoR. In addition, the web API, E-utilities was used to obtain the articles for the corpus generator.

Table 2 shows the evaluation results for our system broken down by the 4 cytochromes. In total, 35 variants with verified information were recognized and predictions were generated by our system, where 30 of the 35 were correctly predicted. The total precision is 85.71%, which proved the efficacy of our algorithm. Note: the wild type (*1) is not counted here since it is always normal.

The 5 prediction errors are shown in detail in table 4. The predication errors were due to predicting “poor” metabolizers as “intermediate” metabolizers. The error analysis is further explained in the discussion.

Discussion

In this paper, an automated system for metabolic phenotyping of cytochrome polymorphisms using PubMed abstract mining has been introduced. Initial evaluation based on a current reference standard for clinical care showed promising results with a precision of 85.71%. The main strength of our approach is its specific focus on cytochrome polymorphisms and its association with particular metabolic phenotypes. As this information is crucial for implementing pharmacogenomics-driven clinical decision support (CDS) at point of care, automated tools which may constantly update an underlying CDS knowledge repository based on the most recent evidence have significant potential in promoting evidence-based precision medicine.

Our results conform to previous reports which demonstrated an ability to query the “bibliome” (compendium of biomedical textual resources) in order to answer questions about genes and their associations. Successful efforts in mining pharmacogenomics literature resulted in automatic recognition of various relevant named entities including genes, gene variants and corresponding proteins, associated diseases and pathological syndromes, medications and other factors pertinent to clinical care. “Bibliome” mining was shown to automatically convert massive volumes of unstructured knowledge into a structured actionable form supporting scientific discovery and clinical care. These approaches were used for interpretation of findings in genome-wide association studies as well as identification of candidate gene lists. Pharmpresso is an example of one of successful tools for text analysis aimed at extracting pharmacogenomic concepts from the literature and determining gene-drug interactions. Approaches for mining pharmacogenic literature are widely used to support the Pharmacogenomics Knowledgebase (PharmGKB) and work of the Clinical Pharmacogenetics Implementation Consortium (CPIC).

In recent years, a number of NLP systems have been developed to retrieve information from biomedical text, especially to extract biomedical information from the literature, demonstrating that NLP methods could efficiently generate information through abstracts mining. There has been very limited work regarding automated metabolic phenotyping of cytochrome polymorphisms using natural language processing. Rubin et al developed an automatic system to obtain PubMed abstracts containing some pharmacogenetics knowledge, including gene products, drug effects, genetic variants, and the relationships among them, by using the Porter Stemmer to preprocess the articles and then implementing supervised machine learning algorithms to classify the most relevant articles based on relevant pharmacogenetics terms; they achieved the best F1-score of 0.82. Yeniterzi et al implemented an algorithm based on regular expressions and supervised machine learning models to automatically identify the PubMed abstracts containing information on protein level mutations which have impact on a given enzyme, and achieved greater than 85% accuracy for all categories. Coulet et al, started from a preliminary pharmacogenic entities lexicon and implemented a drug-gene interactions extractor by detecting the syntactic structure of the relevant entities within the statements of PubMed abstracts. Based on Coulet’s work, Percha et al designed a supervised machine learning model to infer drug-drug interactions from the drug-gene interactions. Mallory et al used DeepDive, a supervised information extraction tool, to extract gene interactions from over 100 000 full-text articles.

While the studies above achieved desirable efficacy for text mining tasks, most of them used either large sets of references (e.g. lexicon for entities) or supervised machine learning methods to identify relations such as drug-gene interactions, or to classify the focus of articles based on a set of annotated data. Such methods are not applicable in our task. A significant challenge for our task is that, to the best of our knowledge, there is no annotated corpora for cytochrome polymorphisms and that reference standards to help validate results are usually incomplete. Hence, approaches using large external reference sets or supervised machine learning algorithms could not be used for our task. Therefore, we used rule-based NLP methods and scoring based on a development set, and the results based on
the text set showed that the metabolic phenotypes of cytochrome variants were successfully extracted. Although  
regular expressions are simple NLP methods, it is practical to study performance using simple methods before using  
more complex ones, especially if they require an annotated corpus that has not yet been generated. If machine  
learning methods are developed in the future, the simple regular expression method could be used as a baseline.  

There were 46 gene variants obtained by the system that were not in the reference table, as shown in Table 5. They  
were not considered as false positives because the reference table was incomplete. The reference table from EBM  
Consult was used for a clinical decision support application, and was established as being 100% correct to avoid  
errors in the system. Only gene variants whose metabolic functions had been generally accepted by physicians and  
researchers were included in the reference table, and consequently some variants whose metabolic phenotypes were  
not generally accepted or had not yet been discovered by those generating the reference might not be included in it.  
For example, CYP3A4*22 which was predicted as an “intermediate” metabolizer by our system was not included in  
the reference standard we used, but was listed as the same metabolic phenotype in the Human Cytochrome P450  
(CYP) Allele Nomenclature Database, which was not chosen as our reference standard because this database is  
maintained by an individual webmaster and the reliability of this database is unknown. In addition, for gene variants  
whose metabolic functions were not yet recorded in any reference set, they might have been discovered more  
recently by researchers, or they may not have been included because they still needed more evidence to confirm the  
functioning. Our system could point to potentially new reference material since it finds related articles and predicts a  
possible result which could be further studied and judged by experts upon manually reading and assessing the  
information that was generated by the system. Hence, gene variants obtained by our program but had no  
corresponding metabolic functioning in the reference table might also be correct and should not be treated as false  
positives.

</tbody>
</table>
Similarly, we did not compute sensitivity because some metabolic phenotypes recorded in the reference standard but not found by our system should not be considered as false negatives. First, the reference standard contained in-vitro or animal-related metabolic functions of some gene variants. Those were not determined by our system because we deliberately used articles discussing metabolic functions in humans and removed articles recording others, and therefore the in-vitro or animal articles should be excluded in the results. This was the major cause of missing the metabolic phenotypes of those variants. Additionally, some metabolic phenotypes in the reference were from review articles, or from articles published in journals considered not relevant, and those articles were excluded as we explained in the methods. Secondly, some articles did not mention the variants in the abstracts or titles, and we could not find them since PubMed citations only contain the titles and abstracts.

There were some errors in our system that did cause actual false negatives. Some were caused by articles (especially articles early stage) which mentioned the gene variants in irregular ways (i.e. used “dot+number” like “.7” to refer the variant, or directly used its abbreviation without mentioning its general name), and the regular expressions were not able to handle such cases. This could be improved by using more complicated regular expressions and introducing abbreviation vocabularies.

In total, our system missed 7 cytochrome polymorphisms, as shown in Table 6. If all of them were considered as false negatives, the sensitivity here would be 81.08%. However, five of them are in-vitro phenotypes and one was missing because there was no mention in the abstract. Those 6 variants should not be considered as false negatives as stated above. But for CYP3A4*7, the reasons for the error were more complicated. In total, there are 4 articles in PubMed discussing CYP3A4*7. Two of them were published in journals we excluded, and the remaining two used the term “CYP3A4.7” to name this variant. Thus, this variant should be counted as false negative. If we excluded the first 6 misses as false negatives, we would have 30 true positives and 1 false negative, and the sensitivity of our system would be 96.77%.

Table 6. All missing cytochrome variants and reasons

As shown in Tables 3 and 4, all the problems in our prediction were incorrectly predicting “poor” metabolizers as “intermediate” metabolizers. There are several reasons for these errors. In general, “intermediate” indicates a variant which will inhibit the metabolic activity, while “poor” indicates inhibition of a higher level of inhibition. Thus, if a variant is a poor metabolizer, it could also qualify as an intermediate metabolizer, especially when the degree is difficult to capture. Consequently, only explicit signal words, “poor” and “absent”, indicate poor metabolizers, while other negative signal words that are more numerous can indicate intermediate metabolizers, and thus were assigned to the “intermediate” category. However, those negative signal words for “intermediate” category might also occur around “poor” metabolizers in the text to indicate negative effects on the metabolic activity. In addition, explicit signal words for poor metabolizers occurred much less frequently than other negative signal words associated with intermediate metabolizers, affecting scoring. For example, “CYP2D6*9 is an allelic variant conferring reduced enzymatic activity...” is a sentence from a paper in our corpus 29, which has a relation between “CYP2D6*9” and
“reduce”. However, “CYP2D6*9” is a poor metabolizer but “reduce” is a signal word for intermediate metabolizers. Another source of error occurred when pairing the variant and signal word because we simply chose the closest pair since it demonstrated a relatively good performance during development. However, such a pairing strategy was inaccurate for some situations, especially when multiple variants were mentioned. For instance, in the sentence “The proportions of non-functional alleles were 0.4, 10.6, 0.8, 2.1, and 0% for CYP2D6*3, *4, *4 x N, *5, and *6, respectively. Genotypically, only one of the subjects (0.9%) was homozygous for two inactive alleles and phenotypically classified as a poor metabolizer (PM)” 30, “CYP2D6*5” was paired to “inactive” rather than “poor” because “inactive” was closer to “CYP2D6*5”. Another source of error occurred for some variants which were associated with less than five articles. For these, the metabolic functions were more difficult to predict accurately due to the lack of evidence.

Future work will involve addressing some of the errors discussed above. We intend to establish a more sophisticated and accurate classification system based on use of contextual information in the abstracts to distinguish poor metabolizer and intermediate ones. This should be the most significant future work direction regarding NLP. However, since there is no annotated corpus available at this time, we will generate one. Also, the simple closest pairing method will be improved. The problem concerning a lack of articles cannot easily be solved, but this lack-of-evidence problem is expected to be improved as more research and articles are published. However, even though our predictions for those variants that are infrequently published may not be accurate regarding functionality, they still contain useful clinical information, and can be shown with a lower confidence.

In addition to the prediction system, the evaluation method also needs improvement. In the current study, only precision was computed due to the lack of a comprehensive reference set and annotated data. In the future, more comprehensive evaluation of our algorithm will be carried out based on manual review of the resulting articles. With constantly growing body of pharmacogenomics literature and new alleles and phenotypic associations reported in PubMed, tools to support decision making at the point of care should have ability to account for new evidence. The algorithm presented in this paper could be applied to automatically extract the metabolic phenotypes for cytochrome variants and assist in updating the relevant knowledge. It can summarize existing evidence by providing an estimate of phenotypic impact of new and current alleles based on the current state of literature even for alleles which metabolic phenotype is not yet reflected in authoritative sources. In addition, this algorithm could be adapted to other gene variants by simply changing the regular expressions, and is expected to have equally desirable results as this study. Overall, automated metabolic phenotyping of cytochrome gene variants can assist physicians in personalizing drug therapy and avoiding adverse drug reactions resulting in better clinical outcomes.

Conclusion

This paper presents a system to obtain currently available PubMed abstracts of a given cytochrome, extract gene variants from the retrieved articles, and predict the metabolic phenotypes based on the information in the retrieved abstracts. The preliminary evaluation resulted in a proof-of-concept assessment and demonstrated the efficacy and accuracy of this system, which was 85.71%. Our initial results are very promising and have shown that it would be feasible to use this system for automated metabolic phenotyping of cytochrome polymorphisms from the continually growing information from PubMed abstracts.

Large-scale Analysis of Opioid Poisoning Related Hospital Visits in New York State

Xin Chen, MS, Yu Wang, BS, Xiaxia Yu PhD, Elinor Schoenfeld, PhD, Mary Saltz, MD, Joel Saltz, MD, Fusheng Wang, PhD
Stony Brook University, Stony Brook, NY

Abstract
Opioid related deaths are increasing dramatically in recent years, and opioid epidemic is worsening in the United States. Combating opioid epidemic becomes a high priority for both the U.S. government and local governments such as New York State. Analyzing patient level opioid related hospital visits provides a data driven approach to discover both spatial and temporal patterns and identity potential causes of opioid related deaths, which provides essential knowledge for governments on decision making. In this paper, we analyzed opioid poisoning related hospital visits using New York State SPARCS data, which provides diagnoses of patients in hospital visits. We identified all patients with primary diagnosis as opioid poisoning from 2010-2014 for our main studies, and from 2003-2014 for temporal trend studies. We performed demographical based studies, and summarized the historical trends of opioid poisoning. We used frequent item mining to find co-occurrences of diagnoses for possible causes of poisoning or effects from poisoning. We provided zip code level spatial analysis to detect local spatial clusters, and studied potential correlations between opioid poisoning and demographic and social-economic factors.

Introduction
The United States is experiencing an epidemic of opioid related deaths. Since 2000, the rate of deaths from drug overdoses has increased 137%, including a 200% increase in the rate of overdose deaths involving opioids\(^1\). Given these alarming trends, combating opioid epidemic becomes a high priority for both the US government and local governments such as New York State. For example, the U.S. Department of Health and Human Services (HHS) has implemented evidence-based approaches to reduce opioid overdoses and the prevalence of opioid use disorder\(^2\). The MOON (Maximizing OpiOid safety with Naloxone) study tries to find out more information about the public's perception of opioid safety, naloxone distribution, and the use of the pharmacy as an integral site for public health intervention\(^3\).

With increased accessibility of health data driven by open data initiatives, large-scale patient level data analysis provides an opportunity of data driven approach to identity patterns of opioid epidemic and discover potential causes of opioid related deaths through studying large scale diagnoses from hospital visits. This will provide quantitative measurements and essential knowledge to support the governments for decision making on prevention, treatment, recovery and enforcement. Analyzing opioid data at fine spatial resolutions such as zip code can also reveal community level distribution patterns in terms of demography, regions and historical trends, which will provide crucial knowledge for residents, schools, businesses and health and human service professionals for seeking solutions.

As part of New York State’s open data initiative, New York State Statewide Planning and Research Cooperative System (SPARCS)\(^6\) collects patient level details on patient characteristics, diagnoses and treatments, services, and charges for each inpatient stay and outpatient visit (emergency department, ambulatory surgery, and outpatient services). It also includes locations of patients (street addresses). Researchers can benefit from SPARCS data by leveraging patients’ diagnosis histories, co-occurrences of diagnoses (primary and secondary ones), and location. Such unprecedented amounts of patient records make it possible for us to explore opioid poisoning in New York State with significant improvement of accuracy and coverage compared to prior studies on opioid abuse at global level\(^4\) or urban level\(^5\).

In this paper, we provide large scale analysis of opioid poisoning based on SPARCS data. We extract all patient records with opioid poisoning related primary diagnosis codes from all visits (inpatients, outpatients, emergency and ambulatory surgeries) from year 2010-2014 for our main studies, and from year 2003-2014 for temporal trend studies. We aim at four types of studies: 1) demographical based studies to explore disparities between population groups; 2) historical trends of opioid poisoning; 3) co-occurrence based studies to discover possible causes of opioid poisoning or effects from opioid poisoning; and 4) spatial analysis (zip code level) to explore potential local spatial clusters, and potential correlations between opioid poisoning and demographic and social-economic factors.
Methods

Data Sources

SPARCS Data. In this work, we used hospital discharge data from New York State SPARCS\(^6\). Any New York State healthcare facility certified to provide inpatient services, ambulatory surgery services, emergency department services or outpatient services is required to submit data to SPARCS. The purpose of SPARCS was to create a statewide data set to contribute to the goal of providing high quality medical care by serving as an information source\(^7\).

Opioid Poisoning Hospital Visits. While the SPARCS data contains a comprehensive list of diagnosis and treatment procedure codes for each discharge record, this paper focused on analyzing patient level patterns of opioid poisoning hospital visits.

In SPARCS data, each hospital discharge record contains only one primary diagnosis code. Each record also contains one or more optional secondary diagnosis codes that include all conditions that coexisted at the time of admission, or developed subsequently, which affected the treatment received and/or length of stay\(^7\).

In this work, we generated a subset of the SPARCS data using selected the International Classification of Diseases 9 (ICD-9) codes (also called billing codes) that pertain to opioid poisoning diagnoses, for both inpatient stays and outpatient visits (including emergency department visits, ambulatory surgery, and outpatient visits). We extracted opioid poisoning hospital visits by filtering the discharge records with their primary diagnosis code as the selected opioid poisoning ICD-9 codes.

The selected ICD-9 codes were a collection of poisonings by opiates, opium, heroin, methadone, and other related narcotics, including 9650 (Poisoning; Opiates and Related Narcotics), 96500 (Poisoning; Opium/alkaloids, unspecified), 96501 (Poisoning; Heroin), 96502 (Poisoning; Methadone), 96509 (Poisoning; Other opiates and related narcotics), E8500 (Accidental Poisoning; Heroin), E8501 (Accidental Poisoning; Methadone), and E8502 (Accidental Poisoning; Other Opiates and Related Narcotics).

* 2010-2014 American Community Survey (ACS) 5-year estimates

Patients’ Residential ZIP Codes and Hospital Admission Years. We conducted analyses at ZIP code level with basic demographics for the year 2010-2014 given in Table 1. We approximated patients’ home location by combining the 5-digit ZIP code number with the patients’ home address and geographic data from TIGER/LINE data\(^8\). We then aggregated opioid poisoning hospital visits at ZIP code level (Figure 1) and generated opioid poisoning incidence rates for the following spatial and temporal analyses (Figure 4-5).

For temporal trend studies, we used the hospital admission year for the time range 2005-2014 for inpatient stays and 2003-2014 for emergency department visits (Figure 3).

Analysis Methods

Opioid Poisoning Incidence Rates
We counted opioid poisoning patients with at least one opioid poisoning hospital at ZIP code level as shown in Figure 1. The opioid poisoning incidence rates by ZIP code were calculated through dividing counts of patients with opioid poisoning hospital visits by ZIP level population counts from Census data. In this paper, we evaluated both statewide rate and rates at ZIP code level. The incidence rates provided useful information about how common a disease is when compared to other diseases, or how common a disease in a specific location is as compared to the global baseline.

**Frequent Co-Occurrence Patterns**

Disease co-occurrence, also known as comorbidity⁹⁻¹⁰ in public health studies, may imply the potential association across different types of diseases. The comorbidity is the presence of one or more additional diseases or disorders co-occurring with a primary disease or disorder¹⁸.

We explored frequent disease co-occurrence patterns to find the frequent disease diagnoses that co-exist with opioid poisoning diagnoses. We first ranked all the secondary diagnosis codes by their counts in all the opioid poisoning hospital visits (Table 2). We then use Apriori-like algorithm¹¹ to discover top co-occurrences of diseases for opioid poisoning diagnoses (Table 3).

Apriori Algorithm is a common data mining technique to identify co-occurrences or temporal patterns between diseases in clinical domain¹². This work tried to adopt Apriori algorithm to identify comorbidities among hospital visits. Apriori algorithm discovers frequent comorbidities by comparing their supports with a user-specified minimum support threshold.

For example, if the support of comorbidity pattern {96500 Poisoning by opium, 9670 Poisoning by barbiturates} (in Table 3) is 0.002, it means that 0.2% of all hospital visits have this comorbidity pattern. If the minimum support threshold is greater than 0.2%, this pattern will not be identified. However, if the minimum support threshold is set smaller than 0.2%, the comorbidity pattern will be extracted. In this work, we set the minimum support threshold as 0.1%.

**Spatial Clustering**

To test whether there is global spatial clustering tendency for opioid poisoning incidence rate or other spatial impact factors, we used Moran’s I (Tables 4)¹³. Moran’s I is a widely used global cluster test, which determines the degree of clustering or dispersion within a data set. The test result may range from 1 (perfect correlation), 0 (complete spatial randomness) to -1 (perfect dispersed). For the opioid poisoning incidence rate, a positive spatial autocorrelation means that the ZIP code areas with high rate are close to other areas with high rates.
In addition to the global cluster test (with Moran’s I index in Table 4) and visual analysis for mapping raw counts of opioid poisoning incidence (in Figure 1), we also took cluster and outlier analysis with Anselin Local Moran’s I statistics\textsuperscript{13} to quantitatively detect local clusters for opioid poisoning incidence rates (Figure 4). The Anselin Local Moran’s I statistics is a local cluster test that, given a set of weighted features, identifies statistically significant hot spots, cold spots, and spatial outliers.

*Spatial Regression*

To identify potential correlations between diseases and spatial impact indicators, we assessed both non-spatial and spatial correlation\textsuperscript{13}. Ordinary least square regression analyses (OLS) was used to determined non-spatial correlation between opioid poisoning and demographic/socio-economic factors. We then used Geographically Weighted Regression (GWR) to assess the spatially varying relationship at a local level.

OLS is a linear regression method that closely fits a function by minimizing the sum of squared errors. To determine potential candidate factors, we evaluated several possible factor combinations that form a properly specified OLS regression model. GWR is a local form of linear regression used to model spatially varying relationships. To evaluate the correlation between opioid poisoning and spatial impact factors accounting for data in surrounding areas, we then conducted GWR with a selected spatial impact factor based on OLS results. Specifically, a fixed kernel type function was used to calculate the GWR regression coefficients. The extent of the kernel is determined using the Akaike Information Criterion (AICc)\textsuperscript{14-15}.

*Results*

*Demographic-based Analysis*

Table 1 compared the demographics between New York State population and patients with opioid poisoning during 2010-2014. The overall opioid poisoning incidence rate in New York State was 12.33 per 10,000 persons per five years. The percentage of female in New York State were 51.5% compared with only 40.0% of female patients with opioid poisoning, suggesting that female was less likely to have opioid poisoning hospital visits.

![Figure 2. The age distribution of opioid poisoning in New York State, 2010-2014.](image)

Comparing different race and ethnicity groups, we can see significant disparities between racial-ethnic proportions in patient and general population. Whites made 72.2% of patients that was higher than the whites proportion in general
population. On the contrary, Asians had a very low percentage of patients that may require further investigation for the specific causes.

Figure 2 showed the age distribution of opioid poisoning in New York State, 2010-2014. We found a peak of opioid poisoning among young adults aged 21 to 25. Prior work has shown an increasing trend of adolescents and young adults with prescription drugs misuse. Our statistics on age for opioid poisoning hospital visits (Figure 2) was consistent with the prior national-wide survey.

Temporal Trends

Outpatient emergency departments (EDs) and inpatient stays play an important role in the treatment of drug poisoning. For the period of most recent year available 2010-2014, both opioid poisoning hospital EDs and inpatient stays continued to increase in the United States, as is true for New York State from our results. Statewide, there were 4,238 outpatient ED visits and 2,909 inpatient stays in 2014, a 116.4 percent increase and a 17.3 percent increase respectively from 2010.

Figure 3 showed temporal trends of the proportion of opioid poisoning hospital visits for the past decade. While we found a modest rising trend for inpatient stays, there was an increasingly rising trend for outpatient EDs. In prior studies, the rise in opioid consumption has also been associated with a sharp increase in emergency room visits for nonmedical opioid pain reliever (OPR) use. Such findings suggested potential misuse or abuse of the drugs as opiate overdoses may seek controlled substances during emergency department visits.

Frequent Co-Occurrence Patterns

We used frequent item mining to find co-occurrences of diagnoses for possible causes of poisoning or effects from poisoning. We used all ICD-9 diagnosis codes from opioid poisoning hospital discharge records. The diagnosis codes mark medical conditions, such as chronic ischemic heart disease, pure hypercholesterolemia, type 2 diabetes, and many other types of diseases.

Table 2 presented the top 20 diagnosis codes that co-existed with opioid poisoning diagnoses by their total counts in all opioid poisoning discharge records.

We found several diagnoses that were the well-established comorbidities of opioid dependence. For example, opioid use disorder is often associated with other substance use disorders, such as tobacco, alcohol and benzodiazepines, which are often taken to reduce symptoms of opioid withdrawal or craving for opioids, or to enhance the effects of administered opioids. Individuals with opioid use disorder are also at risk for the development of mild to moderate depression. Periods of depression are especially common during chronic intoxication or in association with physical or psychosocial stressors that are related to the opioid use disorder.
As we didn’t find any infection disease among the top co-existed diagnoses in Table 2, most of the opioid poisoning hospital visits may come from patients with prescription opioids. Usually, the most common medical conditions associated with opioid use disorder are viral (e.g., HIV, hepatitis C virus) and bacterial infections, particularly among users of opioids by injection. These infections are less common in opioid use disorder with prescription opioids.\textsuperscript{18}

The other co-existed diagnoses listed in Table 2 should be the effects from opioid poisoning, including acute respiratory failure, acute kidney failure, pneumonitis, hypopotassemia, and rhabdomyolysis.

</tbody>
</table>
Table 3 presented the top co-existed diagnoses for poisoning by different substance. Poisoning by heroin should be mainly caused by drug abuse as it generally co-existed with opioid abuse and resulted in a life-threatening cardiac arrest. Poisoning by opium more likely co-existed with poisoning by barbiturates or other sedative-hypnotic drugs. On the other hand, poisoning by methadone mainly co-existed with accidental poisoning by methadone. Such findings may require further research for the potential driving factors.

**Spatial Analysis**

In this section, we performed zip code level spatial analysis to detect local spatial clusters, and studied potential correlations between opioid poisoning and demographic and social-economic factors.

Figure 4 demonstrated the results of spatial clusters and outliers. The cluster/outlier type field distinguishes between a statistically significant cluster of high values (High-High cluster), cluster of low values (Low-Low cluster), outlier in which a high value is surrounded by low values (High-Low outlier), and outlier in which a low value is surrounded by high values (Low-High outlier). Statistical significance is set at the 95 percent confidence level. We applied the False Discovery Rate (FDR) correction to reduce this p-value threshold from 0.05 to a value that better reflects the 95 percent confidence level given multiple testing. The FDR procedure will potentially reduce the critical p-value to account for multiple testing and spatial dependency. 13
