This work addresses the problem of identifying assertion in EHRs. Assertion is an important attribute to any event in information extraction. In EHRs, assertion can be understood as a physician’s belief status with regards to a particular patient’s medical problem. Specifically, as shown in Table 1, a medical problem could be current or happened in the past. The problem could be present, absent, or hypothetical and conditional. Knowing the assertion status of a clinical event (e.g., bleeding) is important for physicians to make clinical decisions (e.g., prescribing anticoagulants). Therefore assertion identification of clinical events is critical for information extraction and data mining from EHRs. Assertion identification was also one of the 2010 i2b2/VA challenge task\textsuperscript{1}, which classified assertion as present, absent, possible, conditionally present, hypothetically present and not associated with patients. In our task, we classify the presence status of a clinical event conditioned on the current time period. We have the same six categories for presence assertion as the 2010 i2b2/VA challenge task, and we have extra four classes of period assertion for the same clinical event as current, history, future, and unknown to capture the temporal information about statements. To better describe the task and our model, we present an exemplary explanation in Table 1.

Table 1 shows the period and presence assertion categories and corresponding representative texts to the clinical event “fever” (an adverse drug event). Our goal is to develop natural language processing (NLP) approaches to automatically identify both the belief status of a clinical event and its period status. It is important to identify both types of assertions as the task represents a more accurate scheme for reasoning about the physician’s belief status of the patient’s medical problem. For example, to identify the assertion in the sentence “His fever caused by the drug is resolved”, one needs to consider the dependency between period and presence. In this particular scenario, “fever” is present if period is history. In contrast, “fever” is absent if period is current. Also as the presence and period assertions are related to each other or even conditionally dependent on each other, a joint learning model can be of advantage. We incorporate such relations in our model and propose a neural network based framework to jointly predict the two types assertions for a given medical entity.

Previous efforts for the assertion identification (or classification) task include rule-based and machine-learning-based methods. Rule-based approaches required hand-crafted rules, which limited their performance. Therefore, it is no surprise that in the 2010 i2b2/VA challenge task, eight of the top 10 participating systems employed machine-learning approaches (e.g., SVM-based classifier, sometimes employing millions of features). With the recent advance in deep learning, neural network models have shown in automatically capturing semantics and syntax as compared to traditional SVM based models, which require significant feature engineering. Additionally, neural network models also have the added advantage of capturing long-distance dependency in text.

In this study, we explored deep learning models. Specifically, we used recurrent neural network with gated recurrent unit (GRU) to represent a clinical event using the left and right context of the event in its sentence. For each generated hidden unit, residual neural network was used for better representation generation. After combining the entity and context representations with additional attention weights, the framework outputs two labels for presence and period assertion. In this architecture, the two tasks leveraged a common feature-set generated by the recurrent neural networks and then used different attention weights for each assertion task. We also used two extra parameters to add mutual influence for the final prediction of the two types of assertion. Experiments on an expert-annotated EHR narratives show the effectiveness of our deep learning model. We provide more details about our model in Section 3.

The main contributions of this paper include a novel neural network architecture that not only leverages recurrent residual network for assertion classification task, but also jointly predicts both the presence and period assertions in one framework. Our method obtains good results on both types of assertion classification tasks. The rest of the paper is organized as follows: we present the related work in Section 2 and introduce our proposed model in Section 3. In Section 4 we report the experiment results and our analysis. And we conclude the paper in Section 5.

Related Work

Medical Assertion Classification

Determination of the assertion status of clinical events is an important area of clinical NLP research. Previous efforts mainly include rule-based methods and machine learning approaches. Popular rule-based methods include the NegEx algorithm and ConText algorithm. The NegEx algorithm is a simple regular expressions algorithm to determine whether a medical entity is present or absent in a patient. The ConText algorithm extends the NegEx algorithm to detect four assertion categories: absent, hypothetical, historical, and not associated with the patient. Uzuner et al. studied the rule-based Extended NegEx system and a SVM-based Statistical Assertion Classifier (StAC) and showed that a machine learning approach achieved competitive results for assertion classification. Four assertion classes as present, absent, uncertain in the patient, or not associated with the patient were used in their system. Wu et al. conducted a multi-corpus analysis of negation detection and concluded that it was easy to optimize for a single corpus but not to generalize to arbitrary clinical text.

The 2010 i2b2/VA Challenge designed a specific assertion classification task. For each “problem” concept mentioned in a clinical text, systems were built to classify the concept’s status associated with the patients as “present”, “absent”, “possible in the patient”, “conditionally present”, and “hypothetically present”, or mentioned in the patient report but “associated with someone other than the patient” based on the context that describes it. The task as a multi-class categorization problem allows the use of machine learning classification methods. SVMs were still the common theme for the task. For some SVM models, millions of features were employed from lexical, syntactic to contextual level.
In addition to those text features, concept-mapping features derived from existing annotation tools like cTAKEs, MetaMap (UMLS) etc. are also used. The best system addressed the task in two stages: in stage 1, assertion class predictions were generated for every word that was part of a “problem” concept by using three parallel different SVM classifiers. In stage 2, a secondary classifier predicted a class for the complete concept, based on the separate per-word predictions from the ensemble of stage-1 classifiers, by using SVM-multi-class with a linear kernel. Later Kim et al. revised their participating system and added specific features to improve the performance on minority classes (e.g., the conditional class) and obtained better results.

Our task is more challenging than the 2010 i2b2/VA Challenge assertion task in that we not only classify the presence assertion, we also jointly classify the period assertion as being “Current”, “History”, “Future”, or “Unknown” in a joint model architecture.

Related Neural Networks

Our deep learning model is based on neural network models to learn feature representations for clinical events and their context for classification. Our model is related to learning representations for long text (sentence/paragraph/document), an important task which draws much efforts. Recurrent neural networks (RNN), and their variants are widely used. Closely related work to our model is the recurrent neural network with gated recurrent unit (GRU) and deep residual network.

RNN can be used effectively to learn distributed representations over a variable-length sequence. At each time-step, it takes both the output of the previous step and the current token as input, convolutes the inputs, and forwards it to the next step. A gated recurrent unit (GRU), a variant of RNN, was proposed by Cho et al. to make each recurrent unit to adaptively capture dependencies of different time scales. It has similar unit as the long-short term memory unit (LSTM) with two gating units named reset and update gates modulating the flow of information inside the unit. However, without having a separate memory cells as LSTM. GRU has been proved comparable results and faster training with less parameters than LSTM. Figure 1 provides an illustration of RNN and GRU.

The deep residual network has two significant characters compared with RNN. The first one is the residual learning. In a neural network model, normally the data is passed from one layer to the adjacent layer. In the residual network, an additional layer is used to connect layers that are far away. During the back propagation, errors can be passed from a higher layer to a lower layer directly. This character is of advantage as it may capture the long-distance context determining the assertion. The second character is the depth of such models. A typical residual network has hundreds of layers, which is much deeper than most existing models. Thus the training of such a model becomes a challenge. In addition, given the number of the layers, the number of parameters also exceeds most networks. When trained on a small dataset, a deep residual network may suffer from over-fitting. The residual neural network has been proved useful in capturing information from images for classification. A number of variants have been introduced for a series of tasks, we do not go in to the details due to the space limitation.

Attention mechanism is also adopted in our system. Attention mechanisms in neural networks are inspired by the presence of attention in human visual system. Human beings’ visual system is able to focus on the most salient part of an image and adjust the focal point over time. The concept of “attention” has gained popularity in training neural networks and have been applied to various computer vision and NLP tasks and we don’t enumerate here.
Figure 2: A Residual Learning Block. Compared with a traditional multi-layer perceptron, the change is that some layers that used to be non-adjacent are connected.

In the following Section, we will show how to employ the recurrent neural network with gated recurrent unit and residual network in the targeted task.

Methods

We address the assertion classification task as a supervised learning problem and build one framework to jointly predict both presence and period assertion labels. Given a sentence with an annotated clinical event, the model predicts both the presence tag and the period tag for the event. The presence tag is chosen from six categories and the period tag has four categories.

Given a clinical event and its sentence, our HNN model use three recurrent neural networks with gated recurrent unit (GRU) and residual networks to generate representations respectively for the clinical event, sentence tokens to the left of the clinical event entity, and the right. These representations are further passed to following layers conducting interactions and predicting the tags.

For better illustration, we provide Figure 3 and Figure 4 to show how the proposed HNN model works for the medical entity “fever” in the sentence “He has fever caused by the drug”. The sentence is splitted into three parts, the entity, its left neighbor and its right neighbor. We firstly have a representation for the entity “fever”, as this is a single word, RNN GRU is not needed to generate the representation, we can just use the embedding of “fever” instead. But for an entity with longer sequence, for example like “lung cancer” or any entity longer, an RNN model is needed for generating the representation. Two RNNs are also employed for “He has” and “caused by the drug” which are the left and right neighbors of the entity. The three representations we get from the three RNNs are fed to the following part of the network as shown in Equation 1. In Equation 1, R_{Block} stands for residual learning block. L stands for linear function.

\[
\begin{align*}
    h_{i_{tmp}} &= GRU(h_{i-1}, x_i) \\
    R_{Block}(h_{i_{tmp}}) &= \\
    &\text{Dropout}(L(Dropout(L(\text{tanh}(h_{i_{tmp}})))))) \\
    \text{repeat twice} \\
    \text{ResidualNet}(h_{i-1}, x_i) &= R_{Block}(h_{i_{tmp}}) \\
    \text{repeat 7 times} \\
    h_i &= \text{ResidualNet}(h_{i-1}, x_i)
\end{align*}
\]

Equation 1 and Figure 4 explain the residual recurrent neural networks with gated recurrent unit (GRU) we used in this work.

Their representations are then fed to the linear transformation node which outputs the final score. The linear function

---

1Please note that in this example sentence, “drug” is also a medical entity, but we just address the entity “fever” as an example here.
takes as input the final left representation $out_{L_i} = h_i^{final}$, final right representation $out_{R_j} = h_j^{final}$ and the final representation for the medical entity $out_{E_k} = h_k^{final}$, and outputs the comprehensive representation for this entity $R_e$ as in Equation 2.

$$R_e(out_{L_i}, out_{R_j}, out_{E_k}) = f(out_{L_i}W_0 + out_{R_j}W_1 + out_{E_k}W_2 + b)$$ (2)

Then we get to consider features that are specific to each sub-task. We assume that for each sub-task, the model should attend to different parts of the original sentence. In the mean time since the two sub-tasks are related as we have stated, the knowledge what sub-task A is attending to will help improve the performance of sub-task B, we formulate the representations of the two sub-tasks to interact with each other. Equation 3 defines the details.

**Step 1**

$$R_e^1 = f_1(R_e) + \sum_{i=1,n} att^1_i w_i; w_i \in S$$

$$R_e^2 = f_2(R_e) + \sum_{i=1,n} att^2_i w_i; w_i \in S$$ (3)

**Step 2**

$$R_e^1 = R_e^1 + \alpha R_e^2$$

$$R_e^2 = R_e^2 + \beta R_e^1$$

We use $S$ to represent the sentence which contains the entity. In Equation 3 $n$ is the number of its containing words. $w_i$ is the embedding of the $i^{th}$ word in $S$. We use $R_e$ to distribute attentions over the $n$ words in $S$. The weights are calculated using a softmax over the sum of all $w$ in $S$. $att^2 = Softmax(Linear^3([R_e \cdot \sum_{w_i \in S} w_i])$. Step2 defines our way to interact the two sub-tasks with weights $\alpha$ and $\beta$. $\alpha$ and $\beta$ are learned according to $\alpha = WR_e^2 + b; \beta = W'R_e^1 + b'$.

To boost performance, we add some basic features here including the entity position in the sentence, entity length, entity bag-of-words features, sentence length, number of nouns in the sentence, number of verbs in the sentence, the verb tense in the sentence, and part-of-speech tags of words in the sentence. They are concatenated with $R_e^1$ and $R_e^2$.

The score for each label was fed into the softmax classifier using $R_e^1$ and $R_e^2$ to make predication of the presence and period assertion.

Equation 4 defines our loss function:

$$loss = hinge_{loss}(pred_{label1}, gold_{label1}) + hinge_{loss}(pred_{label2}, gold_{label2})$$

$$hinge_{loss} = \frac{1}{N} \sum_{n=1}^{N} \sum_{k=1}^{K} \left[ \max(0, 1 - \delta(\{l_n = k\}t_{nk})) \right]^p$$ (4)

**Experiments**

**Datasets**

We used an annotated corpus of 1089 EHR notes. The corpus comprises of a three-year longitudinal provider notes of 21 cancer patients, which include progress notes and discharge summaries – essentially all note types in the longitudinal EHRs of the cancer patients. Each note was annotated by two clinical professionals. For each annotated medical entity, including four different types respectively as Drug (Medication information of drug and its attributes), Indication (reason for prescribing medication), ADE (Adverse Drug Event as an injury resulting from the normal use
Figure 3: The architecture of the proposed model.

Figure 4: How the residual network functions in the proposed model. Note that it contains dropout which is not shown in this figure explicitly.
of a drug at a normal dose), and SSLIF (other signs which the physician can observe and symptoms which the patient reports) in the corpus, presence and period assertions are used together to assign property to it. Presence assertions include six categories which are respectively present, absent, possible, conditional, hypothetical, and not associated with patient. The period assertions include four categories as current, history, future, and unknown. Presence and period assertion annotation statistics in the corpus are provided in the Table 2 and Table 3.

**Experiments Setup**

Our experiments used word embeddings of 100 dimensions learnt on a combined corpus of PubMed open access articles, English Wikipedia and an unlabeled corpus of around hundred thousand Electronic Health records which are not the EHR used in our dataset\(^1\). We used Chainer, a flexible framework for neural networks for the implementation of the proposed model\(^2\). We report the micro-averaged and macro-averaged accuracy results and also the performance on each class.

**Experiment Results**

For comparison, we used a standard SVM and a standard LSTM model as baseline. To be specific, the Linear SVM classifier\(^1\) with bag-of-words features is used. The LSTM is implemented using Chainer. It runs through the whole sentence, without splitting the sentence according to entities as what we do in the proposed model. Bag-of-words features is also employed. In addition, the presence assertion and period assertion classification task are conducted separately for the baseline systems.

Experiment results for presence assertion is shown in Table 4 and results for period assertion is shown in Table 5. We use HNN as abbreviation for our model. As can be seen, the proposed model by jointly training the two task in one unified framework obtain good results in both two tasks.

**Analysis**

As mentioned in the previous sections, HNN addresses the combined classification tasks of presence and period assertion in one joint framework. Assertion prediction is a complex task from the NLP perspective. The difficulty

---

\(^2\)https://chainer.org/

\(^1\)Trained using LIBSVM\(^2\)
of this task is further exacerbated by the fact that we predict assertions on four different underlying medical entities (Drug, ADE, Indication and SSLIF). The difference among these entity types induces a domain difference in assertion prediction which increases the complexity of our task.

The HNN model in general achieves competitive results on both tasks. The overall result of all methods on the period task is lower than that on the presence task. One possible factor behind this discrepancy is that an EHR document is largely written in past or present perfect tense, irrespective of the relative timeline of events in that document. Due to this ambiguous use of tense in EHRs, learning algorithms are often forced to rely on contextual clues, which are more difficult to recognize and extract. Presence assertions on the other hand have more direct linguistic clues such as negation. However, even though the period assertion task is a more difficult one, our system is able to outperform the baseline by a large margin. In fact, the performance gap between HNN and the next best baseline (around 3.4% micro accuracy and 18.4% macro accuracy) for period task is significantly higher than that in presence task. This indicates that HNN can learn to recognize a more diverse set of contextual patterns, and is less dependent on tense based indicators.

The SVM model is ineffective for presence and period assertion in minority classes. LSTM model also only shows small improvements in minority class prediction. In contrast, our HNN model leads to significant improvement on several minority classes such as “Not Patient”, “Possible”, “Future” and “Unknown”. This performance indicates that HNN can better capture the semantics of minority class and subsequently learn to generalize better from fewer examples.

All the three models get zero accuracy on the conditional and hypothetical classes (except a very small accuracy of our model on conditional class) because these two are the rarest classes in our dataset. As a result, our data-driven models do not have enough corresponding positive samples for meaningful training.

Conclusion

We have proposed a novel hybrid neural network framework for prediction of assertions in Electronic Health Records. Our model can jointly predict both the presence and period assertion values ascribed to the medical entities associated with patients in clinical texts. Our experimental results show that the HNN model leads to significant improvement in both minority and majority class for period and presence assertion.

Abstract

Sleep spindles are a hallmark of stage 2 non-REM sleep that contain information about heritable traits that play an important role in neurological diseases. One of the key challenges in leveraging spindles for clinical research is the lack of a data processing pipeline and web-based platform for managing and visualizing spindle-specific data at scale. We propose SpindleSphere, a scalable integrated data management and visualization platform for spindle research. SpindleSphere has several features: (1) standardized, metadata-based search and query of annotated polysomnography (PSG), the gold standard for sleep diagnosis; (2) event-specific signal exporting; (3) interface for interactive waveform visualization; (4) multi-scale spindle rendering; and (5) parallel algorithm in MapReduce for detection of spindle segments. SpindleSphere provides real-time visualization of multi-modal signals from National Sleep Research Resource (NSRR) for spindle characterization. Preliminary evaluation of SpindleSphere was performed on the NSRR (130 GB of PSG data from 300 subjects).

1 Introduction

Sleep spindles (or spindles, as shown in Figure 1) are one of the most important clinical phenomena in sleep studies\textsuperscript{1}. Sleep spindle characteristics (e.g. spindle density) are reflected in many disorders such as mental retardation\textsuperscript{2}, epilepsy\textsuperscript{3}, schizophrenia\textsuperscript{4,5}, and sleep disorders\textsuperscript{6,7}. Spindles also play an important role in memory reorganization and consolidation\textsuperscript{8–10}. As an electroencephalographic (EEG) phenomenon, the spindle is traditionally characterized as a group of rhythmic signals from between 12 and 14 Hz with a maximum of 3 seconds in duration\textsuperscript{11}. Spindles are most frequently observed during stage 2 Non-rapid eye movement (NREM) sleep (Rechtschaffen and Kales rules\textsuperscript{12}). Spindles are traditionally characterized as one of the hallmarks of stage 2 NREM sleep. Changes in spindle characteristics result from interactions of several regions of the brain, which are linked to learning, behavioral arousal, and sensory gating during wakefulness\textsuperscript{13}. Therefore, identifying variations in spindle characteristics could have diagnostic value as a biomarker for disease states.

Spindle analysis typically involves the following steps (Figure 2). First, the overnight PSG data (European Data Format (EDF) files) are obtained from the data repository and stored on a local machine. Second, using the annotation file, overnight or partial signals of useful channels or montages are extracted and then used as the input for spindle detection algorithms. After spindle detection, detected spindles are visualized and reviewed using existing EDF tools or other software. The last step allows the user to perform specific analysis using verified spindles. Using this workflow, there are several challenges including storage limitations, redundancy and low scalability, data management and visualization limitations, and data format and cross-platform limitations.

Storage limitations. During data acquisition, each EDF file is stored but only a small part is used in spindle detection. Therefore, storing whole EDF file dataset causes storage issues when detecting spindles with large datasets, and simply expanding storage will not allow us to cope with the rapidly expanding volume and increasing complexity of biomedical data.

Redundancy and low scalability. Storing datasets as files, at the abstraction layer, presents barriers that make data access, processing and analysis tasks even more difficult, redundant, and ineffective. Current spindle detection programs...
extract a specific channel or montage from an EDF file for every independent spindle detection study, which is a redundant and time-consuming process.

**Spindle visualization and reviewing limitations.** Most sleep-related datasets do not provide spindles that have been identified and verified by experts. As such, it is difficult to handle large datasets using existing EDF tools in visualizing and reviewing the automatically detected spindles, especially comparing the performance of different automatic spindle detection approaches. Moreover, most existing EDF tools are stand-alone software, which makes it a challenge to share the detected spindles since it requires both sides have the same software and signal files.

![Sleep spindle analysis (on the local machine)](image)

**Figure 2:** The traditional workflow of spindle analysis.

In this paper, we propose a scalable integrated data management and visualization platform (SpindleSphere) for spindle research to address the challenges presented here with a new efficient and effective spindle analysis workflow. SpindleSphere is a web-based application developed using Ruby on Rails framework and a special spindle format as the back end. It has a set of key characteristics described below that are not available elsewhere.

**A scalable spindle processing pipeline,** which includes 1) standardized, metadata-based search and query of annotated PSG signal data. We specially designed new data schemas for efficient storing, exporting and visualizing PSG data in our database; 2) interfaces for querying, importing, event-specific extraction, and repackaging of PSG data. Files that only contain useful signal data require less storage space and can be partially downloaded instead of using the entire large EDF file; in addition, there is no longer a need to execute the redundant and time-consuming step of extracting signals from specific channels.

**A web-based spindle analysis and visualization platform,** which includes 1) online visualization of single, multiple, or cross-sectional event-specific waveforms; 2) multi-scale spindle visualization and reviewing interface, which, for the first time, provides an intuitive and efficient solution for spindle reviewing, verification and comparison in sleep-related studies; 3) leveraging the advantages of the Web application, it is unnecessary to download and install specific EDF tools, so the results can easily be shared with others; moreover, the spindles can be reviewed on any computer with a browser on it, i.e. no platform limitations.

**Large-scale processing of PSG data with parallel computing.** We designed a key-value-based JavaScript Object Notation (JSON) format for representing spindle data, which breaks through format limitations (existing EDF is not compatible with input file format for parallel computing) and is suitable for both sequential and parallel computing. In order to verify the feasibility of SpindleSphere on a parallel programming model, we designed a parallel spindle detection algorithm based on Mölle’s work. Then we applied both sequential and parallel algorithms to over 130GB of PSG data from NSRR and evaluated the performance. The evaluation results indicate that the data format in SpindleSphere supports cloud computing models and provides high scalability for large-scale dataset processing.

## 2 Background

### 2.1 National Sleep Research Resource (NSRR)

The National Sleep Research Resource is a comprehensive, well-integrated retrospective repository of sleep and sleep-related data, consisting of bio-physiological signals linked to risk factor and outcome data for participants in nearly 20,000 sleep studies with thousands of overnight sleep recordings, collected as a part of prior and ongoing NIH-supported efforts. The NSRR data repository encompasses a wide variety of signals, data collection protocols, and processing algorithms, thus representing a significant but under-utilized resource of “big data.”

For this paper, we use a dataset that consists of 300 subjects from the Cleveland Children’s Sleep and Health Study (CCSHS). The CCSHS is one of the largest population-based pediatric cohorts with objective sleep studies. The
cohort is a stratified random sample of full-term and preterm children born between 1988 and 1993 at 3 hospitals in the Cleveland area. The cohort includes 517 children, studied at 8 to 11 years of age with in-home sleep studies, acoustic reflectometry, blood pressure, and other sleep-related measures. The study was approved by the Institutional Review Boards of all participating institutions.

2.2 Automatic spindle detection algorithm

It is difficult, time-consuming and labor-intensive to recognize and count sleep spindles in an overnight recording visually, let alone perform these identifications within a large sleep-related dataset, such as NSRR. Additionally, the visual analysis may produce subjective results since it is an operator dependent task. Therefore, developing an automatic sleep spindle detection system can reduce manual work required in sleep studies. Several approaches for spindle detection from the EEG waveform have been proposed.

In order to enhance spindle activity during the depolarizing phase, Mölle et al. proposed an approach that considered the temporal dynamics between faster rhythmic activities and slow oscillations during NREM sleep. Acir and Güzeliş proposed a two-stage classification procedure for automatic recognition of sleep spindles using artificial neural networks (ANN). Duman et al. proposed an algorithm integrating techniques in a decision tree: short time Fourier transform and multiple signal classification algorithms. Wamsley et al. implemented a wavelet-based approach with a complex Morlet wavelet. Tsana and Clifford proposed a method based on continuous wavelet transform with a Morlet kernel function, then identified spindles with a large power of the coefficients in frequencies. In this paper, we designed a parallel algorithm based on Mölle’s work to evaluate the performance of the new workflow using SpindleSphere.

2.3 Apache Hadoop and MapReduce

Apache Hadoop is an open-source framework using the MapReduce programming model, which was developed for processing large-scale datasets. MapReduce is an implementation for processing big datasets using a parallel and distributed algorithm; it consists of two functions named map and reduce. A complex and intensive task is divided into several independent tasks that are executed on distributed nodes in a cluster using the map function, and the results are summarized using the reduce function. The Hadoop framework uses Hadoop Distributed File System (HDFS) for large-scale data storage and management, and it provides a reliable and scalable solution for parallel applications.

In this paper, we used MapReduce to process multiple procedures in spindle detection in parallel to improve the performance of the approach.

3 Methods

3.1 A new spindle analysis workflow using SpindleSphere

To address the limitations in traditional workflow, we propose a new efficient and effective spindle analysis workflow with SpindleSphere shown in Figure 3, which includes 1) PSG data from NSRR that will be imported to our EDF database, with a scalable processing pipeline that associates related specific metadata and provenance information to each signal segment; 2) user requests are processed by a database consisting of metadata-annotated signal segments; 3) users can download event-specific signal segments to their local machine for further analysis; 4) user-contributed and additional spindle data source can be imported to our database; 5) online visualization of single, multiple, or cross-sectional event-specific waveforms, and multi-scale spindle visualization and reviewing.

**Figure 3:** The new workflow of sleep spindle research.
3.2 System architecture

SpindleSphere is a scalable integrated data management and visualization platform for spindle studies. It provides an intuitive web interface for clinicians and researchers to query, visualize and review detected spindles with large PSG signal datasets. Figure 4 shows the system architecture of SpindleSphere: 1) backend database structure to store parsed EDF files that are systematically linked to NSRR; 2) query engine for processing user requests, such as annotation-based signal rendering and exporting of label-specific signal segments; 3) interface design and information display since PSG data are content rich, especially after they are carefully annotated. Overall, the SpindleSphere platform used Model View Controller (MVC) architecture pattern and was implemented using Ruby on Rails technology and Data-Driven Documents (D3), which is an open source JavaScript library for data visualization. Moreover, we addressed scalability of SpindleSphere in two ways: using a highly scalable database system as the backend and support for parallel computing. We describe different components of SpindleSphere in following subsections.

3.3 Data model

For data storage, we selected MongoDB\textsuperscript{21} (version 3.2.7) as the backend database for data storing and management. MongoDB is a free and open-source cross-platform document-oriented database program. It is classified as a NoSQL database program and uses JSON-like documents with schemas, which provide flexible data modelling, considerable scalability and improved data management performance. Three different data models in MongoDB were built to store each signal fragment with its EDF header and annotations. The main idea is to break large, unstructured, sequential data files into minimal, semantically meaningful, fragments. Such fragments can be indexed, assembled, retrieved, rendered, or repackaged on-the-fly. Therefore, based on these models, PSG data can be viewed and exported in various ways for different objectives, such as visualizing and exporting overnight EEG-C3 channel signal or sleep stage 2 C3-A2 montage signal, which is much more flexible compared with original EDF files. In addition, we designed another model to store the characteristics of spindle, which provides high flexibility for visualizing different kinds of spindles, especially in spindle the reviewing function of SpindleSphere. For example, SpindleSphere can visualize the spindles detected from different algorithms at the same time by assigning different event concepts.

3.4 Interface

To support the requirements in spindle research, such as exporting and viewing signals corresponding to special events, we designed and prototyped SpindleSphere with a set of key features not available elsewhere: (1) standardized, metadata-based search and query of annotated PSG signal data; (2) interfaces for querying, importing, event-specific extraction, and repackaging of PSG data; (3) online visualization of single, multiple, or cross-sectional event-specific waveforms; (4) multi-scale spindle reviewing interface, which, for the first time, provides an intuitive and efficient solution for spindle reviewing, verification and comparison. The interface of SpindleSphere incorporates a rich set of query composition and visualization functionalities, including a) signal query and exporting interface, and b) signal visualization and spindle reviewing interface.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{system_architecture.png}
\caption{The system architecture of SpindleSphere.}
\end{figure}
Signal query and exporting interface. The SpindleSphere interface allows users to select a subject study, render the signal with interesting events, and apply montage function. It provides several widgets for user interaction, such as subject selection, montage selection, signal channel selection, spindle display mode and event display selection. These options are implemented as several simple drop down menus with the ability to select various values.

Signal visualization and spindle review interface. The SpindleSphere provides a range selector allowing the user to visually zoom into a particular section of the signal by dragging the scrollbar or the edges of the navigator window to the area of interest. In addition, users have the option of zooming/panning the time-range of interest using the mouse. For spindle reviewing, once the spindle display mode is selected, multiple colorful areas will be shown associated with related channels. Each area indicates a spindle that was detected by the specific approach, and colors represent various spindle detection approaches. The spindle area also can be zoomed in/out using the scrollbar.

3.5 Parallel spindle detection algorithm for computational scalability

In order to verify that SpindleSphere supports parallel computing (cloud computing) and provides more efficient workflow for spindle research, we designed and implemented a parallel version of automatic spindle detection algorithm proposed by Mölle et al.\textsuperscript{14}, named PASD (Parallel Algorithm for Spindle Detection). We used the output of SpindleSphere, i.e. the signal data exported by SpindleSphere, as the input file for PASD, and then compared the results between the original algorithm and the parallel version using our own spindle reviewing interface.

The workflow of the original algorithm proposed by Mölle et al.\textsuperscript{14} is shown in Figure 5(a). For each subject’s signal, it has six steps listed as follows: 1) apply band pass filter to each continuous sleep stage 2 signal. Each subject may have more than one continuous sleep stage 2 signal, therefore, a loop is implemented to process all sleep stage 2 signals; 2) aggregate the results of step 1 and calculate the standard deviation; 3) calculate the amplitude threshold using the result of step 2; 4) apply the same band pass filter to overnight signal from the subject; 5) threshold processing is employed on the filtered overnight signal and then the spindle candidates identified; 6) verify the time duration of each spindle candidate, and then output the final results.

However, two of these steps can be optimized using parallel computing. At first, it is unnecessary to apply bandpass filter to sleep stage 2 signals one by one, and all sleep stage 2 signals can be filtered concurrently due to the independence among each one. Second, step 4 does not need to be executed after the first 3 steps are finished, and it can be done with sleep stage 2 signals in step 1. Leveraging the advantage of parallel computing, multiple procedures can be processed concurrently, so we designed a parallel version PASD based on the MapReduce framework, which is illustrated in Figure 5(b). The input of PASD is the signals of all subjects, including sleep stages 2 signals and overnight signals. In the Map function, all the signals are filtered with bandpass filter, and split to each node in the cluster. In the Reduce function, the sleep stage 2 signals and overnight signal for each subject are grouped together according to the same value of key. Then, three steps mentioned above, including step 3 (T), step 5 (S) and step 6 (M), are executed. The final output consists of detected spindles of all subjects.

![Figure 5: The workflow of spindle detection algorithms. (a) The original algorithm. (b) The parallel algorithm (PASD); In the reduce phase, T is the Threshold step, S is the Segment&thresholding step, and M is the Maximum&minimum step in (a).](image-url)
4 Results

SpindleSphere was used to process PSG data of 300 subjects collected from consented subjects enrolled in the CCSHS study at NSRR. On average, an EDF file is in the size of 452 MB and 18.8% of the file (85 MB) is used in spindle detection. In the following, we first present the interface results of SpindleSphere, including query, exporting and visualization interface; we then describe the performance comparison, including storage space and execution time, of spindle detection using the traditional and new workflows.

4.1 Interface results

The features of the signal query and exporting interface are as follows: 1) Channel/montage selection: after selecting a subject, the user can select the appropriate channel or montage to visualize. A montage is the waveform representing the voltage difference between two different channels, and the deleted signals from the relevant channels were calculated on the fly in response to the user query. Users may also choose to create their own montages using the “Add montage” interface, which has the ability to manage the combination of signals for custom montages; 2) Event selection: the user can choose to view event-related signals to better navigate through the data. The events-related signals are stored in annotation_signals model, and this model enables visualization of the correct signal data segments with specialized events in response to the user query; 3) Spindle display mode: the user can choose to view the annotated spindle signals to review the detected spindles with multi-scale, such as spindles overview, spindles embedded in record and integrated spindles.

**Figure 6:** The query interface and the exporting interface of SpindleSphere.

**Signal query interface.** Figure 6(I) shows the components in query interface, including subject selection, channel type selection, channel/montage selection, montage management, annotation category selection, specific annotation selection, spindle display mode, export annotated data and select button. In subject selection, the user can select the subject’s EDF file they are interested in. In channel type selection, there are two types of signals that can be selected; “original channels” is the original channel in EDF file without any computation, and “montages” is the voltage difference between two different channels. Montage management provides the functions for adding and deleting montages. In annotation category selection, the user can select different types of events, such as wake, REM sleep and stage 2 sleep; then, the signal of the specific event can be selected in specific annotation selection. Opening the show spindle
mode, the detected spindles are labeled using color-areas in the record; otherwise, it only shows the pure signals of each selected channel or montage. Moreover, opening the only spindle mode shows only detected spindles without irrelevant data points. Clicking export annotated data opens a new page with the signal exporting interface. The query is executed by clicking the select button.

Signal exporting interface. Figure 6(II) shows the components in the exporting interface, including subject selection, channel type selection, channel/montage selection, montage management, annotation selection and download button. In contrast to the components in the query interface, subject selection and annotation selection enable the user to select multiple subjects and annotations and download the corresponding files.

The features of the signal visualization and spindle reviewing interface are summarized as follows: 1) functional scrollbar with preview of signals; 2) rendering of long records in a single page with scrollbar for ease of navigation; 3) channel/montage view property editor, such as color configuration; 4) zoom in/out function on both time-range and signal amplitude using functional scrollbar; 5) crosshair that locates each data point and shows its actual value; 6) multi-scale spindle visualization and reviewing using both square waveform and color-area, which are designed for users to review spindles in both integrity and detail.

The signal visualization and spindle reviewing interface. The components are shown in Figure 7, including annotation navigator, functional time-scale scrollbar, signal color configuration, amplitude-scale scrollbar, signal ruler, and spindle reviewing. The user can navigate to other annotation signals, which are listed in specific annotation selection in the query interface, using annotation navigator. Functional time-scale scrollbar provides multiple functions including preview of detected spindles, preview of both signals and spindles, and timespan selection, which enable the user to enlarge and show details of interesting parts of the signal; in addition, amplitude-scale scrollbar provides the function to zoom in/out of the amplitude scale. Moreover, the user can choose different colors for a specific signal using signal color configuration. Signal ruler is designed for verifying the value of each data point in an efficient way. Spindles are visualized with the colorful background in spindle reviewing. Different colors represent different kinds of spindles, such as the spindles detected by different algorithms as shown in F.1 to F.3 in Figure 7. Clicking the circle in the legend of F part can highlight the corresponding spindles. The integrated spindles without irrelevant data points in F part using only spindle mode (as shown in G part).

Figure 7: The signal visualization and spindle reviewing interface of SpindleSphere.
4.2 Spindle detection evaluation

A comparative evaluation was performed to measure the advantages of using SpindleSphere platform for processing, visualizing and reviewing spindle signal data. Two kinds of workflows were applied to the CCSSHS spindle study. For the traditional one, we first downloaded the EDF data from NSRR and stored it on our local machine, and then we detected spindles using the original method. For the new workflow with SpindleSphere, we downloaded the signal data from the exporting interface and applied both original and parallel algorithms. In addition, we imported our results into SpindleSphere, and then compared detected spindles using different methods; the result shows that the spindles detected by the original and parallel algorithm are the same.

Detection performance. In this paper, we mainly focus on the improvement of storage space and execution time, since the parallel algorithm only modified the process of the original algorithm without changing its precision and recall. The details of storage space on the local machine of two kinds of workflows are shown in Figure 8(a). The results indicate that the traditional workflow costs almost six times more than the new one does. Figure 8(b) shows the execution time of three different spindle detection procedures, including the original method with the traditional workflow, the original method with SpindleSphere, and PASD with SpindleSphere. The original method was executed on the local machine with Intel Core i7 2.93 GHz processor and 16 GB main memory, and PASD was executed on a 10-node cluster configured with Intel Xeon E5-2670 processor and 15 GB main memory per node. The results indicate that, for both the original method and PASD, SpindleSphere provides a competitive efficient workflow for spindle-related research. It is nonsensical to compare with applying PASD in the traditional workflow since it needs lots of hours to reformat EDF files to suitable input format. In contrast, the data downloaded from SpindleSphere can be directly used as the input for PASD.

Figure 8: Comparative performance evaluation of SpindleSphere versus the traditional workflow. (a) **Traditional**: the traditional workflow, **With SpindleSphere**: the new workflow with SpindleSphere. (b) **Ori. Traditional**: the original method in the traditional workflow, **Ori. SpindleSphere**: the original method in the new workflow, **PASD. SpindleSphere**: the parallel algorithm in the new workflow. (c) **a1**: algorithm 1, **a2**: algorithm 2, **a3**: algorithm 3.

Multi-method comparison. SpindleSphere offers an easy-to-use system to review and compare spindles across detection algorithms. Figure 8(c) shows the reviewing of spindles detected by three different approaches mentioned in
Simon Warby’s study\textsuperscript{24}. In this way, we can have an intuitive and convenient way to choose which approach has the best performance without knowing the labeled spindles. Figure 8(c) contains three subplots, and each of them shows the highlighted spindles with the corresponding approach. The results demonstrate that algorithm 1 \((a_1)\) and algorithm 3 \((a_3)\) detected similar spindles, and algorithm 2 \((a_2)\) detected the minimum number of spindles among three approaches.

5 Discussion

With the growing demand for multi-center collaborative studies in sleep research using large datasets, there is a need to adopt emerging integrated platforms to meet research requirements, such as less storage utilization, less redundant and highly scalable processing pipeline, intuitive and efficient reviewing system, multiple platform supporting and support for parallel computing. The results of the comparative performance evaluation demonstrate the significant advantages of using SpindleSphere in spindle research with very large PSG signal datasets. SpindleSphere is used in several spindle-related studies, including parallel spindle detection development and spindle analysis with sleep disorders. Some interesting discoveries were found using spindle reviewing interface. In addition, the data model and framework of SpindleSphere can be extended to other medical and clinical studies using large-scale bio-signal data, such as sleep stage analysis and epilepsy seizures detection.

Limitation. There are a few limitations of this paper, such as spindle editing, exporting and sharing. For future development, we will implement an interface for editing spindles, which will provide an easy-to-use spindle annotation tool for experts. The current version of SpindleSphere does not support downloading spindle data, but we are in the process of implementing spindle exporting function in the next phase of development. Moreover, statistical analysis of spindles and results sharing function will be implemented in the future.

6 Conclusion

In the sleep spindle studies, PSG data are often used as the gold standard. However, lack of a PSG data processing pipeline and web-based platform for managing and visualizing spindle-specific data on a large scale is one of the key challenges in leveraging spindles for clinical research. To address this challenge, we proposed a scalable web-based data management and spindle analysis and visualization platform, SpindleSphere. It provides a scalable spindle processing pipeline, and an intuitive web-based platform for clinicians and researchers with querying, exporting and visualizing capabilities of large-scale PSG signal data for spindle research. The results of performance evaluation of the SpindleSphere demonstrated a performance improvement in data storing, exporting, processing and visualizing with more than 130GB of data from 300 subjects from NSRR.

Acknowledgment. This work is supported in part by University of Kentucky Center for Clinical and Translational Science (Clinical and Translational Science Award UL1TR001998), National Sleep Research Resource (NHLBI R24 HL114473) and National Science Foundation under MRI Award No.1626364. We thank the Amazon Web Services (AWS) Cloud Credits for Research program that enabled the implementation of our parallel algorithm.

Representation of Social History Factors Across Age Groups:
A Topic Analysis of Free-Text Social Documentation

Abstract
As individuals age, there is potential for dramatic changes in the social and behavioral determinants that affect health status and outcomes. The importance of these determinants has been increasingly recognized in clinical decision-making. We sought to characterize how social and behavioral health determinants vary in different demographic groups using a previously established schema of 28 social history types through both manual analysis and automated topic analysis of social documentation in the electronic health record across the population of an entire integrated healthcare system. Our manual analysis generated 8,335 annotations over 1,400 documents, representing 24 (86%) social history types. In contrast, automated topic analysis generated 22 (79%) social history types. A comparative evaluation demonstrated both similarities and differences in coverage between the manual and topic analyses. Our findings validate the widespread nature of social and behavioral determinants that affect health status over populations of individuals over their lifespan.

Introduction
Increasingly, the importance of social and behavioral factors on an individual’s health status are being recognized in clinical decision-making and effective population health management. As use of electronic health record (EHR) systems increases, there is a concomitant increase in EHR documentation that can be used to understand both how social history is documented and how these factors change over an individual’s lifespan. Previous studies1-9 have examined how individual social, behavioral, and environmental factors can be represented with controlled data representations as well as how these factors differ across documentation sources. For example, Rajamani et al.1, Aldekhyyel et al.2, and Lindemann et al.3 examined how occupation is documented in standards and reports, free-text comment fields in an EHR, and free-text documentation from multiple clinical note sources, respectively. Chen et al.4,5, Wang et al.6,7, Winden et al.8, and Carter et al.9 examined documentation of tobacco, alcohol, and drug use within free-text fields of the EHR. Finally, Winden et al.10 analyzed living situation, living conditions, and residence in standards. Since social history is often documented as free text and not structured data within clinical notes or in free-text documentation fields of the social history section of the EHR, this documentation and its associated topics, particularly with respect to an individual’s lifespan, has had limited characterization. Ultimately, gaining a better understanding of the social history information documented provides an opportunity to understand these factors across populations and across the lives of patients.

As a patient ages, there is some evidence that relevant social history topics change dramatically. For infants and toddlers, many of the social determinants of health (SDOH) of parents and caretakers are particularly important including their mental health status and social support11-14. Within the literature, many of the direct references to the SDOH of infants and toddlers (ages zero to 24 months)15 may refer to breastfeeding habits16,17, residence18, living conditions19, and palliative care for neonatal infants who have acute or potentially chronic care needs20-22. Residence is defined as the physical dwelling in which an individual lives or physical location, while the term living conditions refers to qualitative factors within these environments, such as secondhand smoke exposure, rodent infestations, water quality, and other relevant factors. As children enter early childhood, defined as ages two through five years by the National Institute of Child Health and Human Development (NICHD)15, topics such as living conditions and residence remain important23,24, and other pediatric-specific patient factors are of increasing importance like sleep habits25 and factors that may cause potential increase in obesity rates26. As children reach middle childhood (6-11 years)15 and enter school systems, exposures related to this new environment are increasingly discussed in literature, such as bullying27 and school performance. During this time, relational dynamics between both peers and family members and psychosocial effects are also increasingly important28, and factors associated with diet and obesity remain popular topics29.
When individuals reach adolescence (12-18 years)\textsuperscript{15}, SDOH topics broaden considerably and may more closely match social history topics for adult age groups. Documentation of alcohol use, drug use, and tobacco use now reflect individual use rather than exposure from parents or caretakers\textsuperscript{30}. Also, sexual history topics may be mentioned during adolescence without the context of abuse\textsuperscript{30}. In recent years, mentions of social media habits increase dramatically within literature as a factor of Internet presence\textsuperscript{31}. Specifically of interest is the impact of social media usage on psychological state and its association with bullying and social dynamics\textsuperscript{32}.

The importance of standardizing how SDOH topics are entered into the EHR for clinical decision-making has been recognized by the National Academy of Medicine\textsuperscript{33}. Towards this goal, understanding the current state of SDOH entry is important for determining what information is most valued by providers. In this study, we sought to identify how EHR social history topics change within clinical documentation as individuals age, and how social history topics vary by demographics, including gender, race, and ethnicity through automated topic analysis and manual analysis of social history topics in social history documentation for a large integrated healthcare system that serves both metropolitan and rural communities with primary and tertiary care.

**Methods**

At a high level, this study sought to provide a: (a) detailed analysis of social history topic variation by age and other demographics and (b) validation of the automated topic analysis through a separate manual analysis of social history documentation. An overview of our approach is provided in Figure 1 and was composed of four high level steps: (1) data collection, (2) topic analysis of pediatric and adult social history documentation, (3) manual validation of pediatric and adult social history documentation, and (4) comparison of social history topics from both analyses.

Figure 1. Overview of assessment of social history topics by age and other demographics. Populations and demographics of the patient set were defined first, while manual analysis and topic analysis were performed simultaneously.

**Data Collection**

Data sources for this study were the free-text Social History Documentation section within the enterprise EHR of Fairview Health Services (FHS). FHS is an integrated healthcare delivery system associated with the University of Minnesota that services both a large metropolitan area and rural parts of greater Minnesota. Social History Documentation from 2011 to 2016 was used for this analysis through the University of Minnesota research Clinical Data Repository (CDR). Each represented patient was used once in this five-year period to avoid oversampling from a single patient. Age groups were defined for pediatric patients according to the NICHD\textsuperscript{15}. The age groups for Neonatal Stage (0-27 days after birth), Infants (28 days after birth to 13 months of age), and Toddlers (13 months of age to 24 months of age)\textsuperscript{15} were combined, due to lower representation in FHS, compared with other age groups. Pediatric age groups for the analysis therefore consisted of: Infant and Toddler (birth to 24 months of age), Early Childhood (2-5 years), Middle Childhood (6-11 years), and Early Adolescence (12-18 years)\textsuperscript{15}. Adult age groups were defined according to the United States Census guidelines\textsuperscript{33} with age groups 19-24 years and 25-44 years were combined into a single Young Adulthood category. Adult age groups for the analysis therefore consisted of: Young Adulthood (19-44 years), Middle Adulthood (45-64 years), and Older Adulthood (65 years and older)\textsuperscript{34}. A representative number of patients within the FHS was used for each age group. Other demographics including race, gender, and ethnicity were also obtained on patients for analysis in the study.
Manual Analysis

To compare the most common social history topics by age, 200 patient entries were randomly selected for each age group from the years 2011 to 2016. An annotation schema based on previous studies with used consisting of twenty-eight major social history topics (Table 2). Annotators were instructed to annotate the text of the entire sentence for as many social history topics as the text contained. For example, the sentence “She lives with Mom and Dad in a single family home” would be annotated as Living Situation, Residence, and Family. An overlapping set of 10% of entries was annotated to perform inter-rater agreement by study investigators (EL, SS). Manual annotation for major social history topics in each age group resulted in a Cohen’s kappa of 0.67 and percentage agreement 0.92.

Automated Topic Analysis

Social history documents extracted from the CDR were pre-processed with an open source biomedical Natural Language Processing (NLP) pipeline to extract sections and split sections into statements. The preprocessed statements were then parsed by Stanford Probabilistic Context-Free Grammars (PCFGs) parser. We observed that multiple social history topics may be contained in a single statement. For example, the social history statement “Mom lives in an apartment and exercises twice a week” includes both information about the living condition and the hobby of the patient. For this reason, we collected all verb phrases of each social history statement separately as inputs for topic modeling. The subject of the verb phrase (e.g., “Mom” or “Siblings”), the verb (e.g., “exercise” or “live”), the verb prepositional conjunction word (e.g. “in”, “at”, or “with”) and sometimes the object of the verb was also collected. Verb frequencies of each group were computed, and those top occurring verbs were examined to decide if the object of the verb should be collected as part of the input for topic modeling. For instance, if a verb denotes no actions (e.g., “feel” or “report”), then the object of the verb (e.g., “safe” or “immunization”) was collected as part of the input for topic modeling. We also normalized language names, country names, relative names (e.g., “grandmother” or “nephew”), occupation name, and month names into single forms (e.g., “January” or “February”). Each word in the input was then normalized based on the SPECIALIST Lexicon.

To decide the optimum topic numbers for each age group, we computed harmonic means of topic models with a sequence of topic numbers from 5 to 70, step by 3. Figure 2 shows the harmonic means change with different topic numbers chosen in topic modeling. In the following step, a topic model was built for each age group with the computed optimum topic number for each group. The R package ‘topicmodels’ was used in this study to compute the optimum topic number and topic model fitting.

Comparison of Major Topics between Corpora

Following annotation, major social history topic occurrences were extracted. The highest frequency topics in the manually validated corpus were compared against topics that arose through topic analysis. A comparative evaluation was performed in order to validate similarities between corpora. Topics generated from topic analysis were grouped according to the annotation schema and coverage was evaluated.

Results

Manual Analysis

For each of the seven age groups, a total of 200 patients were selected at random (Table 1). This provided a total of 1,400 documents that were annotated for twenty-eight social history topics. Table 2 summarizes the representation of social history topics across age groups. A total of 8,335 annotations were made, with Young Adulthood containing the highest number of annotations (1,929) followed by Middle Childhood (1,170), and Early Adolescence (1,158). Sentences were annotated at the sentence level for all present social history topics, so in many cases, there
were multiple annotations made for each sentence. There were slight discrepancies between study investigators in annotations, surrounding a question referring to guns and occupations of guardians. These differences were resolved after the validation stage was completed.

Table 1 summarizes the demographics seen across the manual validation corpus. While a diverse population is represented, patients were selected at random, and therefore, may not be completely representative of populations across the greater FHS system.

**Table 1. Demographic information for patients included in manual validation corpus.**

</table>

For all pediatric age groups, Family had the highest frequency of annotations, followed by Occupation and Living Situation. These topics are often seen together in the same text; for example, “She lives at home with Mom, Dad, and 2 siblings.” Occupation can refer to the occupation of an individual, “He works in IT,” or that of a parent or guardian, “Mom works from home, while Dad works in an office.” While annotations for these categories remained high for all age groups, there is a decrease in the frequency of these annotations, and a subsequent increase in the annotations of the Social History (SH) “Other” category. There is a large portion of the Older Adulthood annotations that account for Marital Status; for example, “He is a widower” or “Lives at home with Husband.” Although overall annotations for this Marital Status decrease by Older Adulthood, this type accounts for the third highest annotations for the age group.

**Topic Analysis**

A total of 187,920 patients were included in the automated topic analysis. Table 3 summarizes the demographics of the FHS population served from the years 2011 to 2016 with the Social History Documentation part of the analysis. This population is representative of the individuals serviced in the years specified. The age group for Young Adulthood has the most patients represented. Since adult age groups together contain more years compared to pediatric age groups, more patients are represented in adult age groups.

Table 4 summarizes the ten most frequent topics for each age group identified using the topic analysis methods. These topics were grouped according to the schema of social history topics created for the manual analysis corpus. Many topics are slightly overlapping, causing there to be multiple entries for topics with similar content. For example, Marital Status is mentioned as the second, third, and fourth most occurring topic for Infant and Toddler, but may contain granularity that is not captured by the social history type classification.
Table 4. Representation of ten most frequent topic analysis topics, in order of frequency, with keywords and examples.

<table>
<thead>
<tr>
<th>Topic #</th>
<th>Assigned Name</th>
<th>Keywords</th>
<th>Examples</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>

<td>Tobacco Use</td>
<td>Cigarettes, Smoking, Exposure</td>
<td>They live in a house with no smoke exposure. Grandmother smokes outside. The patient has 20 yr hx of intermittent pipe and cigar use.</td>
</tr>
</tbody>
</table>

Comparative Evaluation

Table 5 summarizes the comparative evaluation performed to analyze similarities between SH topics that arose through manual analysis and topic analysis. Several topics were consistent through all age groups: Family, Living Situation, Living Situation Exposure, Marital Status, Occupation, Residence, and SH Other. Early Adolescence has the widest variety of social history topics included. Several topics become more prevalent with age, including Physical Activity, Diet, and Caffeine Use.

Table 5. Distribution of topics generated from manual and topic analyses, grouped by manual annotation schema.

Discussion

Variations Between Topic Analysis and Manual Analysis

The findings of this study demonstrate and validate the hypothesis that social history topics change over the course of an individual’s lifespan. The manual analysis conducted demonstrates the breadth of social history information that is contained within social documentation, while the topic analysis provided further granularity and depth to this information with a larger number of patients. Some of the richer pieces of information from the topic analysis includes references to languages individuals speak both primarily and in the home specifically, abuse factors, access to guns, seatbelt use, and helmet usage.

From twenty-eight potential social history types we have previously described, twenty-four were used at least once. There were no entries for Hobby Exposure, Hobby Other, Physical Activity Exposure, and Physical Activity Other. However, all other topics were observed in multiple age groups. There were minor variations in annotations between study investigators, contributing to the Cohen’s kappa of 0.67. These discrepancies were related to the occupations of parents and guardians and how to annotate the presence of firearms in the home. These discrepancies have also since been resolved at the close of the annotation process. In comparison, the topic analysis contained twenty-two of these topics. No topics were generated for the four types that were not present in the manual analysis. The number of social history topics represented in the topic analysis was fairly consistent across age groups, although Early Adolescence and Young Adulthood contained the best coverage for topics.

The comparative evaluation showed large areas of overlap between the manual analysis corpus and the topic analysis corpus, despite variations in size. This overlap demonstrates the complexity of information characterized within FHS Social History Documentation, and that this analysis is representative of the large clinical population in the Fairview Health Services system, since each patient with Social History Documentation was represented. The presence of SH Other topics in both the manual analysis corpus and the topic analysis corpus demonstrates how broad SDOH for individuals can be, and how difficult it might be to create structured documentation for SDOH that adequately encompasses an individual’s factors.

This work will serve as a basis for further natural language processing efforts, providing more robust tools for examining how social determinants affect individuals as they age. Providing a larger understanding of how SDOH are currently entered into the EHR will support understanding of what providers value and help to further standardization of entry, ultimately aiding in clinical decision-making.
Social Determinant Changes through Lifespan

With respect to social history documentation for pediatric individuals, there is a heavier focus on Living Situation observed prior to adulthood. This is also true for Occupation, possibly due to the focus on occupations of parents and guardians as it relates to a child’s care needs, although occupation continues to be well documented through adulthood and potentially in the structured Occupation fields in the EHR elsewhere for adults. Many social history types may refer to usage of parents, guardians, or exposure. For example, Alcohol Use, Drug Use, and Tobacco Use mentions largely refer to habits of individuals a child lives with in these corpora. Hobbies show the highest occurrence for pediatric individuals in the Middle Childhood and Early Adolescence age groups. Family maintains highest frequency, followed by Occupation, and Living Situation for all age groups throughout childhood.

Family remains prevalent as a subject of documentation through adulthood, but accounts for a smaller portion of annotations than in pediatric age groups. Family is the only social history type that is seen consistently in highest frequency groups. As individuals enter Older Adulthood, mentions of Marital Status account for a larger portion of annotations. The prevalence of Family mentions may be due to the relationship family history and with whom an individual associates with has on health status and outcome.

Following SH Other, the topics that arose with highest frequency from the topic analysis concerned Residence, Living Situation Exposure, Family, and Marital Status. These topics are largely related to one another and very difficult to separate by nature of their juxtaposition within. These findings demonstrate the interdependent nature of these factors within an individual’s SDOH. While Occupation topics were high in frequency for most age groups, the content of this topic was likely to change with age, and referred more directly to work experience rather than education as individuals enter adulthood.

Both corpora show a change in documentation as individuals reach adolescence and adulthood. Specifically, Caffeine, Diet, and Physical Activity show marked increases in documentation as individuals reach Young Adulthood. The largest change documented in these corpora that occurs as individuals enter adulthood is the increase in annotations for SH Other. The prevalence of SH Other topics is reflected through the topic analysis as summarized in Table 4. This category serves as a place to catch any social, behavioral, and environmental factors that are not related to the other types in Table 2. For all adult age groups, SH Other accounts for the most frequent annotations. This could possibly indicate that as we age, standard language around social history becomes harder to capture consistently and potentially more complex. Documenting the SDOH of parents and guardians might correlate to this, prove to be complex, and directly affect the SDOH of children. The complexity and variety of information included in this category will inform extensions to annotation schema for future work.

As patients within FHS reach adulthood, there is a shift in gender prevalence. This was evidenced in the demographics of the randomly selected manual analysis corpus as well as the topic analysis corpus that accessed all patients with Social History Documentation from 2011 to 2016. In pediatric sets, male patients represent a majority in both corpora. At Early Adolescence, genders are fairly comparable, leading up to a major shift at Young Adulthood. As patients enter adulthood, women represent more than 70% of patients in both corpora. This is likely due to a number of factors, but demonstrates that this analysis may be more accurate to the SDOH of adult women and pediatric males. The ratio between men and women becomes slightly more balanced as individuals enter Middle Adulthood and Older Adulthood. The demographics of this patient set also points to a lack of diversity in race. In all age groups, individuals who indicate their race as “White” predominate documentation. This is also subject to a number of factors, but could also point to this analysis more heavily representing the SDOH of those individuals.

Conclusion

Social history documentation in EHR systems will become increasingly valuable to understand for clinical care and other downstream consistent uses of this information. The content of this documentation over different age groups likely in part reflects changes of social history factors affecting individuals throughout their lifespan. The findings of this study point to the changing nature of SDOH as individuals age, and demonstrate the breadth and depth of SDOH that can affect a patient’s health status. Further work to standardize how social, behavioral and environmental factors are documented within the EHR is particularly needed to ensure robust documentation of diverse SDOH topics for different age groups.

Automatically Detecting Likely Edits in Clinical Notes Created Using
Automatic Speech Recognition

Kevin Lybarger, M.S., Mari Ostendorf, Ph.D., Meliha Yetisgen, Ph.D.
University of Washington, Seattle, WA, US

Abstract

The use of automatic speech recognition (ASR) to create clinical notes has the potential to reduce costs associated with note creation for electronic medical records, but at current system accuracy levels, post-editing by practitioners is needed to ensure note quality. Aiming to reduce the time required to edit ASR transcripts, this paper investigates novel methods for automatic detection of edit regions within the transcripts, including both putative ASR errors but also regions that are targets for cleanup or rephrasing. We create detection models using logistic regression and conditional random field models, exploring a variety of text-based features that consider the structure of clinical notes and exploit the medical context. Different medical text resources are used to improve feature extraction. Experimental results on a large corpus of practitioner-edited clinical notes show that 67% of sentence-level edits and 45% of word-level edits can be detected with a false detection rate of 15%.

Introduction

The use of ASR has increased within the clinical setting as speech recognition technology has matured and the availability of computational resources has increased. The creation of clinical notes using ASR offers system-level benefits, like short document turnaround time; however, note quality is negatively impacted by speech recognition errors, including clinically significant errors, and higher document creation times for practitioners associated with editing. Automatic detection and flagging of likely edits in ASR transcripts through a correction tool could reduce the time required to edit ASR transcripts and improve note quality by reducing the prevalence of uncaught errors. In this work, we investigated the automatic detection of sentences and words that are likely to be edited in the clinical note ASR transcripts by applying data-driven, machine learning detection strategies.

Practitioners may edit ASR transcripts to correct errors and disfluencies, but also to rephrase portions of the transcript. ASR errors are portions of the dictate that are incorrectly transcribed. Disfluencies include dictation that is repeated (e.g. “the patient the patient”), repaired (e.g. “hypertension I mean hypotension”), and restarted (e.g. “heart has abdomen is”). Rephrasing is associated with changes to the transcript that are not ASR errors or disfluencies (e.g. changing “patient got up” to “patient awoke” or changing “nothing by mouth” to “NPO”). Practitioners may also edit the transcripts as a continuation of the note creation process, deleting information that is no longer relevant or correct and inserting additional information such as test results and new plans for patient care. Word sequences and sentences in the ASR transcript that are edited by practitioners during editing are collectively referred to in this paper as transcript edits.

We identified ASR transcript edits within a corpus of clinical notes created through the voice-generated enhanced electronic note system (VGEENS) Project. We applied ASR error detection techniques to the detection of transcript edits within the VGEENS Corpus, utilizing medical domain knowledge, including clinical note structure and medical terminology. ASR error detection identifies discrepancies between what is dictated and what is transcribed, while our investigation of transcript edits focused on identifying differences between what is transcribed and what the practitioner wants. Table 1 contains an example transcript edit, with the ASR transcript text and the corresponding text from the final note. The ASR transcript includes an incorrect categorization of the patient’s cognitive status and a disfluency with the repair word “correction.” In the final note, the cognitive status is corrected and the disfluency is deleted. In this example, our edit detection model correctly identified all of the words in the ASR transcript that should be replaced or deleted (indicated by bold font).

</tr>
</tbody>
</table>

Within the VGEENS corpus, practitioners deleted words and entire sentences from the ASR transcripts. We hypothesized that sentence-level deletions and word level deletions within the ASR transcripts have different
characteristics and split the edit detection task into two tasks: *sentence-level edit detection* and *word-level edit detection*. The primary goals of this investigation were to evaluate the performance of ASR error detection techniques on the broader category of transcript edits at the sentence-level and word-level and explore methods for leveraging medical context and text resources to improve detection. We find that a substantial fraction of the errors can be detected with simple lexical context features but further gains are possible by leveraging medical context.

The rest of this paper is organized as follows. The Related Work section presents relevant ASR error detection work. The Methods section describes the data used in experimentation and the modeling approaches used to automatically detect transcript edits. The Results section presents the performance of the detection models, and the Conclusions section summarizes this investigation and discusses future work.

**Related Work**

There is a significant body of ASR error detection work (also known as ASR confidence estimation). ASR error detection has been approached using a range of discrete models, including the hidden Markov model (HMM), maximum entropy (MaxEnt) model, and conditional random fields (CRF) model, as well as continuous sequence models, including recurrent neural networks (RNN)\(^3\)-\(^11\).

Many studies have explored ASR error detection using the linear chain CRF model, which is a discriminative sequence modeling variant of the general CRF framework\(^12\). Bechet and Favre created a CRF error detection model using ASR posterior probabilities, lexical features (word n-grams and word length), and syntactic features (part of speech (POS) and dependency labels)\(^1\). In their work, the inclusion of both lexical and syntactic features improved error detection performance. Ghannay, Esteve, and Camelin explored the use of the Multi Layer Perceptron (MLP) neural network architecture, as well as a CRF model as a baseline\(^6\). The input features included ASR posterior probabilities, word representations (orthographic for CRF and embeddings for MLP), lexical features (word length and trigram indicator function), and syntactic features (POS tags and dependency labels). The best results were achieved using the MLP.

RNNs are currently a popular neural sequence model for ASR error detection, and several RNN variants have been used. Kalgaonkar, Liu, Yifan, and Yao compared the performance of a MLP model with a standard RNN and an RNN with an output decoder consisting of a two-state (no error/error) bigram language model\(^9\). The input features consisted of acoustic, linguistic, and confidence scores from the speech recognizer. The recurrent approaches outperformed the MLP, and the output decoder provided a small benefit. Ogawa and Hori created ASR error detection models based on CRF and bidirectional RNN frameworks, using acoustic and linguistic features and speech recognizer states and scores\(^10\). The bidirectional RNN outperformed the CRF. Ángel del-Agua, Piqueras, Giménez, Sanchis, and Civera explored speaker-adapted ASR confidence estimation using Naïve Bayes, CRF, and long short-term memory (LSTM) RNN models\(^11\). The models used pre-trained word vectors and speech recognizer-derived features, and the LSTM RNN achieved the best performance.

Much of the work on ASR error detection has focused on constrained domain human-computer interaction or human-directed broadcast news. The creation of clinical notes using ASR differs from other ASR transcription tasks in that the goal is note creation, not faithful transcription of what was dictated. The goal of note creation is to create a medically accurate document that articulates exam findings and plans for patient care and that meets formatting requirements/norms. Edit detection is motivated by this note creation goal and attempts to find a range of edit types (ASR errors, disfluencies, rephrasing, and note continuation) that impact the quality of the clinical notes. Edits within clinical ASR transcripts include sentence-level and word-level edits, where sentence-level edits tend to be a continuation of the note authoring process and word-level edits tend to be associated with disfluencies, speech recognition, and rephrasing. Another important difference with respect to ASR error detection work is that widely used medical dictation systems do not provide the detailed acoustic scores available in research systems, which makes error detection more challenging. On the other hand, in medical dictation, there are more context constraints that can be used to identify errors. Domain contextual constraints includes clinical note structure (e.g. topical sectioning), structured patient data in the Electronic Health Record (EHR), and ranges of numerical values (e.g. drug dosages and vital signs) and motivates the exploration of different features.

There is a relatively small body of work related to ASR error detection within the medical domain. Voll explored the automatic detection of ASR errors in radiology notes using language models, point-wise mutual information, and hand-crafted rules\(^13\)-\(^14\). Schreitter and Trost investigated the correction of medication dosages within ASR transcripts by extracting medications and the associated dosages and then evaluating dosages based on medication databases\(^15\).
Methods

Medical transcript edits comprise more than ASR errors and impact a larger portion of the note. Edit regions within ASR transcripts can be identified by aligning pairs of ASR transcripts and final notes. In clinical settings where practitioners dictate to a recording device without viewing ASR output in real time (noninteractive setting), ASR transcript-final note pairs are created as part of the existing workflow, providing efficient and low cost access to training data for detection models.

Data

The automatic detection of transcript edits was explored through the corpus of free-text clinical notes created through the VGEENS Project, which was conducted at the University of Washington Medical Center and Harborview Medical Center. As part of the VGEENS Project, inpatient progress notes were created by resident and attending internal medicine physicians using ASR through a multi-step process. First, a doctor dictated the note to a recording device during rounds, verbalizing punctuation and topical section headings (e.g. Chief Complaint). Then the dictation was transcribed using a commercial ASR system (Dragon Medical by Nuance Inc.) and automatically post-processed to format section headings. Lastly, the ASR transcript was reviewed and edited by the doctor, and the final note was entered into the EHR. The VGEENS Corpus of clinical notes includes 669 records created by 15 practitioners, where each record consists of an ASR transcript-final note pair.

Transcript edits were identified through the alignment of each ASR transcript-final note pair using Gestalt Pattern Matching. Gestalt Pattern Matching finds the longest sequence of matching tokens and then finds the next longest sequence of matching tokens to the left and right of the longest matching sequence. This process is applied recursively, until all of the matching sequences are identified. Based on the alignment, each word within the ASR transcripts was labeled as keep or delete. The capitalization of tokens was ignored during the alignment of the note pairs.

Sentence boundaries were determined based on the location of colons, periods, and line breaks, rather than using an off-the-shelf sentence boundary detector, because of the structure of the VGEENS notes (verbalized punctuation; section headings, numbered lists, etc. explicitly indicated). Approximately 10% of the sentences within the ASR transcripts were deleted during editing. In the subset of sentences that are not deleted, approximately 9% of the words were deleted during editing. Given the difference between the characteristics of sentence-level and word-level deletions, the detection of transcript edits was split into two tasks: sentence-level edit detection and word-level edit detection. Word-level gold standard labels were determined based on the keep or delete labels from the note alignments. Sentence-level gold standard labels were determined as follows: sentences were labeled as delete when all word-level labels were delete and sentences were labeled as keep when at least one word-level label in the sentence was keep.

The labeled ASR transcripts associated with the VGEENS Corpus were used in model training and testing (80% training/20% testing). Since this data set was relatively small, we explored use of the MedTrans17 and the i2b218 corpora of clinical notes (referred to as the External Corpora) for learning word classes and embeddings and a language model (LM). Table 2 contains a summary of the corpora used. In addition to these corpora, feature extraction utilized a list of medical terms derived from SNOMED CT, RxNorm, and the UMLS SPECIALIST Lexicon.

Detection Models

The goal of the sentence-level edit detection task was to label sentences within the ASR transcripts as keep or delete. Logistic regression, which is a binary discriminative classifier, was selected for the sentence-level edit detection model because it is known to work well for text classification with relatively small amounts of training data when combined with regularization. The goal of the word-level edit detection task was to label words within the ASR transcripts as keep or delete. Word-level edit detection models were only trained and evaluated on sentences from the ASR
transcripts that had sentence-level *keep* labels from the note alignment. Because of the importance of sequential context at the word level, word-level edit detection was explored using the linear-chain CRF modeling framework, which estimates the highest probability sequence of labels given a sequence of observations12. We also experimented with an LSTM RNN in the word-level edit detection task; however, the LSTM RNN did not outperform the CRF, and only the CRF modeling results are presented in this paper.

**Feature extraction**

The VGEENS Corpus only includes the text output of the ASR system and does not include acoustic information or speech recognizer internal states (confidence scores, alternative word sequences, etc.), which are often used in ASR confidence estimation tasks. For both detection tasks, we utilized domain knowledge and unlabeled training data, in order to compensate for the limited information and relatively small size of the VGEENS Corpus. We explored interpretable features, like topical coherence, that may be useful to physicians.

A fixed vocabulary was selected based on the words that occur in the VGEENS Corpus training subset and External Corpora at least four times, resulting in a vocabulary size of 20.7k words. Out of vocabulary (OOV) tokens were mapped to one of seven OOV tokens, depending on whether the token was a medical term, numerical, lower case, upper case, title case, alphabetic, or other.

**Word-based Features**

In both detection tasks, text-based features were created using discrete and continuous word representations. In the sentence-level edit detection task, word-based features were intended to automatically learn relevant sentence attributes, like: numbered lists (e.g. “1. Liver cirrhosis…”), additional information required (e.g. “…waiting for LFT results…” or “Continue to monitor”), or topical headings not conforming to EHR format (e.g. “Cardiovascular:”). In the word-level edit detection task, word-based features were intended to automatically identify frequent ASR errors (e.g. phonetically similar words like “he” and “she”), disfluencies (e.g. repair words like “I mean” and “correction”), and rephrasing (e.g. abbreviating “daily” to “qd”).

Discrete word representations included orthographic and word class forms. Word classes were used to reduce data sparsity by grouping words based on syntactic/semantic similarity. Because of the small amount of VGEENS data, we leveraged external data to learn more reliable classes7,22. Two types of classes were used: manually-defined (e.g. “hypertension” → “<med_term>”)) and automatically learned (e.g. “patient” → “class00101”). Manual classes (rule-based classes) were created indicating punctuation, capitalization, numbers, and medical terms. Automatically learned word classes were created using unsupervised clustering approaches where words that appear in similar context are merged into the same class so as to maximize the mutual information between consecutive words, referred to as Brown clustering22. 500 Brown classes were learned from a merged corpus of the final notes in the VGEENS Corpus training set and the External Corpora.

Words were also represented as continuous word embeddings (vectors of real numbers), in which a sparse (one-hot) representation of words is mapped to a low-dimensional continuous space capturing syntactic, semantic, and topical information. Word embeddings were created using two unsupervised learning approaches. The first method starts with a term frequency-inverse document frequency (TF-IDF) representation of 4k VGEENS note sections and learns a linear transformation of words (and documents) into a 200-dimensional space using non-negative matrix factorization (NMF). (Performance was similar with 100 dimensions.) Word embeddings were also created using the neural word2vec skip-gram model, which is a single-layer neural network that predicts context words given the current word23. The skip-gram embeddings were created using the final notes in the VGEENS Corpus training set and the External Corpora (embedding size 200, context width 10). K-mean clustering was used to create 500 discrete skip-gram classes from the skip-gram embeddings.

**Language Modeling**

We hypothesized that atypical (infrequent) word sequences were more likely to reflect ASR errors or disfluencies (and require editing) than frequent sequences and therefore used word sequence probability as an input feature in both detection tasks. In order to create a LM that did not include the ASR transcript edit regions and did not overfit to the final notes in the VGEENS Corpus, a LM was trained on a subset of the External Corpora that best matched the VGEENS Corpus. The Moore-Lewis data selection approach was used to select the subset of the External Corpora24. An LM was created using the final notes in the VGEENS Corpus training set, and a second LM was created from a random sampling of the sentences within the External Corpora of similar size to the final notes in the VGEENS Corpus training set. The cross entropy of each sentence in the External Corpora was calculated using each LM, and the
difference between the cross entropy scores was used to select the best matching sentences in the External Corpora (approximately half of the corpora selected, 3.3 M words). A LM based on the selected subset of the External Corpora was used in subsequent experimentation. All LMs were trigrams models with Kneser-Ney smoothing.

Topical Coherence

The topical coherence between the target word or sentence and the local context was scored using word embeddings. In the sentence-level edit detection task, topical coherence features were intended to identify sentences that were out of place within the section, potentially belonging in a different section of the note. A sentence-level vector representation was created by averaging the embeddings of each word in the target sentence, and a section-level vector representation was created by averaging the embeddings of each of the remaining words in the note section. The cosine similarity and the vector difference between the representations was then calculated. In the word-level edit detection task, topical coherence features were intended to identify words that did not fit the surrounding context, due to an ASR error. The target word embedding was compared to the averaged vector representation of words in the local context (current sentence without this word and +/- two sentences) using cosine similarity and vector difference.

Task-Specific Feature Sets

Table 3 and Table 4 contain a list of the features for the sentence-level and word-level edit detection tasks, respectively.

**Training and Evaluation**

The edit detection models (logistic regression and CRF) were trained using the VGEENS Corpus training set. Cross validation (three folds) was used to determine the best regularization type (L1-norm, L2-norm) and regularization weight for each feature set. For each feature set, the optimum L1-norm weight was determined with the L2-norm weight set to zero, and the optimum L2-norm weight was determined with the L1-norm weight set to zero. During cross validation, model performance was assessed using the Receiver Operating Characteristic (ROC) area under the curve (AUC). The final model for each feature set was trained on the entire training set using the selected regularization type and weight from cross validation.
The performance of the edit detection models was evaluated using the VGEENS Corpus testing set. Model performance was evaluated through ROC AUC and a performance analysis. In the edit detection tasks, the false detection rate ($P_f$) is the frequency of labeling a target as delete when the true label is keep, and the missed detection rate ($P_m$) is the frequency of labeling a target as keep when the true label is delete. In the performance analysis, $P_f$ was fixed at 15%, and $P_m$ was calculated. Conversely, $P_m$ was fixed at 15%, and $P_f$ was calculated. These $P_f$ and $P_m$ values were selected to understand model performance at different precision-recall operating points.

**Results**

*Sentence-level Edit Detection*

The sentence-level edit detection ROC AUC test results are presented in Table 5. The best performing single feature set was the words feature set, followed closely by the Brown classes. This suggests that the Brown classes capture the salient aspects of word context and syntax. The Brown classes, which are based on bigram occurrences, outperformed the skip-gram classes, which are based on word cooccurrence within a context window of length 10. The length/position feature set, which leverages the section structure of the clinical note, achieved high performance, despite a relatively small number of features (16 features). The TF-IDF/NMF topic modeling (VGEENS section feature set) achieved higher performance than the skip-gram topic modeling (skip-gram section feature set), even though the skip-gram embedding training set was approximately 13 times larger than the TF-IDF/NMF embedding training set. The TF-IDF/NMF approach utilized the structure of the note during topic learning, which may account for the higher performance. Two combined feature sets were tested: combined VGEENS using features based only on the VGEENS data and combined external, which added features based on external data. The combined feature sets outperformed the highest performing single feature, but the features based on external data had no added benefit. Figure 1 presents the error tradeoff curves for a subset of the feature sets evaluated.

**Figure 1.** Sentence-level edit detection error tradeoff curves
Table 6 presents more detailed performance analysis for three systems at three different operating points of the sentence-level edit detector. First, we compare $P_m$ for the different systems at $P_f=15\%$. At this operating point, the $P_m$ of the combined VGEENS feature set was 67% lower than the status quo where all targets are labeled *keep* (no edit detection used). Next, we compare $P_f$ for different systems at $P_m=15\%$. At this operating point, $P_f$ of the combined VGEEN feature set is 57% lower than the status quo. Since many studies assess performance using F-score, we include the results for the operating point with the best F-score for each system. The best performing feature set for all metrics was the combined VGEENS feature set, and the word indicator feature set performed only slightly worse than the combined VGEENS feature set.

Table 7 presents section-level edit examples based on predictions from the detection model trained on the combined VGEENS feature set at $P_f=15\%$. The first example, which was correctly labeled as *delete*, illustrates a case where the sentence indicates that additional information is required. We hypothesized that during the time between dictation and editing, new findings or conclusions were available, resulting in the sentence being deleted. The second example, which was incorrectly labeled as *delete*, is similar in that it includes the word “continue;” however, it does not imply additional follow-up. The third example was correctly labeled as *delete* and has a similar format (short phrase followed by a colon) to the topical headings within the notes. This heading does not conform to the section headings defined by the EHR, and the practitioner appears to have deleted this section heading and the associated note content. In example 4, the sentence was incorrectly labeled as *keep*. Similar to the first example, the example 4 implies additional information is needed, but there were insufficient cues for the system to predict a *delete* label. The sentence may have been deleted because the required consultation was performed.

Word-level Edit Detection

The word-level edit detection test ROC AUC results are presented in Table 8. For the CRF approach, the single feature sets with the highest performance were Brown classes and words. Similar to the sentence-level edit detection task, the discrete features defined by Brown classes outperformed those based on the skip-gram classes. While both word class approaches reduced the size of the feature space significantly, the Brown classes appeared to better capture the salient syntactic aspects of the words. In contrast to the sentence-level edit detection task, the skip-gram topic modeling approach outperformed the VGEENS topic approach for characterizing the word-level context match. This suggests that the external text is useful for characterizing words but not sentences, as is not surprising because of the more controlled format of the VGEENS notes.

The combined VGEENS feature set was created using the words and VGEENS section feature sets. The combined external feature set was created using the best performing word class (Brown classes) and topic model (skip-gram context) feature sets and the remaining feature sets. The combined VGEENS feature set did not outperform the words feature set, but the combined external feature set outperformed the highest performing single feature set and the combined VGEENS feature set by approximately 3%. Figure 2 presents the error tradeoff curves for a subset of the feature sets evaluated.

Table 9 has more detailed performance analysis again at three different operating points for two word-level edit detectors. Comparing $P_m$ for the different systems at $P_f = 15\%$, the $P_m$ of the combined external feature set was 45\% lower than the status quo (assuming all targets are keep). With $P_m$ fixed at 15\%, the combined external feature set $P_f$ was 46\% lower than the status quo. Again, the best performing feature set for all metrics was the combined external feature set, and the words feature set performed only slightly worse than this combined feature set.

Table 10 presents word-level edit detection examples based on predictions from the model trained on the combined external feature set with $P_f = 15\%$. Example 1 is from the Laboratory results section of the note and includes the word “restaurant,” which is a low probability word in this context and is not topically relevant. At $P_f = 15\%$, the model misses the deletion associated with the word “restaurant;” however the model correctly identifies this deletion at higher $P_f$. Example 2 includes the disfluency repair word “correction,” and the detection model correctly identified the deletion but incorrectly labeled “Temperature” as delete. Example 3 includes a common phrase that is abbreviated, which the model correctly labeled as delete; however, the model incorrectly labels additional words in the sentence as delete. Example 4 appears to include an ASR error (transcription of “technetium” instead of “magnesium”), which the model correctly labels as delete. Similar to examples 2 and 3, a false delete label is also applied within the sentence.

Conclusions

In this paper, we applied ASR error detection techniques to the automatic detection of sentence-level and word-level edits within clinical ASR transcripts. The results demonstrate that a substantial number of sentence- and word-level edits can be automatically detected with a small false detection rate. In both tasks, the word and word class feature sets were the highest performing single feature sets, indicating that word classes learned from external medical text resources using unsupervised Brown clustering are effective prediction features. Although the language model and topic-based features achieved lower performance than the word-based features, the results show that these features are relevant for edit detection in that the best performance in both detection tasks was achieved through a combination of features. The high performance achieved in the sentence-level tasks suggest a strong relationship between sentence editing habits and topical coherence within note sections. The best performance in the word-level task was achieved through the incorporation of external data.

This work is limited by the size of the corpus of clinical notes created using ASR and the number of practitioners involved in the creation of this corpus. A larger corpus, created by a larger sample of practitioners, would likely improve detection performance and improve the generalizability of the detection models to notes created with different dictation protocols. The methods used were also constrained by the ASR system configuration; access to alternative recognizer hypotheses or word confidence estimates would lead to further improvements in performance.

This work was motivated by the hypothesis that a correction tool that automatically detects and flags likely edits within ASR transcripts could improve note quality and accuracy. While the performance achieved in this investigation is likely not adequate to create a viable correction tool at this point, this work produced promising results that warrant further exploration, including the procurement of additional training data. Future work to improve performance would likely include incorporating additional, unlabeled data through semi-supervised learning and the inclusion of biomedical knowledge sources. A user study with practitioners is required to assess the required level of performance, determine the appropriate performance metrics and thresholds (precision, recall, etc.), and design the correction tool interface.

Abstract

Failure of timely follow-up imaging recommendations can result in suboptimal patient care. Evidence suggests that the use of conditional language in follow-up recommendations is associated with changes to follow-up compliance. Assuming that referring physicians prefer explicit guidance for follow-up recommendations, we develop algorithms to extract recommended modality and interval from follow-up imaging recommendations related to lung, thyroid and adrenal findings. Using a production dataset of 417,451 radiology reports, we observed that on average, follow-up interval was not mentioned in 79.4% of reports, and modality was missing in 47.4% of reports (4,819 reports contained a follow-up imaging recommendation for one of the three findings). We also developed an interactive dashboard to be used to monitor compliance rates. Recognizing the importance of increasing precision of follow-up recommendations, a quality improvement pilot study is underway with the goal of achieving a target where follow-up modality and interval are both explicitly specified.

Introduction

Radiology reports often contain follow-up imaging recommendations to monitor stability of potentially malignant findings, to ensure resolution of potentially serious disease, or for further diagnostic characterization [1]. However, failure to comply with imaging follow-up recommendations in a timely manner is common and can lead to delayed treatment, poor patient outcomes, unnecessary testing, lost revenue, and legal liability [1-3].

Follow-up recommendation detection in radiology reports has been an active area of research recently, although much of the focus has been on identifying recommendations associated with specific incidental findings [4, 5]. Incidental findings are those that were unexpected by the ordering provider and incidental to the primary reason for the current exam; for example, a small pulmonary nodule in the lower lobe of the lung may be detected on a CT abdomen and pelvis study that was ordered to evaluate right lower quadrant pain. Other studies have focused on identifying follow-up recommendations for a specific modality, such as CT [2], critical findings [6] or a particular type of finding, such as pulmonary nodules [7] or adrenal masses [8]. In order for follow-up detection algorithms to be more useful in routine practice, there is an opportunity to make algorithms scalable and generic so that recommendations can be identified from all radiology reports irrespective of modality or type of finding.

Imaging follow-up adherence rates have been reported to be low, with over 35% of follow-up imaging recommendations not followed-up [9]. In one study, 12% of cases of potential malignancy were not followed up appropriately [3]. Often, clinicians may determine that follow-up is unnecessary, especially when a follow-up recommendation is made non-applicable by clinical findings that were not available to the radiologist at the time of recommendation [1]. Various other reasons have been attributed to failure to follow-up, including the referring physicians missing the recommendations or losing track while addressing a more acute illness, loss of information during handover between care-teams, the recommendation not being communicated to the patient, and the patient failing to schedule or show-up for the follow-up appointment [10].

Despite various factors that may affect follow-up imaging adherence, one area where radiologists have room for improvement is in the quality and clarity of follow-up imaging recommendations. Referring physicians, especially primary care physicians who may not be as familiar with the latest imaging guidelines, value more explicit follow-up imaging recommendations by radiologists [11]. In fact, in a recent study, imaging follow-up rate was found to drop from 78.8% for no conditional language to 43.8% when conditional language was present [12]. Based on the assumptions that referring physicians prefer more explicit recommendations for follow-up imaging and specific recommendations will in turn improve follow-up compliance rates, in this paper we present a radiology report-processing pipeline that can be used to assess the quality of follow-up imaging recommendations. Further, to be clinically useful as a quality improvement tool, it is often important to identify the anatomy associated with a
follow-up recommendation since some clinical findings are more important to follow up than others. As such, we present a generic methodology to extract the anatomy with a focus on lung, thyroid and adrenal nodules. These three sets of findings have well established guidelines that include mentioning of specific time intervals and imaging modalities. We also present a dashboard that has been developed as part of a quality improvement initiative that can be used to routinely track follow-up recommendation rates by radiology academic section and/or anatomy as well as the quality of the recommendations.

Methods

Dataset
We extracted 417,451 radiology reports generated between 1-January-2015 and 31-May-2016 from the University of Washington radiology information system for three network hospitals. For each report, several meta-data fields were also extracted, including exam date, radiology subspecialty, patient class and modality. The Human Subjects Division at the University of Washington determined that the study was IRB exempt as part of a quality improvement project.

Report processing pipeline: follow-up detection (previous work)
The first step in the process was to identify reports that contained a follow-up imaging recommendation. This was performed using a previously developed follow-up detection algorithm which parses the radiology report to extract sections (e.g., “Clinical Indication”, “Findings” and “Impression” as shown in Figure 1), paragraph headers within each section if any (e.g., “Abdomen” and “Pelvis”) and the sentences within the paragraphs. The algorithm then evaluates the sentences within the “Findings” and “Impression” sections to determine if a sentence contains a follow-up recommendation (e.g., “Given history of malignancy, follow-up CT chest in 3 months is recommended”). Follow-up detection is performed using keyword searches and other heuristics. The output of this first step is a list of follow-up recommendation sentences as shown underlined in Figure 1 (along with meta data, such as whether it is a negated sentence – e.g., “no further follow-up is necessary”). Using 532 reports annotated for follow-up imaging recommendations by a radiologist (senior clinical author MG) as the ground truth, the detection algorithm was evaluated to have 93.2% PPV (95% CI: 89.8-94.5%), 99.5 NPV (95% CI: 98.4-99.9%) and 97.9% accuracy (95% CI: 96.2-98.5%).
Figure 1: Sample radiology report with multiple follow-up imaging recommendations. Underlining is added for emphasis and is not present in the original report.

Report processing pipeline: quality of recommendations

For the purposes of this study, a quality improvement oversight committee composed of multiple clinical and quality stakeholders decided that explicitly mentioning the suggested follow-up duration and modality of the recommended follow-up exam is an important indication of the quality of a follow-up imaging recommendation. For example, we hypothesize that “follow-up with a CT in 3-6 months to assess stability” will be preferred by more referring physicians compared to “follow-up to assess stability”. Due to the nature of specific health conditions, explicit mentioning of time interval and modality is not always possible, and as such, the initial goal of the pilot project was to achieve a reasonably high rate (e.g., 70%) agreed upon by relevant stakeholders.

Once a follow-up recommendation sentence was detected, the next step in the processing pipeline was to determine the modality and time interval associated with the follow-up recommendation sentence. Given the finite number of modalities and the numerical nature of the duration, we used regular expressions to extract this information. Sometimes the interval is explicit (e.g., follow-up in three months) and we accounted for this case as well. We observed that most intervals are specified in months, although in a few cases, “days” was used as well as “annually” (usually when referring to routine screening/monitoring related follow-ups). Therefore, intervals were calculated in
days, and a minimum and a maximum value were extracted (e.g., values 3 and 6 will be the minimum and maximum respectively from sentence “follow-up in 3-6 months”). Minimum and maximum were set to be the same if only one value was specified (e.g., “follow-up in 3 months”).

**Report processing pipeline: anatomy extraction**

Next, to identify the anatomy associated with the follow-up recommendation, we used an ontology based natural language processing engine previously developed [13] along with the publicly available NCBO annotation service [14]. Queries to both services were constrained to extract anatomies as defined by the SNOMED-CT ontology. Results were then merged and unique values selected. This approach was selected to optimize the capabilities of the two systems, for instance, if the text contains “right lower lobe”, the anatomy engine would detect “Structure of right lower lobe of lung” corresponding to SNOMED ID 266005 whereas NCBO would not find a mapping. Conversely, from the sentence “hypervascular liver lesion, MRI follow-up is suggested”, NCBO detected “Liver Structure”, corresponding to SNOMED ID 10200004 whereas the internal engine identified “Lesion of liver” (SNOMED ID 300331000), which is a finding. Since our focus is on identifying anatomy, in this instance, the engine did not find any relevant anatomy since a longer phrase was already matched.

Our follow-up anatomy detection algorithm was developed such that it first attempts to extract anatomy from the follow-up sentence – for instance, concept “Thoracic Structure” corresponding to ID 51185008 will be extracted from “Follow-up CT chest is recommended”. If no anatomy is identified in the follow-up sentence, the algorithm steps backwards from the follow-up sentence, processing one sentence at a time, until at least one anatomy is identified in a sentence. Search was restricted to the section in which the follow-up sentence occurred (which is usually ‘Findings’ and/or ‘Impression’ sections). Once identified, the ‘anatomy context’ becomes the text from the beginning of matched sentence to end of follow-up sentence. This process was repeated for all follow-up sentences when a report contained multiple recommendations. Table 1 shows four examples of extracted anatomy. For each follow-up recommendation, we also keep track of the previous two sentences which is referred to as ‘search context’. This search context can then be queried using regular expressions to detect the type of follow-up (e.g., whether follow-up recommendation is for a pulmonary nodule).

</tbody>
</table>

**Clinical use case and data visualization**

The stakeholders from the oversight committee decided to focus first on three commonly occurring findings for which published follow-up guidelines exist: lung, thyroid and adrenal nodules. Consequently, the scope of current research identified follow-up recommendations for these three findings. Keywords ‘nodule’, ‘lesion’, ‘tumor’, ‘lump’ and ‘mass’ were included for all three, while several additional descriptors were included at a finding-
specific level. We included ‘opacity’ for lung findings; ‘hypodensity’ and ‘fullness’ for adrenal findings; and ‘hypodensity’ and ‘opacity’ for thyroid findings. We required one of these nodule-related words to be within a 6-word proximity (after removing stop words) of where the anatomy was detected within the anatomy context to ensure the finding was actually related to the detected anatomy. When multiple anatomies are extracted, these results are consolidated in a post-processing step so that follow-up recommendations can be tracked at an exam level. For instance, if there are two follow-up recommendations in a report, one for lung, and one for thyroid, the consolidated anatomy will become “lung and thyroid”.

To accommodate routine monitoring of follow-up rates along with quality compliance rates (in terms of specifying duration and modality), we developed a dashboard that is updated on a monthly basis. An automated report is produced from the radiology information system that contains data for the previous month and the report processing pipeline is executed automatically. The dashboard was developed (using Microsoft Power BI, Redmond, WA) to share monthly quality metrics with specific radiology administrators, including Section Chiefs.

Algorithm validation

To validate our algorithm’s ability to correctly determine the anatomy associated with a follow-up imaging recommendation, we manually selected a total of 200 reports – 50 reports for each of the three follow-up finding types as well as 50 reports that contained a follow-up recommendation but were unrelated to the lung, adrenal or thyroid. This was performed by searching for the specific finding types in the “Findings” and “Impression” sections of randomly selected reports and repeating the process until the required dataset of 200 reports was created. The algorithm performance was 98.7% sensitivity (95% CI: 96.5-98.7%), 100% specificity (95% CI: 93.6-100%) and 99% accuracy (95% CI: 95.8-99%). There were two false-negatives, one related to an adrenal nodule and the other related to a lung nodule. A false-negative was defined as an instance where follow-up detection or anatomy extraction failed. Overall accuracy of 99% was slightly better than 97.9% follow-up detection accuracy reported previously since detection errors were rectified prior to anatomy extraction, which is the focus of the work presented herein.

Results

There were 27,375 (6.6%) reports that had at least one follow-up imaging recommendation sentence, a rate comparable to that observed by other researchers [15]. Of these, 4,819 exams contained at least one of the three specific finding types of interest. Table 2 shows the distribution of the follow-up recommendations by finding type and Table 3 shows the distribution by scanned modality (this is the modality of the performed exam for which the report contained a follow-up imaging recommendation). There were 3,909 CT Chest exams for all three anatomies that contained a follow-up recommendation of which 2,905 (74.3%) were lung related (lung: 2,775; lung and thyroid: 87; lung and adrenal: 43).

There were 3,828 (79.4%) lung, thyroid or adrenal related follow-up exams that contained at least one follow-up recommendation sentence where the minimum and/or maximum duration was not specified, and 2,282 (47.4%) reports with at least one follow-up recommendation sentence where the follow-up duration was not specified. 1,973 (40.9%) of the exams contained follow-up imaging recommendations that did not have the follow-up interval or the modality specified. Distribution of these by modality is shown in Table 4.

In order to provide radiology administrators with a quick overview of departmental trends and the ability to monitor the effectiveness of any quality improvement interventions over time, we also developed an interactive dashboard that shows the number and percentage of reports containing follow-up sentences by anatomy, modality as well as by month. Various filters have been provided so that a user can explore the data to understand various trends and opportunities for improvement. Figure 2 shows the number of reports containing follow-up recommendation sentences that are lung, thyroid or adrenal related for all sections across all three hospitals for the 18-month duration. A user can easily explore the underlying data that contributes towards a particular metric, for instance, a user can right-click on the CT bar showing ‘3.9k’ and examine the various report attributes (commonly referred to as a “drill down” capability).
Figure 2: Dashboard showing exams with follow-up recommendations

Note that a given report may be included simultaneously under the ‘Y’ and ‘N’ categories in the ‘Min/Max Duration Specified’ and ‘Modality Specified’ charts (shown in the center of the dashboard). This is because a report can contain multiple recommendation sentences. For instance, a report may contain the sentences “Follow-up recommended to ensure stability” with respect to a suspicious thyroid nodule and “Follow-up CT recommended in 3 months” for an indeterminate pulmonary nodule. This report will be included under ‘Lung and Thyroid’ row in the ‘#F/up Exams by Anatomy’ chart, and contribute to the values under ‘Y’ and ‘N’ in both ‘Min/Max Duration Specified’ and ‘Modality Specified’ charts. As a result, the sum of the ‘Y’ and ‘N’ categories in these two charts will be greater than the number of reports (4819 in this case). The bottom right chart shows the percentage and number of exams (in parenthesis) where duration and/or modality has not been specified as a function of the month of the exam, for instance, 82% is 196/240 for January 2015, and 56% is 135/240 (value 240 can be seen in the top right chart which shows the number of exams with follow-up recommendations by month).

In Figure 2, the ‘Anatomy filter’ (in top left) shows the consolidated list of anatomies for a given report. Since a report can contain multiple recommendations, if the multiple recommendations are not consolidated at a report level (e.g., to “lung and thyroid”), the default dashboard behaviour is to count the report independently under each anatomy (e.g., the same report will be included once under ‘lung’ and again under ‘thyroid’) resulting in an inaccurate total exam count; therefore, after anatomy associated with all follow-up recommendations were extracted for a report, an additional step was performed to consolidate the anatomies associated with the extracted recommendations.

Discussion

In this manuscript, we outlined a generic report processing pipeline that can be used to determine the consistent use of language within follow-up recommendations. Using production data, we have also demonstrated how the pipeline can be used to extract follow-up recommendation sentences associated with lung, thyroid and adrenal nodules for multiple imaging modalities. A key strength of this work is the integration of multiple components to provide an end-to-end solution, starting with a raw data extract from the radiology information system all the way through to automatically updating a dashboard that can be used to support quality improvement initiatives. The technology presented can be used in several ways, including: (1) radiology administrators can use the dashboard to determine
how the number of follow-up recommendations is trending over time as well as the quality of these follow-up recommendations by section; (2) the technology has the potential to be used as a surrogate to identify incidental findings by filtering for exams where the anatomy of follow-up recommendation is different from anatomy of ordered exam; and (3) follow-up detection can be used as a basis to determine follow-up recommendation adherence rates and design appropriate interventions if adherence rates are low.

Despite using a production dataset from three institutions, the current study has several limitations. First, we have only anecdotal evidence that referring physicians value the inclusion of follow up interval and modality when follow-up imaging is recommended. Although follow-up language has been cited as one of the factors that influences a referring physician’s decision to follow-up on imaging recommendations [11, 12] and we believe that more specific recommendations can aid in referring physician to have a more informed conversation with the patient, we did not validate this in the current study. Second, all reports were created using common dictation macros that are shared across the network hospitals and therefore the methods used to parse radiology reports may not be readily generalizable to other institutions. However, follow-up recommendation sentences within these reports did not uniformly use macros. Third, the algorithm performed imperfectly in 2 out of the 200 reports we examined to extract the anatomy. In one of these instances, the algorithm missed the follow-up statement which was mentioned in conjunction with another (“The attenuation coefficient of the left adrenal nodule is about 10 Hounsfield units. Therefore, it cannot be characterized as an adenoma. This could be characterized by CT at the same time as a renal mass protocol”). Although the pipeline failed to recognize this recommendation, it did identify the follow-up recommendation for the renal mass in the previous sentence, likely ensuring that follow-up would occur. In the other failed instance, “Multiple gray nodules are unchanged in size compared to prior, but remain indeterminate. Recommend follow-up CT in 12 months to assess for stability.”, the follow-up recommendation was correctly detected, but the anatomy was not (“gray nodules’ does not match any anatomy concepts in SNOMED). “Gray nodules” was almost certainly a voice recognition mistranscription of “pulmonary nodules.” This also shows some of the limitations of using an ontology-based approach to detect anatomy. Complementing the ontology-based approach with domain-specific dictionaries (e.g., using a text-to-anatomy dictionary where “gray nodule” is a key used to refer to anatomy “lung”) could be one option. We are also looking into generalizing the detection of nodule-related concepts. For instance, filtering for ‘morphologic abnormality’ concepts in SNOMED could be an option instead of specifying variants for ‘nodule’.

There are several potential applications for this algorithm in our department. First, we are planning to use the quality of follow-up imaging recommendations as one of the measures for performance based incentives for radiology seconds as part of a quality improvement pilot project. The goal is to achieve a target where follow up interval and modality are both explicitly specified in an attempt to improve the precision of follow-up recommendations. Incomplete follow-up recommendation sentences can be confusing for ordering clinicians who are unfamiliar with published imaging follow-up guidelines. We are in the process of implementing standardized follow-up macros and ensuring guideline uniformity among radiology sections in our department, and plan to measure their impact using this pipeline. Second, we can use this algorithm to benchmark our own follow-up compliance rate and variability with published clinical and departmental follow-up guidelines. Third, we can use this algorithm to ensure timely follow-up imaging of the appropriate body region using the appropriate duration and modality where applicable. Certain interventions can also be implemented within the department, for instance, by adopting techniques that have shown success in previous studies, such as asking radiologists to dictate certain phrases into the reports and alerting when follow-up is due [16], or by assigning explicit scores to indicate the degree of how suspicious a lesion is for possible malignancy and the need for follow-up [17].

We have demonstrated how a robust pipeline can be developed to quantify the quality of follow-up imaging recommendations, with proof points for lung, thyroid and adrenal related nodules. To improve appropriate follow-up language, it is important to be able to identify and to assess consistent phraseology of follow-up imaging recommendations. Given poor adherence rates with follow-up imaging recommendations, new techniques that are easily extensible without excessive human rework are needed to allow radiology administrators to easily identify opportunities where improvements can be made. With the gradual transition to value-based healthcare, improving precision of follow-up recommendations could be one of the ways radiology can provide more value to the referring physicians and contribute more towards the overall management of the patient.

Abstract

Nursing care documentation in electronic health records (EHRs) with standardized nursing terminologies (SNTs) can facilitate nursing’s participation in big data science that involves combining and analyzing multiple sources of data. Before merging SNTs data with other sources, it is important to understand how such data are being used and analyzed to support nursing practice. The main purpose of this systematic review was to identify studies using SNTs data, their aims and analytical methods. A two-phase systematic process resulted in inclusion and review of 35 publications. Aims of the studies ranged from describing most popular nursing diagnoses, outcomes, and interventions on a unit to predicting outcomes using multi-site data. Analytical techniques varied as well and included descriptive statistics, correlations, data mining, and predictive modeling. The review underscored the value of developing a deep understanding of the meaning and potential impact of nursing variables before merging with other sources of data.

Introduction

The main frontline providers of care are nurses who also represent the largest category of health workers in the hospital setting. Among the 2.8 million registered nurses currently working in the United States (U.S.), 61% work in hospitals whereas 19% of 297,100 pharmacists and 41.9% of 854,698 physicians in practice work in hospitals. Nurses are responsible 24 hours each day for continuously identifying care issues, implementing and adjusting care prescribed by themselves and other providers to achieve desired patient outcomes. To date, however, it has been difficult to effectively evaluate the impact of nursing on patient outcomes. The growing use of electronic health records (EHRs) to document care now offers the opportunity to use the data captured in practice for discovering knowledge to transform health care. Thus, the documentation entered by nurses into EHRs, for the first time ever, is a potential source for discovering the impact of nursing care on patient outcomes and using the knowledge to improve care. In this article, we report our systematic review of studies that utilized nursing EHRs data to answer a variety of research questions from describing nursing care for a specific population to predicting patient outcomes. The publications reviewed provide a foundation for identifying future paths of inquiry involving nursing and other data retrievable from EHRs.

The use of standardized nursing terminologies (SNTs) to document nursing care enables the easy retrieval and analysis of nursing data while also representing the nurse’s clinical reasoning. The integration of nursing data into large datasets requires the frequent and rapid input of new valid information from EHRs. These can be achieved through the use of controlled vocabularies in EHRs, which helps overcome the major challenges of aggregation, processing and analysis associated with unstructured text data. In nursing, SNTs are controlled vocabularies that represent nursing care as nursing diagnoses, interventions and outcomes. The SNT coded data retrieved from EHRs can be analyzed alone or merged with other EHRs data. The use of SNTs to document nursing practice is a big step toward supporting the aggregation of nursing data to large datasets and big data science.

Different sets of SNTs are used to document nursing care. The American Nurses Association (ANA) recognizes and supports the use of certain nursing terminologies to guide and document care if those have clear and unambiguous concepts, are coded with a unique identifier per concept, and if those terminologies were tested for reliability, clinical usefulness and validity. The following nursing terminologies are recognized by ANA: NANDA-International (NANDA-I); Nursing Interventions Classification (NIC); Nursing Outcomes Classification (NOC); International Classification for Nursing Practice (ICNP); Omaha System; Clinical Care Classification (CCC); and the Perioperative Nursing Data Set (PNDS). While ICNP, Omaha System, CCC and PNDS sets contain diagnoses, interventions and outcomes terms; NANDA-I (diagnoses), NIC (interventions) and NOC (outcomes) are three separate terminologies. Since NANDA-I, NIC and NOC are very often used together, we will refer to them as a terminology set (NNN).

Systematically reporting and analyzing studies that used SNTs nursing data retrieved from EHRs is important to understand the analytic issues related to the complexity and richness of data generated from the use of these
terminologies. Given the growing emphasis on using existing health care datasets, there is a need for new statistical, computational, and visualization methods to analyze EHRs data, given their complexity and volume. For nursing to join this effort, an important first step is to identify and examine the studies that analyze EHR data coded with SNTs.

To date, there are few reviews that report secondary analysis of SNTs nursing data. One recently published systematic review described study focus, sample characteristics and frequency of publications that studied SNTs. The authors also identified a limited set of studies in which SNTs nursing data were being analyzed. However, substantial evaluation and discussion on the analysis of SNTs nursing data were not performed. Another review described characteristics of nursing research data (ranging from patient demographics, social history, medical history, medications, among others) and evaluated if a specific index metadata system represents sufficiently nursing data. Our systematic review differentiates from the previous investigations as we focused only on studies that analyzed nursing data coded with SNTs retrieved from EHRs. The earlier literature review included all types of unstructured nursing data, and different types of studies, such as controlled clinical trials. The authors also did not restrict their selection criteria for nursing data retrieved from EHRs.

The systematic review presented below was conducted to describe and critically analyze the body of studies in which secondary analyses of data coded with the ANA recognized SNTs was performed. These nursing data were documented during the delivery of nursing care and retrieved from EHRs. We believe that the findings from the present systematic review will emphasize the importance of coded nursing data and will encourage a wider use of SNTs that will allow greater participation of nursing in big data science initiatives.

Objective

The objective of this systematic review was to uncover the state of the science related to the use of standardized nursing data (coded with SNTs) retrieved from EHRs to answer research questions, describe the analytical techniques employed, and outline the lessons learned applicable big data science and nursing.

Methods

Search strategy

A comprehensive literature search was conducted to identify publications in which secondary analysis was performed on data extracted from EHRs and documented using terms from the ANA recognized nursing terminologies (or sets). There were two phases used in this process: 1) study selection and 2) data collection process.

Building from the work of Tastan et al. that reported secondary uses of SNTs documentation in studies up to 2011, the databases PubMed and CINAHL were searched using keywords encompassing all ANA recognized SNTs, along with “nursing” and “electronic health records” from 2010 to 2017. Keywords were defined for each database with the help of a librarian, who was a specialist in Consumer Health, Nursing and Health Education and Behavior. The limiters since 2010, abstract available and published in English were used. Potential publications identified in both databases were downloaded into a reference management program (EndNote X7, Thompson Reuters ISI ResearchSoft), in which duplicates were deleted and abstracts were reviewed. Finally, grey literature search was conducted using Google Scholar to identify possible publications not captured by the traditional search methods, including relevant publications not in PubMed or CINAHL, but in computer science databases like IEEE. Name of authors of publications already reviewed and included in this study’s sample were individually searched in Google Scholar. Publications pertinent to the subject were reviewed and included.

Study selection

The studies identified using the specified search strategy were submitted to abstract review according to the following inclusion criteria: 1) publications that conducted secondary analysis of nursing data retrieved from EHRs, 2) nursing data were coded with one of the ANA recognized nursing terminologies and documented at the point-of-care, as part of the institution’s routine, and 3) publications were published in English. Following PRISMA guidelines, Figure 1 shows the number of publications first identified, retained after selection from abstracts, and reviewed as full text.

The team utilized a two-stage selection process. In the first stage, two doctoral students in nursing informatics (TM, ND) independently conducted the literature search in the databases using the same keywords and found the same number of studies. A guide created by the authors was used to systematically review the abstracts. The reviewers first identified if the article contained at least one of the ANA recognized SNTs. If the abstract described the use of a SNT, the reviewer would continue to verify if the data analyzed were retrieved from EHRs. In the case of an affirmative answer, the reviewers would further analyze the abstract to assess if the SNT coded nursing data were documented as
part of routine clinical practice and not solely for research purposes. Publications selected by one reviewer but not the other were discussed until agreement was reached. In the second stage, TM and MS (doctoral students) conducted a full-text review for further eligibility screening.

Data collection process

Data from the eligible publications were independently collected by TM and MS. Tables were created to summarize and analyze the content of the articles. The following information was extracted: study foci; sample characteristics (number of health records); variables (dependent, independent, descriptive); and statistical analysis. Data extracted from the selected articles were also reviewed by two faculty members, one specialist in nursing informatics and one statistician. Consensus agreement was reached. The present study aimed to report the diverse statistical analysis methods utilized and studies foci addressed through the use of SNTs coded nursing data. We did not intend to report the results of those publications.

Quality appraisal

Quality appraisal of publications is common in systematic reviews, however, it is challenging when the publications being reviewed are of the secondary data analysis nature. For the purpose of this review, quality appraisal of articles was evaluated regarding completeness of reporting of information. An adapted version of the STROBE Statement-checklist for observational studies was used, including the following items from the original checklist: study size, clear definition of variables, and description of all statistical methods used. Clear definition of variables was scored as 1 (not defined), 2 (partially defined), and 3 (well defined). These ratings considered if the variables in the publications were described with sufficient clarity to be replicated (collected) in further studies. As the previous stages of the review, authors independently (TM, MS) evaluated the completeness of the items mentioned in rounds until agreement was achieved.

Results

Abstracts of 1,809 publications were examined and 75 publications were retained according to the inclusion criteria. In the data collection process (second stage), of the 75 publications remaining, 40 were excluded due to different reasons as described in Figure 1. A total of 35 publications were included in our systematic review.

The studies included represent considerable diversity in terms of sample sizes, ranging from 29 to 379,601 health records. The largest sample sizes represent more than one unit in a single hospital or multiple hospitals, and more than one primary health care center. In these cases, the same EHR and SNTs were implemented across the institutions. Types of records portrayed in the studies encompass daily entries, or shift entries of nursing information into the EHRs at point-of-care. Episodes of care represent the entire history of a hospitalization, typically consisting of several entries for a unique patient hospitalization. For the purpose of this study, health records were defined as representing unique patients and health records entries were defined as daily/shift documentation of care.

In this review, we found studies for only three of the five terminology sets. There were no studies found for CCC and PNDS. There were 21 NNN articles, 10 Omaha System articles, three articles on ICNP, and one article that evaluated both NANDA-I and ICNP. Although all articles were published in English, we identified studies conducted in countries where English is not an official language. All articles on ICNP were conducted in South Korea, while all articles using the Omaha System were conducted in the US. The studies focusing on NNN were from Spain and U.S.

Descriptive, dependent and independent variables of each study were collected. In studies of descriptive nature, the variables analyzed were the nursing diagnoses, interventions and outcomes relevant to each set of SNTs. For studies in which statistical tests for associations were conducted, the majority of independent variables were the sets of SNTs, along with other factors related to delivery of care and the healthcare environment. Dependent variables in those studies varied significantly, including for example, occurrence of falls, pain, gender, age and medical diagnoses, nursing cost, among others.
Research foci encompassed different questions that could be answered by SNT coded nursing data. Twelve studies focused on characterization of units and patients regarding the most common nursing diagnoses, nursing interventions and nursing outcomes\textsuperscript{28-39} (Table 1). In two studies, authors described potential flaws in the terminologies regarding their content\textsuperscript{40-41} (Table 1).

Study of the nursing care through the use of SNTs included differences between standardized and non-standardized plans-of-care\textsuperscript{38}; comparison of nursing care provided and standard nursing care from guidelines\textsuperscript{32}; and testing different search strategies using nursing interventions to analyze the incidence of a medical complication.\textsuperscript{42} The benefits of using SNTs in EHRs to increase availability, validity, and reliability of data for statistical analyses and other research purposes were also described.\textsuperscript{34}

SNTs NOC and Omaha System were used across different studies, measuring changes in outcomes from admission to discharge.\textsuperscript{43-45} Both terminologies have a grading scale to be used by nurses daily to rate the nursing outcomes for each patient. In the studies\textsuperscript{43-45}, authors compared ratings given at admission and discharge to patients as a way of measuring effectiveness of care. Association of those ratings with other variables from EHR was also performed.\textsuperscript{43} One study focused on demonstrating differences between two statistical methods in describing changes in ratings for the Omaha System terminology.\textsuperscript{46}

| NNN  | To describe availability of plans-of-care data<sup>34</sup>  
To describe most prevalent NNN of an SNT-based electronic nursing documentation<sup>37</sup>  
To describe the most frequent NNN documented for hospitalized older patients with a primary discharge diagnosis-related group of pneumonia  
To describe the most frequent NNN documented for hospitalized older patients with a discharge primary diagnosis of heart failure<sup>33</sup>  
To report pain care from admission to discharge or death for end-of-life patients<sup>24</sup>  
To determine statistically significant changes in mean scores of outcomes from admission to discharge for specific medical diagnoses<sup>45</sup>  
To determine changes in outcomes scores from admission to discharge, and describe interventions for pediatric patients with dehydration<sup>44</sup>  
To measure the cost of delivering high surveillance, among hospitalized elders at risk for falling<sup>27</sup>  
To measure association among patient characteristics, unit characteristics, medical, pharmacy, and nursing interventions, and falls for older adults<sup>32</sup>  
To measure the association between high surveillance and low surveillance and the occurrence of failure to rescue<sup>46</sup>  
To establish association between degree of severity of problems and psychiatric diagnosis, number of nursing diagnoses, age, gender<sup>25</sup>  
To determine associations between the variables nursing characteristics and nursing cost per acute care episode<sup>26</sup>  
To identify patient and nurse-related factors associated with nursing outcomes for end-of-life patients with death anxiety<sup>41</sup>  
To report of NOC scores linked with the most frequent nursing interventions, age and length of stay<sup>16</sup>  
To describe the difference between plans-of-care with NNN and plans-of-care without NNN in relation to intermediate health outcomes<sup>9</sup>  
To measure association between the variable nurse continuity and the occurrence of pressure ulcers<sup>36</sup>  
Describe data mining techniques to predict whether a patient would meet the expected pain related outcomes<sup>35</sup>  
To develop predictive models that show how patient and nursing variables impact comfortable death outcome in end-of-life patients<sup>42</sup>  
To predict current NOC rating for each nurse shift based on previous shift ratings and factors related to nurse shift<sup>43</sup>  
To create predictive models that determine whether a patient with pain problems will be re-admitted to a hospital<sup>44</sup>  
To describe infomarkers that mark a shift in pain outcomes from standard care to palliative care among patients that died during hospitalization<sup>45</sup>  
| OS   | To describe client problems, interventions, categories and targets, along with outcomes documented for patients in a low-birth weight program<sup>28</sup>  
To describe all Omaha System data elements across multiple homecare settings using two different EHR vendors<sup>29</sup>  
To describe client risk index, family home visiting interventions between groups of low- and high-risk<sup>30</sup>  
To describe free text entry for the category Signs and Symptoms of the Omaha Classification<sup>31</sup>  
To describe free text entries associated with Omaha System on a software<sup>41</sup>  
To describe ratings of knowledge, behavior, and status on admission and discharge for Latina adolescent and adult mothers with mental problems<sup>43</sup>  
To demonstrate differences between p-values and Cohen’s d in describing clinically meaningful changes in scores for Omaha System problems<sup>46</sup>  
To determine which group of interventions predicts the outcome hospitalization for frail and non-frail elders<sup>47</sup>  
To measure association between patient, support system factors and nursing interventions and improvement in urinary and bowel incontinence<sup>49</sup>  
To determine the association between nurses, Omaha System interventions and client characteristics, and variability in health literacy<sup>40</sup>  
| ICNP | To describe variability in nursing intervention to prevent and treat pressure ulcer patients<sup>32</sup>  
To describe nursing preventive pressure-ulcer interventions and to compare with measures from two published guidelines<sup>35</sup>  
To describe narrative nursing statements of cancer patients treated with cisplatin-based chemotherapy<sup>34</sup>  
To test different computerized search strategies, to analyze the incidence and clinical characteristics of contrast media hypersensitivity<sup>42</sup>  
| N/ICNP | To describe key nursing diagnoses from the two terminologies for patients with heart failure<sup>39</sup>  
|<br>Key = NNN (NANDA-I, NOC, NIC); OS (Omaha System); N/ICNP (NANDA-I and ICNP). |
NOC and NIC were used to estimate nursing cost.\textsuperscript{26-27} Jenkins and Welton\textsuperscript{26} used the NOC rating scale as a measure of nursing intensity, and in turn, nursing cost. A different measure of nursing cost was used by Shever et al.\textsuperscript{27} In their study, NIC was used to measure the cost of delivering the nursing intervention surveillance. Surveillance was used as a measure of intensity of treatment, based on the average number of times a day that it was delivered (low or high). The number of times the intervention was performed was associated with the total hospital cost for the population under study.\textsuperscript{27}

In two studies the researchers examined relationships between nursing interventions and outcomes.\textsuperscript{47-48} Other (n=4) studies in the sample focused on establishing associations among a broader number of variables, such as patient characteristics, support system factors; nursing characteristics, nurse continuity, degree of severity of problems; medical diagnoses, pharmacy and nursing interventions, and nursing outcomes.\textsuperscript{22,25,50-51} Lodhi et al.\textsuperscript{51}, Lodhi et al.\textsuperscript{52}, and Lodhi et al.\textsuperscript{53} identified patient and nurse-related factors associated with meeting expected nursing outcomes.

Almasalha et al.\textsuperscript{23} focused on the use of SNTs to predict whether a patient would meet the expected outcomes by the end of a hospitalization period. Yao et al.\textsuperscript{54} identified specific elements of SNT related to changes in outcomes that could be used as an indicator for the adjustment from standard nursing care to palliative nursing care. Lastly, Lodhi et al.\textsuperscript{55} explored the creation of different predictive models for re-admission of patients that were diagnosed with pain during their last hospitalization.

### Statistical analysis

A total of 15 studies used only descriptive statistics to analyze their data. The following statistical analysis methods were present among the remaining studies: propensity scores\textsuperscript{26-48}, logistic regression and other regression methods\textsuperscript{27-29,48}; generalized estimating equations\textsuperscript{22,25,50-51}; data mining techniques\textsuperscript{22,47,51-53}; chi-square\textsuperscript{22,24,51-53}; t-test\textsuperscript{22,39,44-46};
ANOVA\textsuperscript{35,54}; Pearson correlation\textsuperscript{25,53}; Tukey’s post-hoc test\textsuperscript{4}; logistical mixed-effects model\textsuperscript{50}; effect sizes (Cohen’s d)\textsuperscript{46}; general linear mixed methods models\textsuperscript{43}; and known-group comparative analysis\textsuperscript{54}

Data from same institutions were used across different publications to answer a diverse number of research questions. Table 2 shows the progression of science and knowledge in nursing across the years. Publications are grouped by dataset (each group of institutions used the same EHR). It can be seen (see Table 2) that earlier publications used mostly descriptive statistics and advanced to generalized estimating equations, logistic regressions, and data mining procedures. Sample sizes varied across publications and more specific and complex statistical analysis were related to smaller parts of the datasets.

Quality of publications included

Among the 35 publications included in this systematic review, all described their study size, which was represented by number of health records or health records entries, and listed statistical analyses used. Definitions of variables were scored for the 35 publications; 74\% of the publications\textsuperscript{22-25,27-33,37,39-40,44-46,51-56} scored a 3 (variables well defined), 23\% of the publications\textsuperscript{26,34-35,38,41,42,49-50} scored a 2, and 3\% of the publications\textsuperscript{43} scored a 1. Overall, the studies were rated as good for completeness of reporting of information.

Discussion

The present systematic review provides important information about the types of studies that have been conducted on SNTs coded nursing data retrieved from EHRs. The 35 studies were identified and reviewed through a comprehensive systematic process. The SNTs NANDA-I, NOC, NIC and Omaha System were those implemented most often across different EHRs. Specifically, NNN was represented more in the hospital setting, while Omaha System was present in the primary level of healthcare. Worth noting however is that both of these terminologies can be used interchangeably between hospitals and primary health care centers.

There was great diversity in the questions addressed in each study and the variables analyzed. Characterization of nursing care through the most common nursing diagnoses, interventions and outcomes was the aim of some studies. Others focused on determining significant changes in outcomes from admission to discharge, measure cost of nursing interventions, establishing associations using variables inherent to nursing care and other variables found in EHRs. The creation and use of predictive outcomes models were also studied. This range of study foci show the potential of obtaining and translating new knowledge from nursing data coded with SNTs and the holistic approach of nursing care. It also brings the attention of researchers to the possibility of asking new questions aimed at improving patient outcomes, nursing practice and the healthcare system.

Among the studies included in the sample, most investigators either utilized descriptive analysis (mean, standard deviation, frequency, percentage, etc.) to describe terminology usage in different healthcare settings or relied on classical tests (e.g., ANOVA, Tukey’s Post Hoc, Chi-square, t-test, Mann Whitney U test, correlation test) to determine bivariate associations. Although of limited nature, descriptive studies are a first step to understand a dataset and the target population under study. Descriptive statistics are also very efficient and helpful in the identification of predictors with low variability that could be excluded in further analysis.\textsuperscript{7} The descriptive studies included in this systematic review provide a foundation for the nursing scientific community to move forward to the use of more sophisticated statistical methods.

The association analyses were those between the adoption of SNTs and patients’ outcomes, between nursing diagnosis and episode length, and between nursing interventions and patient outcomes. A number of articles conducted multivariate analysis utilizing regression analysis (e.g., generalized linear mixed regression, generalized estimating equations, logistic regression, etc.) incorporating techniques such as propensity score and clustering to examine the effects of patient, nurse, and care characteristics on patient outcomes. Finally, there were a few studies\textsuperscript{51-53,56} using data mining methods to identify hidden patterns among nursing care data or to construct predictive models for patient outcomes. Interesting results were reported in these studies. For example, the pain management, medication, management, and positioning interventions were collectively associated with pain relief among end-of-life patients.\textsuperscript{13} Continuity of nursing care was not associated with occurrence of pressure ulcers\textsuperscript{56} and predictive modeling on large EHR SNTs data can be used as foundation in nursing decision support.\textsuperscript{57}

Our systematic review revealed strengths of using SNTs to code nursing data. Data stored in digital format that are unstructured or not standardized pose difficult challenges to data processing and analysis.\textsuperscript{19,57} Unstructured data may obscure linkages among elements, adversely impact the validity of the data collected, and inadvertently fuel misunderstandings and errors. Words that describe care might have different meanings from unit to unit, and between
institutions, due to the fact that standards of care and cultures can vary considerably. The processing of unstructured data is also more time-consuming and labor-intensive when compared to SNT coded nursing data.

Nursing data coded with SNTs facilitates comparisons of patient care within and across institutions. The evidence generated in turn can enhance the decision-making process and demonstrate the impact of nursing care making nursing practice visible. The use of valid standardized nursing terminologies makes extraction of nursing data easier, reduces the cost of reporting quality measures, and produces interoperable data.

There are some limitations of this systematic review. The search focused on two databases, which excluded research studies that could have been published in books or sources not indexed by the selected databases, although some articles from other databases were identified through grey literature search. Also, the performed search strategies and the search terms used to uncover the literature may have excluded publications on the subject that used different search terms or keywords. That the focus of our review was on study methods rather than study results limits the overall conclusions that are informed by this review and point to the need for a review of study results.

A limitation identified among the studies included in this systematic review is the scarce integration and analysis of SNT coded nursing data with other parts of EHRs. In our sample, only four studies included other variables from EHRs in their analysis, such as medical diagnoses, pharmaceutical treatments and pressure ulcer rating scale. To be a part of big data science, nursing data not only need to be coded with SNTs, but also should be combined with other parts of the EHRs in order to enable big data analysis. An example of big data analysis in the healthcare field would be to examine relationships among nursing diagnoses, medical conditions and laboratory results and their impact on patients’ outcomes.

A main lesson learned for nursing and big data science is the extraordinary potential of coding nursing care with SNTs and using the data to understand the impact of nursing and continuously expand nursing science. Our systematic review highlights the importance of SNTs to enable faster retrieval and processing of nursing data and the application of big data analysis. Big data science can benefit from the integration of nursing data to other datasets. The care provided by nurses is unique and an important contribution to patient outcomes. Thus, including the nursing component in analyses involving health care outcomes is essential to learning the improvements nurses can make to enhance the overall patient outcomes achieved. In the absence of analyzable nursing care data, the impact of nursing will continue to be elusive. This review provided a lens into the uses and potential benefits of SNTs now and in the future.

Conclusion

The use of SNTs to code nursing data enables the aggregation of this fundamental part of EHRs to big data datasets. Secondary data analyses of nursing data using methods such as data mining and clustering techniques should be used more often as a way of finding more meaningful results that could change positively the nursing practice and impact directly the care received by patients. This systematic review underscored the value of developing a deeper understanding of the meaning and potential impact of nursing variables before merging with other sources of data. Further research is needed to analyze nursing data along with other parts of the EHRs, revealing possible associations among care variables from different health professions.

Detection of Adverse Drug Reactions using Medical Named Entities on Twitter

Andrew MacKinlay, PhD, Hafsah Aamer, BA, Antonio Jimeno Yepes, PhD
IBM Research, Carlton, Victoria, Australia

Abstract

Adverse Drug Reactions (ADRs) are unintentional reactions caused by a drug or combination of drugs taken by a patient. The current ADR reporting systems inevitably have delays in reporting such events. The broad scope of social media conversations on sites such as Twitter means that inevitably health-related topics will be covered. This means that these sites could then be used to detect potentially novel ADRs with less latency for subsequent further investigation. In this work, we investigate ADR surveillance using a large corpus of Twitter data, containing around 50 billion tweets spanning 3 years (2012-2014), and evaluate against over 3000 drugs reported in the FAERS database. This is both a larger corpus and broader selection of drugs than previous work in the domain. We compare the ADRs identified using our method to the FDA Adverse Event Reporting System (FAERS) database of ADRs reported using more traditional techniques, and find that Twitter is a useful resource for ADR detection up to 72% micro-averaged precision. Micro-averaged recall of 6% is achievable using only 10% of Twitter, indicating that with a higher-volume or targeted feed it would be possible to detect a large percentage of ADRs.

Introduction

Pre-marketing clinical trials are used to identify adverse events (such as side effects) of drugs before they are introduced in the market. However such trials will inevitably fail to find many of the Adverse Drug Reactions (ADRs) associated with a drug due to the size and time constraints of such trials. In particular, they are unlikely to find rarer ADRs, those which only occur in combination with other drugs or those which only appear after prolonged usage. The increasing numbers of ADR-related deaths indicate that post-marketing ADRs are an important public health problem, indicating the need for continuous automated ADR surveillance.

There are existing mechanisms to collect adverse drug events, which are typically managed by government agencies. In the US, the Food and Drug Administration (FDA) provides the FDA Adverse Event Reporting System (FAERS) while similar databases exist in other countries. Clinicians and consumers can use FAERS to report serious reactions that they encounter when taking a drug. However, there is considerable friction for users of these systems – consumers may not even be aware of them, and for both clinicians and consumers, the overhead of printing out, filling in and mailing or faxing a multiple-page PDF will act as a disincentive to reporting ADRs. Given that the only motivation for submitting these reports is altruism, it is likely that many ADRs are underreported, particularly those that are not life-threatening. While a more streamlined web-based reporting system could help alleviate this, there will likely always be a barrier to entry to such a formal reporting system which will continue to deter reporting of ADRs. There is also a large delay in these reports, partially due to the pharmaceutical companies which may receive the initial report. Examination of the FAERS data shows that the delay between an event being first encountered and the FDA receiving the first report is on average 1.1 years, with a standard deviation of 6.6 years.

Post-marketing surveillance has been shown to be effective using Yahoo query logs. Other recent studies used Natural Language Processing to extract pharmacovigilance related information from online resources including DailyStrength, Twitter, MedHelp, SIDER and others. In this paper, we concentrate on Twitter as a resource for ADR surveillance. With its high volume of 500 million tweets per day, Twitter is a promising data source to for ADR surveillance from a research and monitoring perspective, as the data is readily available using a simple API and less encumbered by legal and privacy issues than data derived from medical records. For consumers who may report health information including ADRs, awareness of the platform in general is high – even if none would consider it to be an ADR reporting platform – and, crucially, the effort required to actually post information is very low. We investigate whether this lower barrier and corresponding data volume offsets the fact that Twitter is not a platform targeted at ADRs. In contrast to

---

1. The first two authors contributed equally to this work
2. See https://www.fda.gov/Safety/MedWatch/HowToReport/default.htm
previous work, our experiments have been run on a large number of tweets – around 50 billion, spanning 3 years (2012-2014) – and investigated over 3000 drugs reported in the FAERS database, thus it is the largest study around pharmacovigilance using Twitter. We automatically compare identified adverse events in Twitter to those reported in the FAERS database.

**Methods**

To perform Twitter-based pharmacovigilance, we needed to automatically process our Twitter database to identify ADRs related to a given drug. We first detect relevant tweets for ADR, then aggregate tweet information from the set of relevant tweets to identify ADRs related to a given drug. This is summarised in Figure 1, along with the processing of the FDA FAERS database, which is described in more detail below.

A reference symptom list is needed to map symptoms from FAERS and Twitter, so information from both sources can be compared. We propose three symptom lists that make different assumptions in their development. To develop these we use the UMLS (Unified Medical Language System) version 2015AA.

**Symptom lists**

A Twitter user may not mention symptoms as technical terms such as *insomnia*, instead using phrasing such as *can’t sleep*. Relatedly, the informal language can include a wide range of terminology, so that *vomiting* may be described as *throwing up, chucking up or puking* for example. To attempt to incorporate the informal language of symptoms, the UMLS was used as source for synonyms FAERS uses MedDra as controlled vocabulary for adverse events, so it can easily be mapped to entries in the UMLS. Since the UMLS incorporates deliberately less formal terminologies such as the Consumer Health Vocabulary (CHV), the extracted synonyms are more likely to encompass the language used by non-medical users on Twitter although it only includes moderately colloquial language: the moderately informal *throwing up* appears in CHV but highly colloquial *chucking up* does not.

We considered three symptom lists to map the symptoms identified from Twitter and the FAERS database, so it was possible to compare them. These lists are designed to cover different subsets of symptoms to allow for a better understanding of the ADRs covered in Twitter. The first, Wiki, is designed to cover the symptoms that a lay person might use to describe their symptoms, which is further described below. We generated a layperson list of symptoms automatically by combining Wikipedia’s List of Symptoms with those from the Yom-Tov and Gabriovich. The second, UMLS, covers the set of symptoms identified under the *Sign or Symptom* UMLS semantic type, while the third, UMLS2, extends this list with additional UMLS semantic types – specifically T184 (*Sign or Symptom*), T048 (*Mental or Behavioral Dysfunction*) and T033 (*Finding*). The UMLS lists where generated automatically using a local database installation of the UMLS.

Table 1 shows statistics on the symptom lists, including the number of unique symptom terms or synonyms and the average number of synonyms per symptom. Wiki has fewer symptoms but more synonyms. UMLS2 includes more
Table 1: Synonym statistics per symptom list. The number of symptoms (Symptoms), number of unique synonym terms (Unique Synonyms) and the average number of synonyms per symptom (Synonyms/Symptom) are shown.

specific symptoms, which more often have only a single synonym, with 1.66 synonyms on average.

Drug name expansion

Different names might be used for drugs that have equivalent compositions, i.e. compounds might be distributed under several trade names. For instance, *alprazolam* is an anxiolytic that can be distributed under different names including *Xanax*. We used the UMLS Metathesaurus to find all trade names related to an equivalent active ingredient available from RxNorm. We start with an input drug name, then we use the RxNorm portion of the UMLS database (which provides names for all drugs available in the US) to map these to generic names before expanding out again to known trade names matching the generic name, then include all trade names and generic names as synonyms. For example, the trade name *Tylenol* would map to the generic name *Acetaminophen* which would in turn be expanded out to include brand names for other Acetaminophen preparations such as *Panateleve*, and all would be included as synonyms. This expansion process is used for matching drug names both from Twitter and the FAERS database, accounting for the possible variations in describing drugs in each case.

Extracting adverse drug reactions from the FAERS database

We downloaded all the files available up to October 2016 from the FAERS site and processed them following the workflow in Figure 1. FAERS contains adverse events reported much before 2012 (a broader time span compared to our Twitter data set). We extracted all the adverse reaction terms for drugs that were the primary suspect in a report. Drug names were filtered using RxNorm and a set of 3,050 drugs were selected and were used as the reference list of drugs for our study, discarding drugs not mappable to RxNorm. Examples of drugs not in RxNorm include *diclofenac potassium*, but its trade name *Cataflam* was included, even though it is not possible to determine this relationship automatically using the UMLS Metathesaurus.

In FAERS, adverse events are codified using the Medical Dictionary for Regulatory Activities (MedDra) terminology. MedDra terms have been mapped to the symptom lists mentioned above, so adverse events in FAERS can be compared to the adverse events identified from Twitter. Using the drug name expansion described above and the symptoms, the adverse events for a given drug are aggregated, so for each drug it is possible to find the number of reports in which an adverse event is mentioned.

Twitter database

We collected tweets over a three year period from 2012 to 2014 from GNIP Decahose, which provides a random sample of 10% of Twitter posts. We processed this data set of approximately 50 billion tweets by filtering out retweets and non-English tweets – yielding around 13 billion tweets – then automatically annotated them with named entities (NE) in the categories DISEASE, SYMPTOM and PHARMSUB (Pharmacological Substance) using a previously trained linear conditional random field (CRF) model on a manually annotated set of tweets. Tweets containing medical entities – approximately 230 million – were discarded for further processing into our Twitter database while others (the overwhelming majority) were discarded.

---

3[http://support.gnip.com/apis/firehose/overview.html#Decahose](http://support.gnip.com/apis/firehose/overview.html#Decahose)
Filtering of tweets for ADRs

The next step of this process was to filter these 230 million tweets containing medical entities to identify those that are relevant for ADR. This section describes the methods we used for this, using a pipeline of rule-based heuristic filtering followed by a second stage of filtering using machine learning.

Rule based filtering

The first step of the filtering was to select the tweets which mention a drug of interest generated from the FAERS database as explained above. The drug expansion name procedure described above was used for each drug in the FAERS-generated list to match the drugs in Twitter.

We extracted 18.9 million tweets (8.4% of total) with mentions of a drug listed in UMLS RxNorm database. We then filtered the tweets further to include only tweets with a Disease or Symptom entity as well as a PharmSub entity. We included both Disease and Symptom entities in our relevant tweet set because it is difficult to reliably distinguish between the two without considering the context, giving 533,000 tweets.

The automatically-annotated PharmSub entities contain many false positives, particularly due to drug names that coincide with words likely to be used in English. For example, Stay Awake is an alertness medication. Many tweets contained the phrase stay awake as a verb phrase with no relationship to the drug. Other such examples included fml, at 10 and my way. We removed tweets where the drug name was in this list which we produced by manual examination, yielding 393,000 tweets.

We also observed that many tweets mentioned drug names for advertisements, news and other purposes not related to first-hand experience with a drug and which were thus out of scope. For example: RT @BetterHealth1O1: Low fat yogurt contains tons of protein and calcium, which can fight hunger, stimulate weight loss by burning fat. This mentions calcium and weight loss but it is not indicating an ADR. We therefore filtered out the tweets with text that contained http assuming that these linked to advertisements, spam or news articles. Also, since much of the spam contained the word fact, due to usernames such as @AcneFacts, @thegoogleFact, @WhatTheFacts and @FactBook, such tweets were heuristically removed as well. These simple filters greatly reduced the volume of irrelevant tweets with relatively little effort, although more sophisticated relevance detection techniques could be considered.

Finally, there were entities that were annotated as PharmSub but they were too general to be taken as a cure for a disease and not specific enough for our study such as caffeine, cough syrup, vitamin d, zinc and pain killer. We manually prepared a stopword list based on the most frequently occurring mentions of these entities. After filtering out all the irrelevant tweets, we were left with 192,000 tweets potentially containing information about ADRs.

Feasibility of filtering using machine learning

By examining tweets in which a PharmSub co-occurs with a Disease or Symptom, we can find tweets which may describe ADR events. However, it would also be useful to determine whether the Disease or Symptom is the primary target of the drug – the condition which the drug is designed to treat – or an ADR. For example, if allergy is mentioned with a drug name, was the user taking the drug to treat existing allergy symptoms, or did allergy symptoms appear as a side effect of taking the drug? We attempted to answer this question using machine learning, by training a supervised classifier to identify relevant tweets for pharmovigilance.

We manually labelled 2,917 random tweets as either relevant or irrelevant for ADR detection. As tweets are short with limited context, differentiating symptoms which the drug treats from ADR symptoms is not easy for a human to do accurately. We also evaluated the results of merging our data with 4,799 ADR labelled tweets made available by Sarker et al.18, giving us 7,716 labelled tweets for training. We used Weka’s SVM implementation and a bag-of-words model, and evaluated the classifier using 10-fold cross-validation. The results of this are shown in Table 2. Our intention had been to use this classifier as an extra filtering layer for the 192,000 tweets remaining after the previously-

\[\text{This is likely due to the underlying NE tagger using features derived from a UMLS drug name database}\]

\[\text{The human annotator did not look up history for the user to add context, as this information was not available in our automatic classification scenario either}\]
described rule-based filtering, however in the resulting classifiers, the recall was below 36%. Incorporating this classifier into a filtering pipeline would unsurprisingly improve the overall precision, but the large loss in recall would be such that the classifier would be detrimental on balance, especially as achieving good recall is the biggest challenge. Such classification could still have value for precision-focused applications of ADR (for example if we wanted to apply these methods to the entirety of Twitter with lower risk of false positives), but for the remainder of this paper, we report on results without this filtering step.

Results

One of the potential benefits of our approach is timeliness of information compared to government-controlled databases which can be slow to respond to new information. As such, the most informative analysis would evaluate how often the ADRs detected using our method preceded the first mention in FAERS. Our Twitter data set has tweets from 2012, but since many of the drugs considered in this study were released before 2012, it would have vastly reduced the number of drugs that we could have considered, which is a key aspect of this study. The downloadable FAERS data contains information about several dates, including the event date, the date the manufacturer was notified and dates when FAERS received the first notification; this information could be considered in a follow up study to quantify how timely the Twitter ADR detection can be.

Instead, we ignored time information, and compared our ADRs derived from Twitter with those reported in the FAERS database as explained above. We calculated precision, recall and F-score as both macro-averages (aggregated by drug, ignoring drugs which have no positives produced by our method and thus undefined precision) and micro-averages (including all drug-ADR combinations which came from FAERS).

This evaluation is suboptimal in another important way – our ground truth derived from FAERS is imperfect. In particular many ADRs may not have ended up in there due to aforementioned reporting delays or underreporting. So, if our method produces a purported false positive according to this evaluation, it may be a true but hitherto unknown ADR. A manual examination of random selection of tweets relating to false positive ADRs would indicate the plausibility off this, however this is left as an area for future work.

Table 3 shows the micro-averages and the macro-averages when comparing the results obtained from Twitter with the 3,055 drugs reported in FAERS. Note that not all of the drugs have a mapping to the list of ADRs that we have selected. The average numbers of ADRs per drug is significantly lower in our Twitter dataset compared to the number of ADRs reported per drug in FAERS. The approach clearly shows promise but there is much room for improvement in the recall. This work uses the GNIP Decahose, which has a large data volume but still comprises just 10% of Twitter. It is difficult to access the remaining 90% but it is likely that if we could apply these methods to the whole of Twitter (which is computationally very feasible) that the recall would be dramatically improved by detecting more ADRs from the long tail (although perhaps not linearly with the data set size, as many common drug-ADR combinations would be detected repeatedly). It is less clear whether or not expanding the data set would maintain the precision.

To get an idea of the trajectories of the precision and recall figures when changing the data set size, we have plotted learning curves using smaller subsets of the data, shown in Figure 2. The precision does decrease slightly as the data set size increases, however this is more than offset by the improved recall, and as a result the F-score shows a steady improvement as the data set size increases. We cannot justifiably claim that we could simply extrapolate linearly to

---

18Interestingly this was largely unchanged by the addition of the extra training data, perhaps due to different assumptions underlying the other data set meaning there was little extra new and consistent information for the classifier to learn from
Table 3: Results selecting drugs for which FAERS ADRs could be mapped to the symptom lists. Number of drugs from FAERS (FDrugs), number of drugs from Twitter (TDrugs), average number of ADRs per drug in FAERS (FADRs) and Twitter (TADRs) and performance measures are shown. Performance measures are reported for micro and macro-averages: miPr (micro precision), miRe (micro recall), miF1 (micro F1), maPr (macro precision), maRe (macro recall) and maF1 (macro F1). Macro-averages are aggregated by drug name, and exclude results with no predicted positives (and therefore undefined precision).

extend these curves to the right for hypothetical larger data sets, however, it is almost certain that both recall and overall F-score would continue to improve as we added more Twitter data if such data were available.

Discussion

The analysis presented in the Results section summarises results on 3,050 drugs. In this section, we provide examples of the set of ADRs identified in Twitter mapped to FAERS and the ones missed by FAERS or Twitter.

Table 4 shows examples of the most frequent ADRs matched in Twitter and FAERS. There are three results, one per symptom list. The ADRs are similar in the three lists with some lexical variation for the same ADR, which only affects presentation but not performance. The number of distinct ADRs is larger for the UMLS2 ADRs list due to the larger
set of symptoms in this list.

Table 4: True positives: 10 most frequent ADRs in FAERS that could be predicted using Twitter for a given drug. ADRs are shown by symptom list and the row Count shows the number of unique ADRs.

Table 5 shows the most frequent ADRs missed by Twitter. Some of the ADRs are able be identified at least for some drugs in Twitter as they appear in the true positives list in Table 4, and yet are still false negatives for individual drugs (e.g. nausea, vomit and dizziness). These false negatives are the largest category, and thus represent most of the divergences between FAERS and Twitter. Some ADRs such as diarrhea or tachycardia may be difficult to find in Twitter due to a lower likelihood of people mentioning these symptoms in such a medium due to taboos or specificity. Most are likely due to the latter: for any given drug, the majority of false negative ADRs (beyond what is presented in the table) are infrequently reported and often highly specific, representing the “long tail” of ADRs (with little validation beyond a small handful of reports), such as breast skin orange peel texture and edema eyelid. Capturing such events, the extent that is possible based on Twitter, could likely be improved by increasing the data volume even further, which we discuss further below.

Table 5: False negatives: 10 most frequent ADRs in FAERS that could not be predicted using Twitter for a given drug. ADRs are shown by symptom list and the row Count shows the number of unique ADRs.

There are also ADRs that are discovered using our method from the Twitter data but are not present in FAERS. Examples of the most frequent ADRs from this category are present in Table 6. Some are clearly false positives. For example, there are some potential ADRs that are too generic to be collected by FAERS, e.g. sick, illness (finding). There are also some ADRs that seem very similar in meaning, e.g. asthenia and weak or pain and ache, which would require extra analysis to group into the same ADR. Some, such as hangover effect or black out, are sometimes used
colloquially, so it is not clear whether they would match to their literal interpretation if we more diligently mapped them to FAERS symptoms. On the other hand, there are some potential ADRs, for instance stomach ache or pyrosis for certain drugs, which may be hitherto unknown side effects for these drugs.

Table 6: False positives: 10 most frequent predicted ADRs from Twitter which did not appear in FAERS for a given drug. Symptoms are shown by symptom list and the row Count shows the number of unique symptoms.

We have further examined specific drugs, selecting Aleve and Vicodin – some of the top occurring drugs in FAERS – for discussion. Table 7 shows true positive, false positive and false negative ADRs when comparing Twitter vs FAERS, using Wiki as the reference ADRs. True positives are ADRs found in both Twitter and FAERS, false positives are ADRs found in Twitter but not in FAERS and false negatives are ADRs found in FAERS only. Note that we show only the top 10 most frequent symptoms in both FAERS and Twitter.

</tr>
</tbody>
</table>

Table 7: ADRs matched, missed or falsely detected from the top ten set from Twitter against FAERS

Aleve is an over-the-counter (OTC) pain relief drug. Over 10 of the ADRs predicted by Twitter were matched for Aleve. We anticipate that since Aleve is an OTC drug it may not have extreme side effects. We also observed that the true positives included the primary targets of the drug: fever, headache or toothache could easily be the reason for using Aleve rather than a side effect. However, headache and pain also appear amongst the frequent side effect for Aleve in SIDER20 (Side Effect Resource database’s), showing the challenge of differentiating between primary target symptoms and ADRs. Vicodin is a prescription drug used for moderate to severe pain. Most of the side effects predicted by Twitter match the ADRs in FAERS. The false positives in some cases are similar to false negatives (light-headed vs vertigo), suggesting, as seen before, that additional work on normalization of symptoms might help.

Our Named Entity Recognition (NER)-based method is highly scalable to large datasets such as Twitter. However, it misses particular classes of information. In particular, some classes of ADRs are not often encoded as simple medical named entities. For example drug ineffective is a frequent MedDra reaction listed in FAERS, including for the drug Advil. And indeed, when Advil is mentioned in Twitter, it is often in ways which indicate that users are experiencing a lack of effectiveness (but which our method is not able to detect), e.g. I still have a headache, Advil get your shit together or I must have taken like 8 Advil today and I still feel and look like hammered shit #sosore.

4http://sideeffects.embl.de
Our method also has no knowledge of the context surrounding a particular NE mention. Often this is not a problem but in particular cases it greatly affects the semantics of an entity. For example, sleepy was usually annotated as a symptom by our NE tagger, however in many of these cases it was modified by not, e.g. I’m just not sleepy tonight (and there could also be more complex forms of phrasal negation such as never very sleepy these days). This negation changes the symptom from sleepiness to insomnia, suggesting we need to incorporate modification such as negation in our annotations. Finally we could doubtless improve the normalization of the symptoms, so that vertigo could be mapped to light-headed to account for vocabulary differences between people. Word embeddings may be a useful starting point for this but we have not yet investigated this; these could potentially also help with capturing language too informal to be covered in the CHV such as the previously-mentioned chucking up example.

**Conclusion**

In this paper, we extracted relevant posts from Twitter containing mentions of drugs and symptoms from a three year time period (2012-2014) and processed them automatically using natural language processing to identify adverse drug reactions. The method shows promise as an additional source of ADR information to traditional reporting methods, with respectable precision of 42-75% depending on the dataset (or even higher if our ML-based filtering method is used). However, the low recall shows that this method still suffers from Twitter being a data set without any specific medical focus, but as we hypothesised, the volume of tweets available helps to partially offset this. Using 10% of all tweets over only 3 years, recall is only 3-6% but our learning curves support the fact that this would increase substantially with more data, either over a longer time period or with a higher relative proportion of Twitter.

We suspect the ADRs being uncovered using Twitter are at least somewhat complementary to those in FAERS (out of all our false positives, it is likely that some are actually novel ADRs), but this is difficult to assess without further investigation. It would be possible for a small team at a pharmaceutical company or public health authority to manually examine each false positive (ie potentially novel ADR) in close to real time, as after all of the filtering, the data volume is relatively manageable. Over the three year period, we uncovered around 200,000 possibly relevant tweets, of which around 50,000–100,000 would be false positives, which is around 50-100 tweets per day to manually examine. Many could be rapidly discarded (or they could be further pre-filtered using our trained ML model described above to improve the precision) and the remainder could be flagged for further investigation. While there is much room for refinement of our techniques, the primary gains would be by expanding to a larger data set to yield an effective technique for ADR using Twitter.

**Acknowledgments**

We would like to thank Elad Yom-Tov for the support to generate a symptom list based on Elad’s previous work.

Usability and Learnability of RxUniverse, an Enterprise-Wide App Prescribing Platform Used in an Academic Tertiary Care Hospital

Sonya Makhni, MD/ MBA1, Rivelle Zlatopolsky2, Farah Fasihuddin, MPH3, Misael Aponte4, Jason Rogers5, Ashish Atreja MD/ MPH.6

Abstract

The objective of this study was to assess the usability of RxUniverse, a novel platform that enables health care providers to directly disseminate proven, evidence-based mobile health apps to patients. Among five pilot clinical sites, 40 physicians and front-line providers were trained on the RxUniverse platform. They were educated on the platform’s functionality and instructed how to prescribe apps to their patients. The well-validated System Usability Score (SUS) was used to assess the usability of the platform. The adoption goal was set as 100 prescriptions of relevant apps within an 8-week pilot period. Within the pilot period, over 2000 apps were prescribed. Nineteen responses were received from the System Usability Score survey, and the platform received a usability score of 84.2, which is in the 96th percentile across all systems. The pilot study outcomes demonstrate the high adoption and usability of the RxUniverse platform.

Introduction

Digital medicine is the subset of new technologies and mobile applications that demonstrate, or aim to demonstrate, positive impacts in the treatment and management of disease. Several hundred thousand digital medicine tools, such as mobile health (mHealth) applications, have been developed and released. In fact, there are approximately 259,000 mHealth apps available across the major app stores, and these are produced by an estimated 58,000 mHealth publishers. These numbers are increased from 2015 and years prior, and as the clinical community continues to seek solutions that further engage and empower patients, we can expect continued growth within the mHealth space in the years to come.

Such extensive proliferation of mobile health technologies can in part be explained by the increasing body of research that correlates more engaged and activated patients with improved clinical, behavioral, and utilization outcomes. Mobile health applications can potentially serve as tools to empower patients to become more actively engaged in their care, and thus more effective self-managers of their own health. For these reasons, developers are creating mHealth solutions ranging widely from remote monitoring tools, to chronic disease management platforms, to behavioral modification apps.

The rapid proliferation of mHealth apps has led to two notable unintended challenges. The first is that providers have no standardized way of ascertaining which apps are best suited to their patients. Evaluation of clinical interventions traditionally relies on rigorous study design and peer-review, but these are lacking for the vast majority of mHealth apps. Many developers advertise the potential health benefits of a given mHealth app to would-be patients and prescribers, and consumer reviews for some products do exist, but it is difficult to ascertain how much of these claims are substantiated by rigorous, evidence-based proof. As a result, health care providers find it difficult to objectively assess an app’s efficacy and usability.

Second, providers have no streamlined way of directly disseminating the appropriate mHealth apps to patients. Current practices are bulky and place the burden on patients to locate and download the appropriate app, and on providers to accurately and efficiently direct them to the accurate app. There is a lack of effective filtering and organization of the mHealth apps within any given app store, and this translates to worsened execution in finding and disseminating a specific mHealth tool. As such, the benefits of mobile health technologies can neither be fully felt nor properly evaluated.

To address these concerns, RxUniverse (http://rxuniverse.com) was developed at the Mount Sinai AppLab. It is a digital medicine-centric care delivery platform that features a catalogue of apps that have been curated based off of published, evidence-based reviews regarding their efficacy and usability; additionally, it incorporates user-centered
features that enable efficient, direct dissemination to patients. The purpose of RxUniverse is to enable physicians to rapidly adopt digital medicine technologies and strategies within clinical care, to facilitate the effective dissemination of these technologies to patients, and to provide an ecosystem that promotes the evidence-based review of various digital medicine technologies.

A pilot study was conducted at the Mount Sinai Health System to assess the usability and adoption of RxUniverse, the first standardized platform to facilitate both curation and dissemination of mHealth apps.

**Methods**

*Platform Description and Specifications*

The platform assessed in this study was the RxUniverse mobile health platform, which was developed by Mount Sinai researchers at the Mount Sinai AppLab. RxUniverse integrates into any web browser, Android, or iOS device-based workflow. Development environment produced a Node.js web application built using AngularJS 1.4.3 framework hosted on an Azure back-end with a data model persisted in Microsoft SQL Server. Communication on the backend is done through full RESTful API for a data layer running on Azure SQL server. All data was stored on a HIPPA secure database that could only be securely accessed by members of the RxUniverse research team.

The application solves discovery challenges by allowing providers to find healthcare apps using an advanced filter relevant to their specialties, disease, type of app, or functionality, and to prescribe apps directly from their mobile device or within a linked EHR. RxUniverse addresses the evidence challenge by allowing providers to rank apps and share their rating with their peers, to find apps which are FDA approved, and to read a brief peer-reviewed synopsis about the app and links to evidence published in literature.

*Clinical Sites and Participants*

Five outpatient clinical sites within the Mount Sinai Health System were selected to participate in the eight-week pilot study: two primary care clinics, one pulmonology clinic, one gastroenterology clinic, and one cardiology clinic. Clinic sites were chosen based off the following general criteria: outpatient primary care or specialty clinic, standardized work-flows, clinician interest in integrating use of at least one mHealth app into clinical care. Project procedures were carried out as part of standard of care.

*User Training on RxUniverse Platform*

Among these sites, 40 physicians and front-line providers, consisting of medical assistants and receptionists, were trained on the use of the RxUniverse platform. They were individually instructed by one of two researchers using a standardized protocol of instruction, lasting approximately 5-7 minutes. Each instruction session consisted of introduction to the platform’s purpose, a demonstration of its functionality in both the web and mobile interfaces, and an observed trial process of prescribing an app. Upon completion of the training, each new user was given a unique username and password.

Users were instructed to direct message via text or email from the platform’s interface, or “prescribe”, a mobile health app to each patient seen. Eight to ten institutionally approved apps were pre-selected for use during the pilot study and were available to the users on the platform to prescribe to patients. Careful consideration was given to the specific operational workflows of each clinical site, and both office managers and user volunteers were consulted in devising the optimal implementation plan for RxUniverse at each pilot site so as to minimize time burden on the volunteer users. Three clinics primarily relied on front desk receptionists to disseminate mHealth apps upon patient check-in. Two clinics utilized medical assistants to prescribe apps, either during patient intake or while patients waited in the waiting area. Two of these five clinical sites used a hybrid method that integrated both medical assistants and front-desk receptionists.

*Measures*
The System Usability Scale (SUS) is a very reliable tool\(^4,5\) designed to obtain subjective feedback on overall usability and user satisfaction. According to Nielsen, usability is a “quality attribute that assesses how easy user interfaces are to use”\(^3\). Learnability is considered to be a component of usability and refers to the ease by which users are able to learn to use the technology\(^3\). This is a 10-item questionnaire with a 5-point Likert scale, with response options ranging from 1 (Strongly disagree) to 5 (Strongly agree). Items 1, 3, 5, 7, and 9 are positively worded and items 2, 4, 6, 8, and 10 are negatively worded. The SUS is able to effectively discern both good and bad usability features even with small sample sizes (<10). Ratings for SUS scores are as follows: 0–64 is unacceptable, 65–84 is acceptable, 85–100 is excellent, with a score of 82 representing the likelihood to recommend (LTR) threshold. Users are likely to recommend a product that has an average SUS score of 82, whereas users would not recommend a product that has an average SUS score of 67\(^6\). Using factor analysis, the SUS is able to provide additional information via two sub-scales: an 8-item “Usability” and 2-item “Learnability” scale\(^7,8\).

Analysis

Success of the RxUniverse platform was measured in terms of number of apps prescribed and system usability. The number and type of apps prescribed by each user was tracked on a daily basis. The prescription of 100 relevant app prescriptions within the 8-week pilot period was set as the adoption goal. Adoption targets were based off of a prior study conducted by Mount Sinai AppLab researchers in determining the impact of a novel mobile health app, HealthPROMISE, in improving health and satisfaction outcomes. Weekly progress updates were sent to volunteer users and their respective clinic managers and physician sponsors.

Following the completion of the pilot study, the well-validated System Usability Score (SUS) was used to assess the usability of the platform. Descriptive analysis of demographic and individual SUS questionnaire items were conducted in excel to examine measures of central tendency and variability as well as level of use of the users. User responses were then converted to 0–100 percentiles as per SUS guidelines\(^9\) and scored by comparing them to standard rating scales\(^10\). The mean SUS score for all participants was calculated. Likelihood to Recommend (LTR) was determined by comparing overall mean SUS score to industry thresholds.

Results

Adoption

Within the 8-week pilot period, over 2000 apps were prescribed across all users among the five clinical sites. Of the 40 providers trained on the RxUniverse platform, 26 prescribed >5 apps during the trial period. Of these 26 individuals, 18 prescribed >20 apps, 14 prescribed >50 apps, and 5 prescribed >80 apps (Table 1). 58% of users reported frequent use (weekly or daily) of the platform.

Demographics

A total of 19 care providers / users completed the SUS questionnaire (response rate: 47.5%). Three respondents had more than 2 items with missing data on the SUS portion of their survey, they were still reported (Table 3), however
were excluded from the tabulation of the SUS scoring. In all, 63.16% of included respondents (n=12) reported their age as being between 36-45 and between 46-55 respectively. 73.68% of respondents were female (n=14). The sample was also diverse in terms of frequency with which users interacted with RxUniverse. In all, 57.9% (n=11) of the participants reported using RxUniverse “daily” or “weekly”, with the remaining 26.32% (n=5) only using the system a few times per month (Table 2, 3).

* Items 2, 4, 6, 8, and 10 are negatively worded. Lower Means for these items represent higher perceived satisfaction.

SUS: System Usability Scale; CI: confidence interval; SD: standard deviation.

**System Usability and Satisfaction**

Overall, users felt that RxUniverse performed well. The group mean for overall SUS score was 84.2, an “Excellent” rating based on standard SUS¹. RxU met the industry benchmark SUS score of at least 80 for users to likely promote your product. The mean score for the “Usability” sub-scale was 82.7 and the mean score for the “Learnability” sub-scale was 90. Individual item means are reported in Table 4. The majority of users had a favorable opinion about RxUniverse in terms of how confident they felt using the system (Q9) (4.67 with 95% CI of 4.29-5.05) and ease of use (Q3 and Q7). The “I found RxUniverse unnecessarily complex” question (Q2) indicates the respondents who felt mild concern.

A raw SUS score of 84.2 has a higher SUS score than 96.19% of all products. We can be 95% confident the population SUS score is between 78.28 and 90.06. With a mean SUS of 84.2 and a standard deviation of 10.6 – compared to global SUS population benchmark of 68 and standard deviation of 12.5 – a t-statistic was calculated. The sample standard deviation was selected as a point of comparison, since it is more specific to this technology. The resulting t-score yields a p-value below 0.005 (0.001), allowing us to confirm the statistical significance of this pilot sample (Figures 1, 2). RxUniverse scored highest in the learnability category of the SUS score, with an average score found to be 90 (Figure 1).

![Figure 1. SUS Questionnaire Results](image-url)
As the pace of innovation continues to accelerate, health care providers will need to quickly integrate new digitally-based tools into their workflows, and patients will need to be able to easily and readily access these tools. It is equally important, however, to ensure that the technologies being disseminated to providers and patients pass performance and quality standards. RxUniverse not only provides the necessary mechanisms, user-friendly interface, and EHR integration functionality to accomplish these tasks, but it also surpasses industry standards in terms of usability and learnability.

The total number of apps prescribed on this platform surpassed 2000, which far exceeded the initial target of 100 apps. The type of mHealth apps prescribed varied widely, but the most common were MyChart, an app to help patients connect to their personal health records, a Mount Sinai Health Systems app, and two internally developed apps targeted Inflammatory Bowel Disease and Heart Failure. Additionally, the platform also scored an 84.2 (p = 0.001) on the System Usability Score, which is a score greater than 96.19% of all products and is considered to fall in the highest usability category of “excellent” (Table 4). According to industry standards, a score of 68 is considered to be average across all systems. By comparison, other health apps considered to be of respectable usability have reported scores of 77.5\(^10\). Additionally, RxUniverse received a high score within the learnability component of the SUS, which demonstrates the ease by which users were able to learn the technology utilized by the platform (Table 3). Research has shown that SUS scores provide reliable measures of usability and user satisfaction, and the high performance of RxUniverse on this scale demonstrates high achievement in these areas\(^8\). These outcomes demonstrate the high adoption and usability of the RxUniverse platform, an important platform that can be used to prescribe the latest technologies directly to patients.

This study may have some potential limitations. Surveys were offered to all users, but some bias may exist with respect to which users chose to fill out the survey or to participate in the pilot study. Additionally, the patient perspective was not assessed; the primary focus of this study, however, relates to the usability from the prescriber standpoint. Future iterations of this study will more closely involve the patient perspective.

### Conclusion

RxUniverse is the first platform that creates an ecosystem that facilitates a standardized process for dissemination and curation of mobile health apps. The goals of this pilot study were to evaluate the RxUniverse platform and to compare to industry standards of usability and learnability. To further validate this platform, it will be important to conduct additional studies both health system-wide, as well as in partnership with other health systems across the United States. The platform is now being expanded for multisite collaborators. Future plans include full integration within the Mount Sinai health system’s EHR, release of additional mHealth apps and content, assessment of usability from the patient perspective, and continued platform development and modification.

It is our belief that RxUniverse can serve as a valuable tool in connecting health technology innovation to the end users of clinicians and patients, as well as enable evidence-based review of mHealth solutions.

Deep Learning Meets Biomedical Ontologies: Knowledge Embeddings for Epilepsy

Ramon Maldonado, BS¹, Travis R. Goodwin, MS¹, Michael A. Skinner, MD¹,², Sanda M. Harabagiu, PhD¹

¹The University of Texas at Dallas, Richardson, TX; ²The University of Texas Southwestern Medical Center, Department of Surgery, Dallas, TX

Abstract

While biomedical ontologies have traditionally been used to guide the identification of concepts or relations in biomedical data, recent advances in deep learning are able to capture high-quality knowledge from textual data and represent it in graphical structures. As opposed to the top-down methodology used in the generation of ontologies, which starts with the principled design of the upper ontology, the bottom-up methodology enabled by deep learning encodes the likelihood that concepts share certain relations, as evidenced by data. In this paper, we present a knowledge representation produced by deep learning methods, called Medical Knowledge Embeddings (MKE), that encode medical concepts related to the study of epilepsy and the relations between them. Many of the epilepsy-relevant medical concepts from MKE are not yet available in existing biomedical ontologies, but are mentioned in vast collections of epilepsy-related medical records which also imply their relationships. The evaluation of the MKE indicates high accuracy of the medical concepts automatically identified from clinical text as well as promising results in terms of correctness and completeness of relations produced by deep learning.

Introduction

Over the past two decades, the biomedical research community has increased its efforts to produce ontologies encoding biomedical knowledge, justified by the steady increase in biological and biomedical research and the growth of data that is being collected in all areas of biology and medicine. Not only is the number of ontologies increasing and their size growing, but their relevance in biomedical research is also rising as they contribute to the interpretation of the biomedical data and enable complex inference from their encoding. The BioPortal* of the National Center for Biomedical Ontology (NCBO) is the most comprehensive repository of biomedical ontologies in the world (as of this writing it includes 541 ontologies, with almost 8 million classes and almost 40 million indexed records). Many of the ontologies available from the BioPortal became widely used resources, e.g. the Gene Ontology¹ (GO), one of the most important resources available in genomics research. The survey published in Huang et al. (2009)² discusses 68 bioinformatics enrichments tools informed by GO, that have played a very important and successful role contributing to the gene functional analysis of large gene lists for various high-throughput biological studies, evidenced by thousands of publications citing these tools. Moreover, Lependu et al. (2011)³ showed that it is possible to create reference annotation sets for enrichment analysis † using other ontologies than the GO, still available from BioPortal, for example, the Human Disease Ontology (DO). As reported in Noy et al. (2009)⁴, the ontologies in the BioPortal are publicly available in several formats, including OWL, RDF, OBO format or the Protege frame language. As such, they follow the principles of the OBO Foundry⁵, forming graph-theoretic structures, with concepts connected by edges representing relations such as ’Is-A’ or ’Part-Of’ or others from the OBO Relation Ontology (RO), generating well-principled ontologies for many biomedical domains.

Recently, a new ontology was added in the BioPortal, namely the Epilepsy Syndrome and Seizure Ontology‡ (ESSO), encoding 2,705 classes with an upper ontology targeting epilepsy as a disease and designed to be machine readable and to allow for federated queries across distributed databases and patient data capturing systems. The availability and development of the ESSO ontology answers the recommendations of the Institute of Medicine report§ for promoting the understanding of epilepsy by increasing the power of data in comprehensive, timely, and accurate epilepsy surveillance. Because epilepsy affects an estimated 2.2 million people in the United States, it is one of the most common neurological disorders. However ontological resources for this disorder are only now starting be become available to biomedical researchers. Nevertheless, large clinical datasets relevant to epilepsy are also becoming available. For example, the Temple University Hospital (TUH) EEG Corpus⁷ assembles over 25,000 sessions of electroencephalography (EEG) of 15,000 patients collected over 12 years. Clinical electroencephalography is an electrophysiological monitoring method used to record electrical activity of the brain.

§http://biopedia.snomed.org
representing the most important investigation in the diagnosis and management of epilepsies. As expected, EEG reports contain a wealth of epilepsy-related knowledge, derived from clinical practice. This knowledge is expressed by clinical language used in the reports and it explicitly mentions many of the concepts that can be linked to the ESSO ontology. Moreover, many implicit relations between these concepts can be inferred from the EEG reports. While biomedical ontologies have traditionally been used to guide the identification of concepts or relations in biomedical data, recent advances in deep learning were able to capture knowledge from textual data enabling an alternative knowledge representation.

This alternate knowledge representation, known as knowledge embeddings (KE), incorporates deep learning to model the interactions between concepts and relations and generate graphical knowledge structures. Knowledge embeddings are defined as multi-dimensional continuous vector representations of concepts and their relations. The KE methods were inspired, as reported in Weston et al. (2013)\(^8\), by the work of Craven et al. (1999)\(^9\), which matched the Yeast Protein Database with PubMed abstracts.

In this paper, we aim to investigate the medical knowledge embeddings (MKE) automatically learned from the TUH EEG corpus, encoding multiple EEG findings (e.g. EEG events and activities), associated medical problems, and treatments. Unlike the top-down methodology used in the generation of ontologies, which starts with the principled design of the upper ontology, the bottom-up methodology enabled by deep learning observes the likelihood that concepts share certain relations, as evidenced by data. Specifically, whereas the edges in an ontology graph represent hand-coded “hard” relations between entities, the edges in the knowledge graph are “softer”, i.e. probabilistic in nature. Unlike concepts and relations encoded in the BioPortal ontologies, the MKE associate relations between medical concepts with a probability or likelihood, enabling a probabilistic representation of biomedical knowledge. Thus, the MKE are able to account for the variability and inconsistencies in the way this knowledge is expressed in natural language by assigning more plausible relations a higher likelihood. While previous KE were generated from human curated knowledge bases, our work is unique in that we automatically extract entities and relations from free text in a data-driven approach. To the best of our knowledge, this is the first report of an the development of an embedded medical knowledge graph using free text clinical records.

We learned MKE representing 1,195,927 instances of binary relations between epilepsy-related concepts. These relations involved 2,442 instances of medical concepts. We evaluated the MKE by (1) the quality of the medical concepts identified in EEG reports; (2) assessing the plausibility of the potential relations discovered in EEG reports as well as (3) measuring the knowledge completeness as a form of link prediction\(^10\). We believe that the MKE encode medical knowledge that is complimentary to the knowledge available in traditional ontologies and can be used (1) to provide data-driven knowledge that can be linked to ontologies from BioPortal, and (2) as a potential mechanism for enriching existing ontologies using the learned concepts, relations, and probabilities.

**Background**

Recently, qualified medical knowledge graphs (QMKGs) automatically discerned from medical records have been used successfully in a system designed for patient cohort identification\(^11,12\). As reported in Goodwin & Harabagiu (2013)\(^13\) the QMKG was generated using big-data techniques applied to a large set of clinical records available to the participants in the TREC Medical Records track (TRECMed), a task developed in 2011 and 2012 as an Information Retrieval challenge pertinent to real-world clinical medicine and evaluated in the annual TExT Retrieval Conference (TREC) hosted by the National Institute for Standards and Technology (NIST). In another TREC special track on Clinical Decision Support (TREC-CDS), the system reported in Goodwin & Harabagiu (2016)\(^14\) used a knowledge representation as a Clinical Picture and Therapy Graph (CPTG) which was automatically acquired from the MIMIC-III\(^15\) clinical database. The TREC-CDS has addressed the challenge of retrieving bio-medical articles relevant to a medical case when answering one of three generic medical questions: (a) “what is the diagnosis?”; (b) “what test(s) should be ordered?”; and (c) “which treatment(s) should be administered?”. The system described in Goodwin & Harabagiu (2016)\(^14\) answered these types of questions by relying on a medical knowledge representation as a factorized Markov network\(^16\), suited ideally for answer inference.

Medical knowledge embeddings (MKE) enable a new probabilistic knowledge representation which is differs from the QMKG and the CPTG because (1) the relationships are not informed only by cohesive properties of texts, but by patterns of interactions between medical concepts, as captured by deep learning methods; and (2) similar medical concepts and relations share the same neighborhoods in the multi-dimensional space enabled by the knowledge embeddings. The latter property resolves semantic heterogeneity which arises when disparate terminology is used to refer to the same concepts or relations while identical terms may refer to distinct concepts. As noted in Sahoo et al. (2014)\(^17\) a seizure with alteration of consciousness
may be referred to as complex partial seizure, dialetic seizure or focal dyscognitive seizure by different epilepsy experts. An MKE representation should place all these expressions in a similar location of the multi-dimensional space, as it learns that they are involved in the similar relations with other epilepsy-relevant concepts. Thus, unlike the Epilepsy and Seizure Ontology\(^7\) (EpSO), the MKE representation does not require reconciliation of semantic heterogeneity, while being used for retrieving patient cohorts from medical records.\(^8\)

Data

In this work, we used the EEG reports publicly available from the Temple University Hospital (TUH), comprising over 25,000 EEG reports from over 15,000 patients collected over 12 years. Following the American Clinical Neurophysiology Society Guidelines for writing EEG reports, the reports from the TUH EEG Corpus start with a clinical history of the patient, including information about the patient’s age, gender, and conditions prevalent at the time of the recording followed by a list of the medications the patient is currently taking that might modify the EEG (e.g. “Keppra”, “Lamictal”). Both initial sections depict the clinical picture of the patient, containing a wealth of medical concepts, including the medical problems (e.g. “seizures”), signs, and symptoms (e.g. “loss of consciousness”) as well as significant medical events which may be temporally grounded (e.g. “2 years ago”). The following sections of the EEG report target mostly information related to the EEG techniques, findings and interpretation. The introduction section describes the techniques used for the EEG (e.g. “digital video routine EEG”, “standard 10-20 electrode placement system with additional anterior temporal and single lead EKG”), as well as the patients conditions prevalent at the time of the recording (e.g. fasting, sleep deprivation), level of consciousness (e.g. “during wakefulness”), and possible activating procedures that were performed (e.g. “hyperventilation”). The description section is the mandatory part of the EEG report, and it provides a complete and objective description of the EEG signal, noting all observed activity (e.g. “frontocentral beta activity”), patterns (e.g. “K-complexes”) and events (e.g. “eye opening”). The impression section states whether the EEG test is normal or abnormal (i.e. indicating some form of cerebral dysfunction). If the impression is abnormal, then the abnormalities are listed in order of importance. The clinical correlation section explains what the EEG findings mean in terms of clinical interpretation (e.g. “findings are consistent with idiopathic generalized epilepsy”).

Methods

Bottom-up knowledge acquisition methods rely on the automatic identification of concepts and relations from data to enable (i) the population of the knowledge representation and (ii) linking the acquired knowledge to existing ontologies. In learning medical knowledge embeddings (MKE) from EEG reports we do not only perform bottom-up acquisition of medical knowledge from EEG reports, but we also represent the knowledge probabilistically in a multi-dimensional space and perform inference on it. To do so, we followed a methodology which involves the following four steps:

**STEP 1:** Decide which medical concepts and which relations between them are expressed in the EEG reports;
**STEP 2:** Automatically generate the Knowledge Graph by extracting medical concepts and relations from the EEG reports;
**STEP 3:** Learn Medical Knowledge Embeddings (MKE) from the associated Knowledge Graph;
**STEP 4:** Perform inference with MKE.

It is to be noted that the the MKE represent only knowledge available from the EEG reports, which do not discuss the taxonomic organization of medical concepts or their partonymy relations. These forms of relations are encoded in medical ontologies, thus the MKE provide complementary knowledge to medical ontologies. However, many of the concepts represented in the MKE are also encoded in existing medical ontologies, providing a simple mechanism of linking the MKE to various ontologies available in BioPortal. For example, the clinical history and the medication list of EEG reports mention multiple medical concepts already encoded in the Unified Medical Language System (UMLS)\(^9\) ontology:

Example 1: **CLINICAL HISTORY:** This is a 20-year-old female with history of seizures described as generalized tonic-clonic with loss of consciousness for a few minutes. Last seizures occurred 2 years ago. **MEDICATIONS:** Keppra and Lamictal.

Medical problems such as seizures, and treatments such as “Keppra”, “Lamictal” are encoded in UMLS while concepts such as idiopathic generalized epilepsy will be linked both to UMLS and the ESSO ontology. However, these ontologies do not capture relations between such concepts that are implied in the EEG reports, e.g. which brain activities evidence some epilepsy-specific medical problems. Our four-step methodology aims to capture and represent such relationships, while also providing their probabilistic likelihood, learned automatically from the medical practice evidenced in the large corpus of EEG reports.

1228
**Figure 1:** Medical concepts and relations considered for Medical Knowledge Embeddings (MKE)

**STEP 1:** Decide which medical concepts and relations between them are expressed in EEG reports

In addition to medical problems and treatments that describe the clinical picture and therapy of a patient, EEG reports mention EEG events, which represent stimuli that activates the EEG (e.g. hyperventilation) and EEG activities, representing brain waves or sequences of waves. The section of the EEG reports describing the EEG record mention a multitude of EEG activities and events recognized by the neurologist from the analysis of the EEG signal. The following example illustrates mentions of EEG events such as photic stimulation and eye opening, while mentions of EEG activities are beta activity and polyspike discharges:

Example 2: DESCRIPTION OF THE RECORD: …the alpha rhythm was 9-10 Hz in frequency seen in the occipital region, which attenuates with eye opening. …Photonic stimulation was performed at multiple flash frequencies and results in a symmetric driving response without any photoparoxysmal response.

EEG activities are also mentioned in the impression section and in the clinical correlation section. Thus we decided to encode in the MKE four types of medical concepts: (1) EEG events; (2) EEG activities; (3) medical problems and (4) treatments. Whenever these concepts are also encoded in other ontologies, we linked to them. For example, medical problems such as idiopathic generalized epilepsy, when identified in an EEG report, with methods developed in the STEP 2 of our methodology, shall be linked to UMLS through its concept unique identifier (CUI). In addition to these four types of concepts, we decided to discern four types of binary relations that are implicit in the EEG reports. Each of these relations operates between a source argument and a destination argument. The relations along with examples of the four types of medical concepts are illustrated in Figure 1. The four binary relation types that we considered were motivated by discussions with several practicing neurologists and surgeons, corresponding to the implicit knowledge they discern from EEG reports. As shown in Figure 1, the EVIDENCES binary relation always has a medical problem as its destination concept, which is always mentioned in the clinical correlation section of the EEG report. The following example shows how the medical problem idiopathic generalized epilepsy, is evidenced by findings such as polyspike discharges, which is a mention of an EEG activity, in the impression section:

Example 3: IMPRESSION: This is an abnormal EEG recording capturing wakefulness through stage II sleep due to generalized spike and wave and polyspike discharges seen during wakefulness.

CLINICAL CORRELATION: The above findings are consistent with idiopathic generalized epilepsy.

Figure 2: Deep Learning Architectures used for Recognizing Qualified Medical Concepts from EEG Reports.

As shown in Figure 1, the EVIDENCES relation considers EEG events, EEG activities, treatments, and medical problems as providing evidence for the medical problem from the clinical correlation section of the EEG report. The EVOKES binary relation always has an EEG activity as a destination concept, as it attempts to capture the medical concepts that evoke the respective EEG activity. Those medical concepts can be either EEG events, or other EEG activities, medical problems or treatments followed by the patient. The third relation, namely OCCURS-WITH constraints both its arguments to be of the same type, e.g. either EEG activities, medical problems or treatments. The TREATMENT-FOR relation captures the treatments prescribed for certain medical problems. Table 1 illustrates examples of each of the four relations we considered, involving medical concepts illustrated in Figure 1, which lists all the EEG events and EEG activities that we decided to encode in the MKE, while providing several examples of medical problems and treatments, along with their UMLS CUIs. We used the vocabularies of EEG Activities and EEG Events from Maldonado et al. (2017) based on the International Federation of Clinical Neurophysiology’s glossary of terms.

STEP 2: Automatically generate the Knowledge Graph by extracting medical concepts and relations from the EEG reports.

The extraction of medical knowledge from EEG reports consists of (1) automatic identification of medical concepts and (2) binary relation detection. Medical concept identification aims to recognize all the four types of concepts mentioned in EEG reports, along with their inferred polarity and modality. For identifying polarity of medical concepts in EEG reports, we considered that each concept can have either a negative or a positive polarity, depending on whether the medical concept was negated or not in the text. The recognition of the modality, as in Maldonado et al. (2017) uses the modality values of factual, possible, and proposed to indicate that medical concepts mentioned in the EEG reports are actual findings, possible findings and findings that may be true at some point in the future, respectively. Through the identification of modality and polarity of the clinical concepts, we aimed to capture the neurologists beliefs about the clinical concepts mentioned in the EEG report. Thus our medical concept identification method needed also to qualify the concepts by their polarity and modality.

Medical Concept Identification was performed by taking advantage of our existing active deep learning methodology, which is illustrated in Figure 2. This methodology first uses two stacked Long Short-Term Memory (LSTM) networks for detecting the boundaries of medical concepts in the text of the EEG report. The task of identifying spans of text that correspond to mentions of medical concepts is called boundary detection. We relied on one stacked LSTM to identify the boundaries of EEG activities and another stacked LSTM to identify the boundaries of EEG events, medical problems and treatments. The
motivation for using two separate stacked LSTM networks is determined by the fact that different features are used to identify the boundaries of EEG activities than boundaries of the other three types of medical concepts, as detailed in Maldonado et al. (2017). Once the boundaries of each medical concepts are known, two Deep Rectified Linear Networks (DRLNs) are used to (a) identify the medical concepts and (b) discern their polarity and modality. EEG activities are identified only with their polarity, as their mentions are always factual, as illustrated in Figure 2. Moreover, medical problems and treatments are both normalized into UMLS concepts using MetaMap Lite.

Detecting Relations between Medical Concepts was possible when pairs of medical concepts identified in the same EEG report were considered. Specifically, we established the four types of relations illustrated in Figure 2 by considering: (1) a potential EVIDENCES relation between any medical concepts from an EEG report and a medical problem identified in its clinical correlation section; (2) a potential EVOKES relation between any medical concept and an EEG activity, provided that the treatments were not identified in the clinical correlation section, as they may indicate possible or recommended treatments; (3) a potential OCCURS-WITH relation between pairs of EEG activities, medical problems and treatments that are identified in the same section of the EEG report; and (4) a potential TREATMENT-FOR relation between any treatment and a medical problem identified in the history section of the EEG report. We discard potential relations involving medical concepts with “negative” polarities and “possible” modalities since these medical concepts, while mentioned, were not actually observed. All these potential relations are indicative of implied relations, that are not always directly stated in the text of the EEG report.

Taken together, the set of medical concepts extracted from the entire TUH EEG corpus along with the collection potential relations between them constitute a Knowledge Graph, \( G = \{ V, E \} \) where \( V \) is the set of graph vertices and \( E \) is the set of graph edges. In our knowledge graph, \( V \) is the set of medical concepts and \( E \) is the set of relations between them. The medical knowledge embeddings learned in the following step will provide the likelihood of any example of one of these relations.

STEP 3: Learning medical knowledge embeddings (MKE) from the associated knowledge graph

Learning MKE is made possible by relying on the TransE method, widely used for representing multi-relational data corresponding to concepts and relations by modeling concepts as points in a continuous vector space, \( \mathbb{R}^N \), called the embedding space, where \( N \) is a parameter indicating the dimensionality of the embedding space. In our use of the TransE framework, relations between medical concepts are represented as translation vectors, also in \( \mathbb{R}^N \), that connect the two points representing the two medical concepts in the embedding space. TransE learns an embedding, \( \vec{c}_i \), for each concept \( c_i \) and an embedding, \( \vec{r} \), for each relation type \( r \) such that the relation embedding is a translation vector between the two concept embeddings representing its arguments. This means that for any medical concept \( c_i \), the concept most likely to be related to \( c_i \) by the relation \( r \) should be the medical concept whose embedding is closest to \( (\vec{c}_i + \vec{r}) \) in the embedding space. By modeling the medical concepts as points in the embedded space and the relations between them as translation vectors, we can measure the plausibility of any potential relation between any pair of concepts using the geometric structure of the embedding space. The plausibility of a relation between a source medical concept and a destination medical concept, represented as a triple, \( \langle c_s, r, c_d \rangle \), is inversely proportional to the distance in the embedding space between the point predicted by our model \( (\vec{c}_i + \vec{r}) \) and the point in the embedding space representing the destination argument of the relation, i.e. \( \vec{c}_d \). In this work, we use Manhattan Distance as our distance function:

\[
f(c_s,r,c_d) = ||\vec{c}_s + \vec{r} - \vec{c}_d||_1
\]

where \( || \cdot ||_1 \) is the L1 norm. Using this distance function, plausible triples have low value of \( f \) (since \( \vec{c}_s + \vec{r} \approx \vec{c}_d \) for plausible triples) and implausible triples have a high value of \( f \).

Neural Network Architecture for learning MKE. To learn the optimal points and translation vectors, we use a neural network that will in fact produce the MKE. Formally, let \( C \) be the set of medical concepts found in the EEG reports and \( L \) be the set of relation types. Let \( X = \{ x^1 = \langle c_s^1, r^1, c_d^1 \rangle, \ldots, x^m = \langle c_s^m, r^m, c_d^m \rangle \} \) be the set of \( m \) relation triples extracted from the corpus of EEG reports at Step 2; where each \( c_s^j, c_d^j \in C \) is a medical concept and each \( r^j \in L \) is a relation type. The embedding, \( \vec{c}_i^j \), for a concept \( c_i^j \), is calculated by first generating a one-hot vector representation of \( c_i^j \) given by \( v(c_i^j) \) which is a \( |C| \)-dimensional vector of zeros with a one in the dimension corresponding to the index of the concept \( c_i^j \) in the set of concepts \( C \). The embedding \( \vec{c}_i^j = v(c_i^j) \cdot \text{E} \) is derived by multiplying the one-hot vector \( v(c_i^j) \) with the embedding matrix \( \text{E} \in \mathbb{R}^{|C| \times N} \). Each row of \( \text{E} \) corresponds to a medical concept embedding and the operation \( v(c_i^j) \cdot \text{E} \) corresponds to selecting the \( v(c_i^j) \)th row of \( \text{E} \). Likewise, the embedding for a relation type \( r^j \) is given by \( \vec{r}^j = w(r^j) \cdot \text{R} \) where \( w(r^j) \) maps \( r^j \) to a one-hot vector of size...
To learn useful embeddings we must also define a training objective that encodes useful relationships. Inspired by the work of Bordes et al. (2011)\textsuperscript{26}, we use the following training objective: if either the source argument or destination argument from a training triple is removed, the model should be able to correctly predict the correct medical concept. For example, the model should ensure that the value of $f(\text{keppra}, \text{TREATMENT-FOR}, \text{idiopathic generalized epilepsy})$ is less than the value of $f(\text{morphine}, \text{TREATMENT-FOR}, \text{idiopathic generalized epilepsy})$ since keppra is a treatment for idiopathic generalized epilepsy, but morphine is not. Formally, we wish to learn the values of $E$ and $R$ such that for any training triple $x_i = (c_s^{i}, r^{i}, c_d^{i})$, the following two constraints are met:

$$f(c_s^{i}, r^{i}, c_d^{i}) < f(c_s^{i}, r^{i}, c_d^{i}), \forall j: (c_s^{i}, r^{i}, c_d^{i}) \not\in X$$

$$f(c_s^{i}, r^{i}, c_d^{i}) < f(c_s^{i}, r^{i}, c_d^{i}), \forall j: (c_s^{i}, r^{i}, c_d^{i}) \not\in X$$

To learn the optimal embedding matrices $E$ and $R$, we optimize the objective defined by the constraints outlined in Equations 3-4 by iterating the following process:

1. Randomly select a training triple $x^i = (c_s^{i}, r^{i}, c_d^{i})$ from $X$.
2. Create a corrupted version of the triple $x^{i}_{\text{neg}}$ by selecting a medical concept $c^{\text{neg}}$ at random from the set of medical concepts $C$ and randomly replacing either $c_s^{i}$ or $c_d^{i}$ in $x^i$ such that $x^{i}_{\text{neg}} \not\in X$.
3. Update $E$ and $R$ by backpropagating the ranking margin loss\textsuperscript{23}, $\max(0, \gamma + f(x_i) - f(x^{i}_{\text{neg}}))$, where $\gamma$ is the margin parameter that determines how much of a margin should exist between triples in the training set and triples not in the training set.
4. Normalize each row $e$ of $E$ (i.e. $e := \frac{e}{||e||}$).

This process is repeated for each triple in $X$ a fixed number of iterations (200,000 in this work). Our collection of 1,195,927 relation triples extracted from the TUH EEG corpus consisted of $|X| = 138,369$ unique relation triples. It is important to note that, as reported in Bordes et al. (2013)\textsuperscript{10}, the normalization in the fourth step prevents the model from trivially minimizing the loss by artificially increasing entity embedding norms.

### STEP 4: Performing Inference with the MKE graph

Inference from a knowledge base can be viewed as answering questions using its encoded knowledge. Answering questions like (Q1) “what is the most likely treatment for idiopathic generalized epilepsy?”, (Q2) “what EEG activity is most likely to occur with polyspike discharges?”, and (Q3) “what is the likelihood that a patient with background slowing is diagnosed with cerebral dysfunction?” requires the ability to perform probabilistic inference. The MKE can be used to perform probabilistic inference by (1) representing the question as a relation triple $q$ and (2) measuring the plausibility of $q$ using equation 1 with the embeddings matrices $E$ and $R$ automatically learned from the TUH EEG corpus. We estimated the probability of $q = (c_s^{q}, r^{q}, c_d^{q})$ in terms of the geometric structure of the embedding space. Formally:

$$P(c_s^{q}, r^{q}, c_d^{q}) = 1 - \frac{f(c_s^{q}, r^{q}, c_d^{q})}{\sum_{(c_s^{i}, r^{i}, c_d^{i}) \in X} f(c_s^{i}, r^{i}, c_d^{i})}$$

For example, answering (Q1) is the result of $\hat{c}_s = \arg\max_{c_s \in C} P(c_s, \text{TREATMENT-FOR, idiopathic generalized epilepsy})$; answering (Q2) is the result of $\hat{c}_d = \arg\max_{c_d \in C} P(\text{polyspike discharges, OCCURS-WITH, c_d})$; and answering (Q3) is the result of $P(\text{background slowing, EVOKES, cerebral dysfunction})$.

### Experiments

To evaluate the MKE, we measure (a) the quality of the medical concepts that were extracted from the EEG reports as well as (b) the quality of the relations learned between them. When evaluating the medical concepts, we relied on the latest performance of our active deep learning annotation methodology\textsuperscript{21} and found that the quality of boundary detection of EEG activities had an F1-score of 0.9154 while the F1-score for detecting the boundaries of the other three forms of medical concepts was 0.9421. The identification of the medical concept type was performed with an F1-score of 0.9532 and the polarity was detected with an accuracy of 0.978 while the modality was recognized with an accuracy of 0.973.
Table 2: Quality of relations encoded in the MKE, measured using Pairwise Plausibility Accuracy (PPA), Mean Reciprocal Rank (MRR), Precision at 10 (P@10), Hits at 10 (H@10) and Hits at 100 (H@100).

The relations represented in the MKE were evaluated in terms of (a) their plausibility; and (b) their completeness. The plausibility of relations encoded in MKE was assessed in three ways, measuring how well MKE rank triples from a test set $T$, of 1,000 relation triples held out from the data used to train the MKE. For each triple $t$ in the test set, we randomly remove either the source or destination argument and produce a set of candidate triples by replacing the removed argument with every medical concept $c \in C$. We rank the candidate triples in ascending order according to the distance function $f$. This allows us to calculate the following metrics using the rankings produced from every triple in the test set:

- **Mean Reciprocal Rank (MRR)** is a standard ranking evaluation that measures how high the first correct triple is ranked according to the model. $MRR = \frac{1}{|T|} \sum_{i=1}^{|T|} \frac{1}{\text{rank}_i}$ where $\text{rank}_i$ refers to the rank of the first correct triple in the ranking, where a correct triple is defined as any triple from any of the training, validation, or tests sets.

- **Precision at 10 (P@10)** is another standard ranking evaluation that measures the percentage of the top 10 ranked triples are correct. As with MRR, correct triples are defined as any triple from any of the training, validation, or tests sets. The Precision at 10 evaluation shows how well the MKE ranks the triples about which the model is most confident.

- **Hits at K (H@K, H@100)** is a standard evaluation used for knowledge graph embeddings for evaluating link prediction. Hits at K measures how often the specific test triple $t$ occurs in the $K$ highest ranked triples, as opposed to precision which measures how often any correct triple occurs in the $k$ highest ranked triples. We report both Hits at 10 and Hits at 100 to illustrate how often $t$ is ranked among the most plausible triples, and how often $t$ is ranked in the top 5% of triples.

The evaluation of completeness of the relations from the MKE also used the test set, $T$. We evaluated how well the MKE can infer new knowledge in the form of new relations from the test set. To measure how well the MKE can model relations of the held out triples from the test set, we consider each test triple, $t \in T$, and a corrupted version of the test triple, $z$, created by randomly replacing either the source argument or destination argument with a random medical concept and compute the **Pairwise Plausibility Accuracy (PPA)**. The PPA measures the percentage of test triples for which the plausibility, $P(c^t_s, r^t, c^t_d)$, of the test triple $t$ is higher than plausibility, $P(c^z_s, r^z, c^d)$, of the corrupted triple. PPA demonstrates how well the MKE can differentiate between a correct, $t$, and an incorrect triple, $z$, even if the model had never encountered $t$. For these evaluations, the MKE were learned from 137,369 training triples automatically extracted from the TUH EEG corpus as described in the Methods section. We selected the dimension of the embedding space $N = 50$ from [25,50,100,200] and the margin parameter $\gamma = 1.0$ from $[0.1,1.0,5.0,10.0]$ using grid search on a validation set of 500 relation triples.

Table 2 presents these results. The results for the Pairwise Plausibility Accuracy show that the MKE can correctly distinguish between relations that occur in the data (but that the model has not seen during training) and corrupted relations 88.95% of the time. The micro-averaged Mean Reciprocal Rank of 83.33% indicates that for the majority of triples in the test set, the top ranked candidate triple is correct. While the MRR of the OCCURS-WITH relation is the lowest (62.3%), it should be noted that, on average, there is at least one correct candidate triple ranked in the top two. The Precision at 10 metrics show that 66.73% of the top 10 ranked triples were correct, in general. It is interesting to note that the results for the Hits at 10 metric have the most variability between relation types. For the OCCURS-WITH relation, test triple, $t$, only occurs within the top 10 ranked triples 27.77% of the time. In contrast, for the EVOKES relation, $t$ occurs within the top 10 ranked triples 84.91% of the time. In general, the Hits at 100 results show that the MKE correctly ranks $t$ in the top 5% of candidate triples 81.3% of the time.

**Discussion**

To analyze the correctness of medical knowledge distilled from EEG reports in the MKE, we manually inspected the 30 most plausible triples for each relation type. Specifically, for each triple, we determined whether that triple is consistent with established medical knowledge. Many of the triples in the MKE encode general knowledge which is difficult to judge. For example,
consider the triple \(\langle\text{Dilantin}, \text{TREATMENT-FOR}, \text{disease}\rangle\). Determining whether or not \text{dilatinin}\ is a treatment for \text{disease}, necessitates considering additional context specifying the disease. In general, we found the \text{EVOKE}\ relation type to have the highest percentage of correct triples, highlighting the ability of the MKE to capture neurological experience from EEG reports. By contrast, the MKE successfully identified a number of unexpected \text{OCCURS-WITH} relations, including \(\langle\text{hypothyroidism}, \text{OCCURS-WITH}, \text{turner syndrome}\rangle\), and \(\langle\text{infantile spasms}, \text{OCCURS-WITH}, \text{MELAS Syndrome}\rangle\). Whereas the coincidence of hypothyroidism and Turner Syndrome is fairly well known, the relationship between infantile spasms and MELAS syndrome is relatively obscure. Infantile Spasms, also known as West syndrome, is an exceedingly rare condition, with an estimated incidence in the United States of about 0.25-0.4 per 1000 live births\(^{27}\). The MELAS syndrome is an even rarer inherited disorder of mitochondrial function which may be responsible for 8% of cases of infantile spasms\(^{28}\). That the MKE recognized the connection between these two very rare conditions is quite interesting, and suggests that knowledge graph embedding holds promise for the elucidation of unusual concepts and relations from EEG reports in particular, and perhaps in medical reports more generally.

Owing to the data-driven nature of our technique, we generated some incorrect triples, as might be expected when using noisy free text data. For example, we observed two common types of errors when evaluating the \text{EVIDENCES} relation: (1) relation inversion, inverting the source and destination arguments of the relation; and (2) relation confusion, confusing one relation type with another. Consider the following example of a triple exhibiting relation inversion: (E1) \(\langle\text{liver cirrhosis}, \text{EVIDENCES}, \text{encephalopathies}\rangle\). As defined in Figure 1, the source argument of the \text{EVIDENCES} relation is a medical concept suggesting or supporting the diagnosis listed in the destination argument. By contrast, it could be argued that, for triple (E1), the destination argument \text{encephalopathies} more commonly evidences the source argument \text{liver cirrhosis}. We believe these types of error could be addressed by incorporating semantic attributes (e.g. temporal information) to contextualize or constrain the arguments allowed for each relation type. Relation confusion is exemplified by the triple (E2) \(\langle\text{rifaximin}, \text{EVIDENCES}, \text{brain diseases, metabolic}\rangle\). The source argument \text{rifaximin} is an antibiotic used in the management of the encephalopathy (i.e. the destination argument \text{brain diseases, metabolic}) related to severe liver failure. Thus, whereas there is a biologically plausible explanation for (E2), the \text{EVIDENCES} relation clearly does not accurately describe the relation; instead, the relation \text{OCCURS-WITH} may be preferred. This type of error could be mitigated in future work by introducing constraints into the knowledge embedding framework, as reported in Guo et al. (2015)\(^{23}\). Finally, there were rare cases in which the MKE assigned a high plausibility to triples in which the source argument contradicts the destination argument, i.e. \(\langle\text{insulin}, \text{TREATMENT-FOR}, \text{Diabetes Mellitus, Non-Insulin-Dependent}\rangle\). We believe that these types of error may be resolved by incorporating knowledge from existing ontologies to enforce consistency.

**Conclusion**

In this paper, we presented the medical knowledge embeddings (MKE) automatically learned from clinical text in EEG reports. Unlike traditional ontologies which encode curated knowledge, the MKE infers probabilistic knowledge by extracting a large number of potential relation triples. Experimental results demonstrate the promise of this approach and highlight the potential of the MKE for bridging the knowledge gaps of existing neurological ontologies. The MKE presented in this paper showcase the way in which deep learning techniques applied to large collections of medical records can supply medical knowledge derived from clinical practice to complement the knowledge already encoded in existing biomedical ontologies. By encoding the plausibility of medical knowledge, the MKE also enable probabilistic reasoning on its knowledge. Future work will consider techniques for learning plausibility thresholds that will allow MKE to be considered for curation and acceptance in existing, expert and community-validated biomedical ontologies.

Abstract

Healthcare quality research is a fundamental task that involves assessing treatment patterns and measuring the associated patient outcomes to identify potential areas for improving healthcare. While both qualitative and quantitative approaches are used, a major obstacle for the quantitative approach is that many useful healthcare quality indicators are buried within provider narrative notes, requiring expensive and laborious manual chart review to identify and measure them. Information extraction is a key Natural Language Processing (NLP) task for discovering and mining critical knowledge buried in unstructured clinical data. Nevertheless, widespread adoption of NLP has yet to materialize; the technical skills required for the development or use of such software present a major barrier for medical researchers wishing to employ these methods. In this paper we introduce Canary, a free and open source solution designed for users without NLP and technical expertise and apply it to four tasks, aiming to measure the frequency of: (1) insulin decline; (2) statin medication decline; (3) adverse reactions to statins; and (4) bariatric surgery counselling. Our results demonstrate that this approach facilitates mining of unstructured data with high accuracy, enabling the extraction of actionable healthcare quality insights from free-text data sources.

1 Introduction

Improving the quality of healthcare is a fundamental but difficult task in any healthcare system. The first step to such improvements is the identification of specific performance deficits. This can be achieved through measuring healthcare quality by using and/or developing performance measures that can serve as indicators of quality. Such metrics range from simple measures (e.g., patient waiting time) to more sophisticated ones (e.g., time to administration of antibiotics to a patient with pneumonia).

Research methods in healthcare quality can be broadly categorized as qualitative and quantitative in nature. “Quality” is not an easily defined concept, but is a much more complicated and sophisticated issue. Consequently, the research questions that may arise do not always have quantifiable answers. Qualitative research has proven to be an effective way to answer some of these complex questions using approaches based on interviews, observation and data analysis.

Quantitative methods, on the other hand, aim to measure phenomena and statistically evaluate them. Common measures include prevalence, incidence, frequency and severity. This research generates numeric data by applying specific methods to preselected data. It also bears mentioning that mixed methods – those combining both qualitative and quantitative approaches – continue to gain wider currency in the research community.1 Regardless of the research paradigm, informatics plays an important role in obtaining the right data.

One issue with quantitative research is that beyond statistics derived from structured data (e.g., patient records or laboratory results), the development of measures for more sophisticated questions has proven to be more difficult.2 A major hindrance is that while some of the target information is readily available as structured data, the great majority of it is stored as unstructured data, such as free text written by care providers. This use of free text is borne out of the flexibility required by professionals in describing their observations, diagnoses and treatment strategies. However, the unstructured natural language data that they produce is not directly usable in large-scale quantitative analyses. To use this narrative data, it would need to be manually abstracted via labor-intensive chart review. Indeed, retrospective chart review is a commonly used method for identifying issues not well documented by other methods.3 While it is widely considered to be a laborious process, it has also been said that “chart review is more difficult than it appears on the surface.”4 A demonstrative example of these issues is seen in the work of Pivovarov et al.,5 who state:

“Indicators used to assess quality of care are often buried within patient records. To accurately abstract these quality indicators, specially trained nurses manually comb through patient records to locate relevant information. Our 2,600-bed institution employs 35 full-time data abstraction specialists dedicated to reporting quality metrics for 30 databases covering 13 disease states and processes of care.”

Given that these free-text notes contain vital clinical data and that their manual review is a costly process, this has led to the development of computational methods to process and mine them for information of interest.6 This is often done
via information extraction (IE), the task of identifying and extracting relevant fragments of text from a larger, unstructured document. Researchers have been developing such methods to extract the information that they require from their own data sources. Once extracted, this information is used for quantitative research, clinical decision support, evidence-based medicine or further processing.

The overarching aim of the present paper is to highlight how unstructured data can be utilized by researchers for quantitative healthcare research. We approach this by introducing a new platform for extracting information from free-text data, and demonstrate its application in four different projects focused on healthcare quality.

The introduction of information extraction software is an important facet of facilitating more sophisticated quantitative healthcare quality research. This is because despite the importance, cost and laborious nature of this task, as we highlighted above, no readily usable tools for biomedical researchers are available. Ideally, such tools should be easy to use for researchers, even those without any NLP or software development experience. However, no such free or open-source solution exists. In this paper we present Canary, an NLP-based information extraction platform designed to meet these criteria. Canary has been developed for processing clinical documents to support the extraction of data using user-defined information discovery parameters and vocabulary. The various components that form the Canary NLP pipeline and the system for capturing text fragments are described, followed by an empirical evaluation on clinical data from four projects.

2 Background: Approaches to Information Extraction

In this section we describe a number of different approaches that have been used for information extraction, highlighting some of their advantages as well as disadvantages. In doing so we aim to position Canary within the wider context of the information extraction literature.

Simple Text Matching: The most elementary and straightforward approach to IE is based on defining specific words or sequences of words to be matched and output. While this can work in the simplest of cases, such as identifying particular drugs, it is impractical for more complex tasks.

Pattern Matching: Some shortcomings of the string matching method can be addressed by using more expressive and powerful pattern matching methods. Regular expressions are a common technique commonly employed for this purpose. They can be useful in extending patterns to match variations (e.g., different patterns of expressing drugs and dosage) or to account for other patterns like typographical errors. Disadvantages include the large number of rules required to capture all possible variations as well as difficulties in maintaining and updating the rules. They are also unable to capture structure, as we will discuss in the next section.

Language Parsing: The methods described thus far can be considered as “shallow” text processing techniques, relying solely on the words as they appear in text. Another approach involves using a “deeper” understanding of the text by parsing it to produce syntactic representations of the data; this can include constituency or dependency parsing. The parsing process can add linguistic information such as part-of-speech tags for each word as well as structural information such as noun phrases or prepositional phrases. This information can then be incorporated into the IE rules to produce more accurate and generalizable rules. These methods have been successfully applied in recent studies. For example, Wang et al. showed that such parser-based methods can be useful for automatic extraction of substance use information from clinical notes. One disadvantage of this approach is that the parsing process can be slow.

Supervised Learning: A more recently developed family of techniques based on statistical analysis of text is supervised machine learning. This involves the use of labelled training data to train a learning algorithm to identify elements of interest. While it does not involve manually engineering information extraction rules like the previous approaches, the costs of creating labelled data for supervised training are also significant. Moreover, learning algorithms require large amounts of data for effective training, along with the relevant expertise in tuning them. Nevertheless, a number of successful and popular machine learning-based toolkits for clinical information processing have been developed. The Automated Retrieval Console (ARC) is one such tool that attempts to eliminate rule creation via supervised learning. The Apache cTAKES system has also gained wide currency among clinical researchers in recent years. However, there is a population of clinical researchers without the prerequisite NLP and/or computer science skills that are not able to make use of these solutions. In this regard, the solution that we present here is complementary and designed to aid the aforementioned researchers in conducting their investigations in a self-sufficient manner.
3 Methods

3.1 Design

We designed a method for information extraction and developed NLP software implementing it. This platform was evaluated by conducting four quantitative healthcare quality experiments using unstructured clinical notes.

3.2 A Hybrid Information Extraction Method Based On User-Defined Parameters

The Canary software employs a hybrid approach for the IE task, combining the pattern matching and parsing approaches in order to address their shortcomings. The approaches are not mutually exclusive and can be complementary, as we show.

Regular expressions can be very useful for recognizing words or chunks of text, but they are not designed for capturing structure within text. While they can be helpful for identifying text in a pre-specified format, such as dates, numbers, email addresses or measurements, they are not suitable for more sophisticated structures with greater variance in their composition. For example, writing a regular expression to match text fragments describing a body part can be a cumbersome and error-prone task, given the large number of possible variations. Let us consider the following example phrases of interest:

<table>
<thead>
<tr>
<th>(1) left hand</th>
<th>(2) anterior cruciate ligament</th>
</tr>
</thead>
<tbody>
<tr>
<td>(3) lower back region</td>
<td>(4) lateral ankle ligament</td>
</tr>
<tr>
<td>(5) right hand’s index finger</td>
<td>(6) upper left abdominal quadrant</td>
</tr>
</tbody>
</table>

A key shortcoming of regular expressions is their inability to capture recursive structures, such as nested components in a tree structure. For example, they are unable to match nested brackets within a string.

Phrase (5) above is an example of such a nested structure in which a single entity is composed of two smaller entities: right hand and index finger. Capturing such nested constructs requires the definition of recursive rules, something of which regular expressions are inherently incapable.

On the other hand, detecting nested constructs can be achieved through a parsing-based approach in which recursive grammatical rules can be defined. While all aspects of regular expressions can be implemented through parsing, only some of the parsing functionality can be performed using regular expressions.

Another disadvantage of using regular expressions is that the rules encompass both words and their possible ordering. However, given the size of the target vocabulary that researchers use (particularly in the medical domain), it would be advantageous to separate the lexical entries and the ways in which they can be combined. That is to say, split the rules into a vocabulary (a set of recognized words and their categories) and a grammar (rules defining how words can be combined). This can be easily addressed by a parse-based solution by defining a vocabulary of terms and grammatical rules that define how they can be combined.

A related issue with regular expressions is that they can quickly grow in complexity, resulting in an unwieldy set of cryptic rules that can be very hard to comprehend. Updating such rules is also fraught with difficulties. Researchers have noted that the modification and documentation of regular expressions are a source of difficulty in their work. The isolation of vocabulary and grammar rules can help address these issues, as we will demonstrate.

The use of a complete language parser would require that users define their rules on top of the linguistic rules governing the target language (i.e., first categorize words into their grammatical categories and then create subsets of interest). An alternative approach, employed by Canary, is to allow users to create a simple, customizable grammar that enables them to model their target information, e.g., body parts or something broader that includes body parts. Complete language parsing is also a more computationally intensive task.

We now turn to a concrete example to illustrate how this approach works. The first step is to define the vocabulary or lexicon, which is a set of words organized into word classes. A class is a grouping of words from the same semantic category. For our body part example, we can define two classes referring to body parts and anatomical adjectives, which could be defined as:

- ANATOMICAL → (bi)?-?~(lateral)?, anterior, caudal, upper, lower, left, right, [...]
- BODYPART → (gastro)?-?intestinal, (gastro)?-?esophageal, (musculo)?-?skeletal, abdom.?, abdomen, [...]

1238
Users may define as many classes as needed, and the words belonging to each class can be matched using a regular expression, as seen in the above example. This allows users to create customizable ontologies to meet their needs.

The second step involves defining grammatical rules that define how these word classes can be combined for form phrases. A phrase can be a single word or a combination of words, as allowed by the grammar.

$$BODYPARTPHRASE \rightarrow BODYPART$$

$$BODYPARTPHRASE \rightarrow ANATOMICAL BODYPART$$

The above rules state that a body part phrase can be a single body part or an anatomical adjective followed by a body part. These rules are then processed by a parser to match all fragments of a text that match any of the supplied rules. Words that are not found in the vocabulary are ignored. Some examples matched by this simple grammar are shown in Figure 1.

![Figure 1](image1.png)

**Figure 1.** Example fragments of text describing body parts matched by our simple grammar.

We can also extend the grammar to match nested body parts by simply adding a recursive rule:

$$BODYPARTPHRASE \rightarrow BODYPARTPHRASE BODYPARTPHRASE$$

A recursive rule expresses that a phrase may include a sub-phrase of the same type as its own constituent, allowing us to capture the recursive property of natural language. This is important because, for example, English nouns and sentences can be infinitely recursive. In the above example, this extension allows the capture of one or more adjacent body part phrases. We illustrate this with the examples in Figure 2.

![Figure 2](image2.png)

**Figure 2.** Examples of recursive body part phrases that contain other body parts (marked in blue) as constituents.

We can see that this simple extension allows the capture of the more complex phrases. This is something not possible with regular expressions. A parser, on the other hand, can find an arbitrary number of such nested elements.

Furthermore, these constituency grammar rules can be used to build more sophisticated phrases that contain multiple recursive elements, as we show in the next section.

### 3.2.1 Creating Longer Phrases

Researchers often need to extract complex phrases that capture more information than just a body part. To this end, the simple rules we have seen so far can serve as the building blocks for forming longer, more sophisticated phrases. Building on the previous example, we now extend the rules to detect a medical condition involving a body part. We first add additional entries to our vocabulary:

- **ARTICLE**: the, a, an
- **PREPOSITION**: of, in, [...]  
- **POSSPRONOUN**: his, her, your, my
- **CONDITION**: (hepato)?(to)?xicity, aches?, aching, [...]
We also add some grammar rules to capture a phrase indicating a condition involving a body part:

\[
\text{CONDITIONPHRASE} \rightarrow \text{BODYPARTPHRASE CONDITION} \\
\text{CONDITIONPHRASE} \rightarrow \text{CONDITION PREPOSITION BODYPARTPHRASE}
\]

Applying these rules, we can match the phrases shown in Figure 3. We can also observe that the body part phrase in the left example has three levels of nested phrases. This example demonstrates that an advantage of the grammar-based approach is that the items in our vocabulary can be easily referenced and used to build larger and more meaningful phrases, something that is not possible with regular expressions.

![Figure 3. Two parse trees for condition phrases that include recursive body part phrases.](image)

### 3.3 Canary: An NLP-based Information Extraction Platform

In order to facilitate the mining of text documents by researchers, we created a free software program called Canary,\(^\text{12}\) as shown in Figure 4 below. The software, which can be downloaded for free (http://canary.bwh.harvard.edu/), was developed to enable information extraction using the approach discussed in section 3.2. The software also includes numerous sample projects that demonstrate how the grammar-based approach described above is used in practice. A number of factors were considered in designing the Canary platform, some of which we highlight here.

**Ease of Use:** Canary was designed for users without software development or engineering experience, allowing the vocabulary and grammar rules to be defined through a unified graphical user interface (GUI). The output is generated in plain text format for easy analysis.

**Easy Setup:** Canary is made available as an off-the-shelf software solution. It can be installed in a local folder without administrator privileges and can even run off a flash drive. It was designed to work out of the box.

**Security and Privacy Concerns:** Researchers in health informatics often work with data that includes protected health information, requiring compliance with the appropriate legal and security measures to guard this information (e.g., HIPAA compliance). These data may be stored on local networks and behind firewalls, with strict rules governing their transmission. Although a number of cloud-based data processing and information extraction solutions have been proposed, the abovementioned restrictions may rule out their use for many clinical researchers. In such cases, the use of self-contained software packages that can be run on local machines may be a better option. This is one of the motivating reasons that underlies Canary’s design.

### 4 Insulin Decline

The first task we demonstrate is the quantitative assessment of insulin decline. It is anecdotally known that patients frequently decline medications that are recommended by their healthcare providers. However, little systematic data are available on this phenomenon. It is not known how commonly patients decline medications and how frequently they ultimately receive medications they initially declined. This information, if extracted, would be of great value to healthcare quality and outcome research.

Insulin is thought to be one of the medications that are especially frequently declined by patients. Many patients are reluctant to start injectable medications; others express fear that “once you start insulin, you can’t get off it.” Studies show that patients whose diabetes is poorly controlled on oral medications take a very long time to be started on
insulin; insulin decline by patients could be one of the reasons for this. However, data on insulin decline remains extremely limited.

One reason for the paucity of research in this area is that information on patients declining medications is not easily available. As these patients declined the medication before any prescription was written, no trail is generated in the data sources that are typically used to study medication prescribing, such as pharmacy insurance claims or EMR medication records. Instead, medication decline is primarily recorded in narrative notes, requiring labor-intensive chart review. To this end, NLP software like Canary holds great promise for allowing clinical researchers to access the valuable pieces of relevant information locked away among millions of unstructured health records. Accordingly, we evaluate our software on data for this task, using it to extract this information and conduct a study to assess the prevalence of patients who decline insulin.

![Canary Software](http://canary.bwh.harvard.edu/)

**Figure 4.** An overview of the Canary software.
4.1 Data Collection

Data for this study comes from the clinical records of all adult patients with diabetes treated in primary care practices affiliated with Massachusetts General Hospital and Brigham and Women’s Hospital between 2000 and 2014. The number of notes reviewed for each task varied between 600 and 50,000.

4.2 Insulin Decline Language Model

A manual review of a subset of the collected data containing 50,000 notes was conducted to identify instances of insulin decline by patients. This task required the largest set of notes due to the extremely low prevalence of the information. Next, Canary vocabulary and information extraction criteria were created by a clinical researcher with no formal training in NLP or software development. They were designed to detect the language used to document insulin decline in manually identified instances with maximum accuracy and generalizability. After iteratively refining the language model, it resulted in a set of 148 word classes and 284 rules.

4.3 Evaluation

The primary aim of our evaluation is to assess the accuracy with which instances of insulin decline can be detected using Canary. This evaluation was conducted against a held-out gold standard dataset of 1,501 provider notes which were randomly selected and independently annotated by trained pharmacy and medical students. The reviewers marked all sentences describing patients who refuse to take insulin. We then compare the reviewers’ annotation to output generated by Canary. We conducted our evaluation against this annotated gold standard at two levels of granularity:

- **Note level:** detecting notes that contain any mention of insulin decline anywhere in the document.
- **Sentence level:** detecting sentences that mention insulin decline, across all notes.

The sentence-level assessment is the more challenging task. At the note level, sensitivity (recall), specificity and positive predictive value (PPV/precision) were calculated. Specificity has no meaning at the sentence level because of the arbitrary nature of the tokenization process (i.e. token boundaries in free text are implementation specific), so only sensitivity and PPV were calculated. Results from this experiment will be used to estimate the prevalence of insulin decline in the unstructured data belonging to patients with diabetes.

4.4 Results

**Table 1:** Evaluation results on the test set of 1,501 manually annotated gold-standard notes. The 95% confidence interval is provided in parentheses.

<table>
<thead>
<tr>
<th></th>
<th>Sensitivity</th>
<th>Specificity</th>
<th>PPV</th>
</tr>
</thead>
<tbody>
<tr>
<td>Note-level</td>
<td>100.0% (76.8–100.0)</td>
<td>99.9% (99.6–100)</td>
<td>93.3% (68.0–99.8)</td>
</tr>
<tr>
<td>Sentence-level</td>
<td>100.0% (82.4–100.0)</td>
<td>N/A</td>
<td>95.0% (74.4–99.9)</td>
</tr>
</tbody>
</table>

The manually annotated test set included a total of 19 sentences mentioning insulin decline across only 14 notes. This is a note-level prevalence of 0.93%, highlighting the difficulty associated with identifying this information through manual review. It should also be noted that given the length of the average note, this prevalence is significantly lower at the sentence level, i.e., less than 1% of sentences.

We next applied Canary to the same data. The results for this evaluation are listed in Table 1. We observe that at the note level, Canary achieved a sensitivity of 100.0% and a PPV of 93.3%, with even better results at the sentence level.

5 Statin Decline

The study of medication decline, as outlined in the previous section, can be extended to other classes of drugs. Cardiovascular disease is the number one cause of death both in the United States and worldwide, and hypercholesterolemia is the most common risk factor. HMG-CoA reductase inhibitors (statins) reduce the risk of cardiovascular events in patients with hypercholesterolemia. Nevertheless, many patients at high cardiovascular risk are not taking statin therapy, likely leading to thousands of preventable deaths. The reasons for this are not fully understood, but it is thought that medication decline may play a role.

Our methodology can be used to empirically study this phenomenon and analyze initial statin decline rates, how frequently patients ultimately start statin therapy after initially declining it, and whether the provider who eventually prescribes statin is likely to be different from the one whose statin recommendation was initially refused in the population of patients at high cardiovascular risk.
To this end we conducted a preliminary study to assess the specificity and PPV of our method in detecting instances of statin decline.

5.1 Data Collection

Data for this study comes from the clinical records of all adult patients with coronary artery disease treated in primary care practices affiliated with Massachusetts General Hospital and Brigham and Women’s Hospital between 2000 and 2013.

5.2 Statin Decline Language Model

A set of 8,800 notes were used by a clinical researcher with no formal training in NLP or software development to create a Canary model to detect instances of statin decline. Canary vocabulary and grammar rules were created to match the text fragments with maximum accuracy and generalizability. This resulted in a model with 97 semantic word classes and 88 structures.

5.3 Evaluation and Results

A set of 4,000 held-out notes were used for evaluation. The model achieved sensitivity (true positive rate) of 88% and PPV (precision) of 92%. These preliminary results highlight the utility of our approach to studying this healthcare issue. We are now in the process of creating additional resources to measure the specificity of our models, in order to apply them for answering the research questions laid out in section 5.

6 Adverse Reactions to Statins

EMRs are widely used in documenting adverse reactions to medications. Clinical decision support systems that analyze previous allergies and reactions have been shown to dramatically decrease prescription errors, making this a widely-researched area. However, a substantial portion of these reactions are not documented in a structured format but instead persist as free text. To this end, we applied our methodology to quantitatively extract this information and conduct a study to assess the prevalence of adverse reaction information that is not present in a structured format. More specifically, we studied this for 3-hydroxy-3-methyl-glutaryl-CoA reductase inhibitors (i.e., statins), as they are thought to have high rates of adverse reactions reported by patients.

6.1 Data Collection

This study was conducted at Partners HealthCare System, a healthcare delivery network in eastern Massachusetts. Partners Healthcare maintains a network-wide repository of medication allergies called the Partners Enterprise Allergy Repository (PEAR). The EMR system used at Partners allows data entry into PEAR. Data for our study came from all patients who were recorded as having been prescribed a statin between 2000 and 2010. This resulted in a set of 4.7 million provider notes.

6.2 Statin Side Effects Language Model

Trained pharmacy students manually reviewed a set of 3,175 narrative provider notes, annotating instances of adverse statin reactions. These notes were randomly selected from a set of all notes written on the data a statin was noted as being discontinued in the EMR system. After the annotation, Canary vocabulary and grammar rules were created to match the text fragments with maximum accuracy and generalizability.

6.3 Evaluation and Results

The evaluation follows the same scheme as described in section 4.3 above, with the exception that a held-out gold standard dataset of 242 provider notes were randomly selected and independently annotated by two trained pharmacy students. The results for the first stage of evaluation are listed in Table 2. We observe that at the note level, Canary achieved a sensitivity of 87.4% and a PPV of 99.4%. As expected, detection at the sentence level is more challenging, with slightly lower results.

Table 2: Evaluation results on the test set of 242 manually annotated gold-standard notes. The 95% confidence interval is provided in parentheses.

<table>
<thead>
<tr>
<th></th>
<th>Sensitivity</th>
<th>Specificity</th>
<th>PPV</th>
</tr>
</thead>
<tbody>
<tr>
<td>Note-level</td>
<td>87.4% (83.0–91.8)</td>
<td>98.3% (96.5–100)</td>

</tr>
<tr>
<td>Sentence-level</td>
<td>80.6% (75.4–84.9)</td>
<td>N/A</td>
<td>98.6% (96.9–100)</td>
</tr>
</tbody>
</table>
Having validated the model and demonstrated that it can achieve high levels of accuracy, we proceeded to the second stage of our evaluation. Canary was used to process the full set of 4.7 million notes collected for the study. This resulted in the identification of 224,421 patients who were prescribed a statin during the study period, with 31,531 of these being flagged by our software as having had an adverse reaction to a statin side. However, only 9,020 (28.6%) of the patients had a statin reaction recorded in structured format (in PEAR). This result indicates that the great majority of care providers record drug reaction information only in unstructured data.

7 Bariatric Surgery Counselling
Bariatric surgery is the single most effective treatment for significant and sustained weight loss in obese patients and significantly improves numerous obesity-related comorbidities, including cardiovascular risk, hypertension, myocardial infarctions, strokes and cardiovascular deaths.

A critical step in a patient’s decision to undergo bariatric surgery is clinician discussion and recommendation of bariatric surgery to the patient. Little systematic data are available on the epidemiology of bariatric surgery recommendation. It is not known how commonly physicians discuss and recommend bariatric surgery to obese patients who are surgical candidates. One of the reasons for the paucity of research in this area is that information on physician recommendation of bariatric surgery is not easily available. This information is typically not reflected in either administrative or structured electronic clinical data, as no prescription or insurance claims data are generated. Instead, recommendation of bariatric surgery is primarily recorded in narrative notes, requiring labor-intensive chart review.

The methodology we have used thus far can be used to study this issue empirically. In attempting to quantify the recommendation of bariatric surgery within notes, any approach must be able to distinguish between discussion and mentions of prior procedures. Consequently, the identification of notes containing these two categories of information the aim of our preliminary project.

7.1 Data Collection
Data for this study comes from the clinical records of all adult patients with body mass index (BMI) $\geq 35$ kg/m$^2$ treated in primary care practices affiliated with Massachusetts General Hospital and Brigham and Women’s Hospital between 2000 and 2014.

7.2 Bariatric Surgery Counselling Language Model
A set of 300 notes were manually annotated by a trained pharmacy student and subsequently used by another researcher with no formal training in NLP or software development to create a Canary model to distinctly detect instances of prior surgery and surgery discussion. Canary vocabulary and grammar rules were created to match the text fragments with maximum accuracy and generalizability. This resulted in a model with 17 semantic word classes and 160 structures.

7.3 Evaluation and Results
A held-out test set of 300 notes were manually annotated by a trained pharmacy student and used for evaluation, which follows the same procedure as described in section 4.3. The results for both categories at the note- and sentence-level are listed in Table 3. This preliminary evaluation is very promising, showing that our models are able to achieve high accuracy and demonstrate the generalizability to new data.

| Table 3: Evaluation results for both categories on the test set of 300 manually annotated gold-standard notes. |
|---------------------------------|--------|--------|
| **Bariatric Surgery Discussion (Note-level)** | 90%    | 90%    |
| **Bariatric Surgery Discussion (Sentence-level)** | 85%    | 69%    |
| **Prior Bariatric Surgery (Note-level)** | 83%    | 90%    |
| **Prior Bariatric Surgery (Sentence-level)** | 44%    | 96%    |
8 Discussion and Conclusion

We described and demonstrated the application of information extraction for identifying actionable insights by mining clinical documents. We showed that this approach can assist with answering quantitative healthcare quality research questions whose answers are not easily derived from structured data sources.

As part of this approach we also presented Canary, an information extraction tool based on user-defined parameters and ontologies. The principal advantage of our tool is that it is a GUI-based software which does not require any technical background. In this study, this was underlined by the fact that it was used by several researchers without any such technical background to successfully create language models of important clinical phenomena. The feedback from these users was positive and the models were then tested on a large-scale set of provider notes.

This approach is also useful for outcomes research, which involves quantifying treatment patterns and measuring the associated patient outcomes, and is an important area of study for identifying potential areas for improving healthcare quality. To this end, the methodology described here could be used to quantitatively measure complex social and demographic issues in health services research.

Abstract

Unhealthy eating is the most important preventable cause of global death and disability. Effective development and evaluation of preventive initiatives and the identification of disparities in dietary patterns require surveillance of nutrition at a community level. However, nutrition monitoring currently relies on dietary surveys, which cannot efficiently assess food selection at high spatial resolution. However, marketing companies continuously collect and centralize digital grocery transaction data from a geographically representative sample of chain retail food outlets through scanner technologies. We used these data to develop a model to predict store-level sales of carbonated soft drinks, which was applied to all chain food outlets in Montreal, Canada. The resulting map of purchase patterns provides a foundation for developing novel, high-resolution nutrition indicators that reflect dietary preferences at a community level. These detailed nutrition portraits will allow health agencies to tailor healthy eating interventions and promotion programs precisely to meet specific community needs.

Introduction

Unhealthy eating is the leading preventable cause of global death and disability, responsible for 11.3 million premature deaths and the loss of 241.4 million disability adjusted life years¹. Obesity and overweight are recognized as a global public health crisis due to the sharp increase in prevalence and their recognized role as risk factors for debilitating chronic diseases including various cancers, cardiovascular diseases, and type II diabetes²,³. Excess sugar intake is one of the most important contributors of weight gain, and carbonated soft drinks (soda) are the primary source of artificially added sugar in the United States ⁴. Soda intake is especially prevalent among individuals with low Socio-Economic Status (SES), thereby contributing to socio-economic inequalities in nutrition-related chronic illness⁵,⁶.

Effective preventive initiatives aimed at reducing nutritional inequalities and improving dietary patterns at population-level are urgently needed. Examples of such approaches include subsidization of healthy food, taxation of unhealthy food, nutrition re-formulation of food product, and increased regulation of unhealthy food marketing activities⁷–¹². At the community level, nutrition education and health promotion programs using existing community ties play a significant role in empowering individuals and communities to adopt healthy dietary behavior ¹³,¹⁴.

The planning and management of these interventions and providing direction to population nutrition research require a capacity to measure dietary patterns at a population scale ¹⁵,¹⁶. Dietary surveillance programs should provide up-to-date information about trends in dietary patterns that will support evaluation of the effectiveness of policies and the influence of socio-economically significant events¹⁶. Such information should be available at high spatial resolution to allow the identification of community-level nutrition disparities, to evaluate neighborhood-specific responses to policy interventions, and to capture the influence of physical environment (e.g. residential availability of food stores and walkability)¹⁶,¹⁷. In addition, the information needs to provide product-specific information to track the change of nutrition formulation over time.

To date, public health surveillance of nutrition has largely relied on (often ad-hoc, non-repeated) dietary surveys, which suffer from the underreporting of food intake and inaccurate recall¹⁸,¹⁹, a lack of detailed information of consumed products (i.e., nutrition contents, packaging, and promotion such as price discounting), and which prohibit
dietary assessment for small areas, especially for surveys with a small sample size. In Canada, a national nutrition survey is conducted only every 10 years, and it only allows dietary habits to be estimated at a low spatial resolution (e.g., provincial level). Consequently, many public health and community initiatives must be taken with little if any relevant and timely information.

Market researchers, food manufacturers, and retail industries use scanned grocery transaction data generated by retail food outlets to guide food product development and promotional activities. The stream of retail transaction records from a sample of grocery stores and non-conventional food outlets, such as pharmacies, are routinely collected and centralized in an automated manner by marketing firms such as the Nielsen Corporation. The data contain product details including product name, purchased quantity, price and promotion status at weekly level along with time-fixed store attributes including location, chain (banner) name and unique store code. Additionally, product-specific Universal Product Code (UPC) can be linked to existing nutrition composition marketing databases to enable automated classification of healthy/unhealthy food and product marketing activities, including packaging design.

Although infrequently used in public health research and practice, these point-of-purchase (i.e., store-level) data could provide a unique input to an automated nutrition surveillance system. Using these data, such a system could produce information on food purchasing patterns, neighborhood product affordability, and the availability and marketing of foods at a high spatio-temporal resolution. The effective application of this information would allow public health agencies and community health workers to access up-to-date community nutrition status and formulate health promotion planning and intervention required at jurisdictional level.

However, generating useful information from these point-of-purchase data is a non-trivial problem. Because the transaction data are available for only a sample of food outlets, assessment of food purchase patterns at small area requires estimation of sales data for out-of-sample stores. The unobserved sales from these out-of-sample stores can be predicted using data from observed stores and the neighborhood and store-level features available from comprehensive government and commercial business registry data. The objective of this study is to develop a sales prediction model using the data from sampled stores, and apply this model to predict sales for out-of-sample stores using store and neighborhood attributes available in the transaction data and business registry data. As an initial example, we develop and apply such a model for the prediction of soda products due to their recognized interest as the major source of artificially added sugar and highly debated product as a target for taxation to reduce population-level consumption.

Methods and Data

The target geographic region was the Census Metropolitan Area (CMA) of Montreal, Canada, which had a population of 3,824,211 inhabitants in 2011. The Nielsen Corporation selects chain retail stores from the Montreal CMA by stratified random sampling, where strata are defined by urban/suburban status, store size, and store type (e.g., supermarkets, pharmacies, mass supercenters). Inclusion criteria for this study are supermarkets (chain grocery stores), chain pharmacies, and supercenters (e.g., Wal-Mart). Excluded store types are independent stores, Warehouse (e.g., Costco), and dollar stores. Our preliminary work indicates that the grocery market share of these target stores among all retail food outlets is 65.2 percent in the Montreal CMA. To maintain the representativeness of the sample in the face of store closures and openings, periodic partial resampling is performed. We extracted the transaction data covering the 2012 calendar year as the study period of interest.

The scanner data consist of weekly aggregated store-level sales volume and information on each food item as defined by Universal Product Code (UPC). Transactions for soda are extracted from a food category labelled as ‘Carbonated Soft Drinks’, from which diet soda is identified and excluded by terms in the product description suggestive of diet beverages. For each store, we generated the average weekly soda sales in 2012 standardized to a single serving size (240ml), resulting in 128 data points (i.e. 128 sampled stores in 2012). Relevant predictive features of soda sales are chain identification code, store type (e.g., supermarkets, pharmacies, supercenters), store size (number of employee), and neighborhood socio-demographic attributes, which are median family income, proportion of individuals who received post-secondary diplomas, proportion of immigrants, and population density as measured by the 2011 Canadian Household Survey. Using linear regression, natural log-transformed soda sales...
were modelled as a function of these predictive features of soda sales. Selection of the predictors and first-order interaction terms was guided by the minimization of the mean squared error (MSE) using 10-fold cross-validation.

The resulting soda sales prediction model was applied to the out-of-sample food outlets in the Montreal CMA. Predictive features of the sales were supplied by the Canadian Business Point of Interest data, which contain annually updated data for all business establishments in Canada. The predicted store-specific weekly average soda purchases in 2012 were spatially interpolated to provide a graphical representation of the soda sales (indicator of unhealthy purchasing) across the Montreal CMA.

Results

The comparison of beverage category-specific sales indicates that soda, along with milk, were the most frequently purchased beverages in the Montreal CMA. The resulting prediction model as selected by cross-validation demonstrated a good model fit (adjusted R square; 0.95) and prediction error (MSE: 0.20). The highly variable nature of soda sales by chain (Figure 3), and their regression coefficients in the selected prediction model (Table 1) indicate that sales are strongly associated with attributes that are differentiated across the chain, such as store size, product assortment, pricing, and promotional patterns. Interestingly, neighborhood socio-economic status (as represented by income and education in the final model) were substantially less predictive of sales as compared to store chain. The spatial distribution of predicted soda sales is presented in Figure 4.
Figure 2. Trend of beverage category-specific transactions (servings in log base 10) observed between 2008 and 2013 in Montreal CMA.

CI: Confidence Interval.
Chain: indicator variable for retail chain, where chain A was used as a reference.
*Predicted change in natural log soda sales in standardized serving (240ml) by each predictor.
±Area-level proportion of post-secondary diploma or certificate. Thus, store-level log soda sales in an area with all residents having post-secondary education is -0.87 (95% CI: -1.85 to 0.12) lower than the store-level sales in an area with no residents attaining post-secondary education.
‡Area-level median family income in 10,000 Canadian dollars.
Discussions and conclusion

Our study harnessed the existing digital grocery transaction data to provide a novel indicator of neighborhood dietary patterns. This is one of the first applications of point-of-purchase transaction data to generate high-resolution surveillance information on population nutrition for public health. The method we propose creates a foundation for further exploration of how scanner data can be used to improve the assessment of population nutrition. The strong predictive power of store chains indicates that the mix of chains in a neighborhood at least partially explains spatial patterns in soda purchasing. Therefore, neighborhood mix of retail chain may serve as an environmental indicator useful in characterizing communities that are prone to excess soda consumption. Because pricing, product assortment, and various food marketing activities are available in the transaction data, further investigation could identify factors across chains that drive differential sales and which may be important in-store risk factors of unhealthy food selection.

The proposed approach provides an effective and novel solution for the automated and accurate estimation of dietary patterns for small area, which is not possible with the current nutrition surveillance relying on dietary surveys. Effective analysis of grocery transaction data will therefore provide important and novel information to enable evidence-based planning and evaluation of preventive strategies aimed at dietary risk factors. Because objective data collection was achieved by scanner technology at the store-level, the purchase and promotional status are free of measurement error arising from consumption reports from participants. In addition, these data are collected on a global scale by international marketing companies. Therefore, standardization of measurements and comparison of population nutrition status across regional, provincial, international national levels can be readily achieved.

The development and evaluation of a valid sales indicator requires several ongoing and remaining steps (planned as part of primary author’s doctoral thesis);
Spatial dependency of sales is being investigated using Conditional Autoregressive Model.

Using large travel surveys conducted in the Greater Montreal region, we are characterizing the shopping-related mobility of individuals, conditional on the area of residence and socio-demographic attributes. The travel distance and shape will be used to re-parametrize the smoothing method used in this study.

Sales at point locations (stores) are being converted into an area-level measure defined by socio-economically meaningful neighborhood spatial unit, and we are investigating their correlation with the area-level health outcome, including diabetes and obesity/overweight.

Finally, we intend to estimate the predictive performance of our area-level purchase indicator for person-level soda consumption records using dietary questionnaires obtained from residents through nutrition survey.

In addition to the sales measures, it is also possible to predict other store attributes, including the availability of (un)healthy food products and their affordability (food price relative to area-level income). Furthermore, these data also offer a highly time-varying view on marketing activities, such as temporary price discounting and flyer promotion, allowing measurement of neighborhood-level susceptibility to food marketing as demonstrated by our exploratory study. Although these promotional activities are recognized as strong drivers of food selection among market researchers, they are prohibitively expensive to capture by manual field (in-store) investigation. Our modeling can be extended to predict store and category-level promotional activities for healthy and unhealthy food, and it allows profiling food outlets (and thus neighborhoods) based on the exposure to food marketing to identify communities at risk of unhealthy food purchasing.

Three major limitations in this initial study should be noted. Although the study focused on non-diet soda items as an initial example, purchase patterns of a single food category provide limited information for the dietary assessment. Because the transaction data provide a full range of healthy/unhealthy food categories (typically greater than 100 categories in a supermarket), our model could be extended to a multivariate approach (joint modelling of multiple response categories), which will exploit the correlation of food sales across categories. Since the Nielsen corporation does not sample independent (non-chain) stores, our transaction data and thus prediction model is only applicable to chain stores, whose market share of all grocery products is approximately 65 percent. However, because chain supermarkets are the primary location of unhealthy food purchase, we included the most important stores determining the spatial trend of soda sales. Finally, our study estimated the volume of soda, rather than the actual quantity of sugar purchased, which is a more directly relevant public health indicator. Therefore, linkage of transaction data with existing nutrition composition databases should be performed in future.

In conclusion, the current lack of neighborhood-level dietary surveillance impedes effective public health and community actions aimed at encouraging healthy food selection and subsequent reductions of chronic illness. The rapidly increasing digitalization of consumer retail activities creates opportunities for creative public health applications of these data. Our method leverages existing grocery transaction data to address an important gap in population monitoring of nutrition status and food preferences.

Point of Care Research: Integrating patient-generated data into electronic health records for clinical trials

Sara Marceglia, PhD1,2, Pierluigi D’Antrassi, PhD2, Marco Prenassi, MSc1, Lorenzo Rossi, PhD3, Sergio Barbieri, MD2

1University of Trieste, Trieste, Italy; 2Fondazione IRCCS Ca’ Granda Ospedale Maggiore Policlinico, Milano, Italy; 3Newronika S.r.l., Milano, Italy;

Abstract

Integrating patient-generated data into clinical research would improve the reliability of results, especially when longitudinal, chronic, home-based monitoring is needed. To this end, we designed, implemented, and tested a system that allows integrating patient-generated data into electronic case report form (eCRF), using a standards based architecture that ensured the fulfillment of the major requirements for digital data in clinical studies. The system was tested in a clinical investigation for the optimization of deep brain stimulation therapy in patients with Parkinson’s disease that required both the collection of patient-generated data and of clinical and neurophysiological data. The validation showed that the implemented system was able to provide a reliable solution for including the patient as direct digital data source, ensuring reliability, integrity, security, attributability, and auditability of data.

Introduction

Point of Care Research (POC-R) is now gaining increasing attention as a way to enhance the integration between clinical research and clinical practice1 so that the FDA recently drafted a guidance on the “Use of Electronic Health Record Data in Clinical Investigations”2. Including electronic health records (EHRs) as data source for clinical trials would take advantage of the potentials of combining, aggregating, and analyzing longitudinal patients’ information, thus facilitating the collection of valuable information. It is expected that “EHRs may have the potential to provide clinical investigators and study personnel access to real-time and longitudinal health care data for review and can facilitate post-trial follow-up on patients to assess long-term safety and efficacy of medical products”2.

However, longitudinal clinical trials that require patient’s monitoring in a chronic, home-based condition may benefit of systems able to integrate patient-generated data into EHRs and, in turn, to electronic Case Report Forms (eCRFs). Personal mHealth Apps and the Internet of Things (IoT), at a time when there are more mobile connections than the entire human population, can support patients managing medical conditions, monitor lifestyles, and may even provide medical advice. Such technologies may also be adapted to become a new source of data, directly collected from patients in their ecologic environment, that can be used in clinical trials. To do so, patient-generated data in the chronic, home-based environment needs to be integrated with clinical hospital information systems (HISs) and EHRs.

As previously proposed3,4, a standards-based architecture could be used, independently from the specific EHR system considered, to allow the direct exchange between mHealth Apps and EHR systems. The standards-based architecture require specific document templates taking into consideration patient’s identification issues, privacy, reliability, and interoperability, and it was successfully proven in a prototype environment4.

However, integrating patient-generated data collected while the patient is at home into the streaming of clinical trial data poses some challenges, that reflect the “ALCOA” requirements (A – Attributable, L – Legible, C – Contemporaneous, O – Original, A – Accurate) stated by FDA guidance on electronic data sources in clinical trials:

1. Attributable: each document (and modification or review) has to be attributed to an author;
2. Legible: data should be clearly presented in a human-readable format;
3. Contemporaneous: in addition to the synchronous data recording, any modification should be time-stamped, tracked, motivated, and signed and then synchronized;
4. Original: data should be captured directly and kept safe and de-identified, because the mobile environment is supposed unsafe;
5. Accurate: patient-generated data may pose the problem of reliability, being the patient’s health literacy generally low. Also, data collected from personal medical devices should be considered. Finally, data have to be collected strictly following the clinical protocol, otherwise they cannot be used in the clinical investigation;

Considering these requirements, we designed and implemented a standards-based system that uses
(a) a specifically designed web-based platform that integrates EHR features with signal analysis and management;
(b) a workflow engine to manage the clinical trial process;
(c) a set of mobile apps and wearable devices for patient’s data collection that exchange information using a standards-based document set.

We tested the system in a clinical investigation for the optimization of deep brain stimulation (DBS) therapy in patients with Parkinson’s disease that required both the collection of patient-generated data and of clinical and neurophysiological data.

**Methods**

**System Architecture**

The system integrates information from different actors (Figure 1), namely the Patient, the Doctor, and the Researcher. The Patient may be supported by a Caregiver. The architecture has three main components: the Patient System, the Workflow Manager (WFM), and the WebBioBank (WBB).

![Figure 1. System Architecture](image)

**Patient System**

The Patient System consists of both hardware and software to ensure the provision and use at home of the information necessary for the proper implementation of the clinical trial. The hardware is composed of a Wearable Device (WD) and a Mobile Device (MD), while software refers to the mHealth app for the Patient and the Caregiver. The MD collects all the information attained by the WD (in our specific application, it consists of accelerometer acquisition) and the self-reported data (Patient Diary), and communicates them to the WFM via an external gateway. The main components of this device are a large touchscreen (>3.7”) for better filling out the Patient Diary, a storage system (larger than that made available by the WD) to temporarily store collected data before sending it to the WFM, a Bluetooth transceiver to communicate with and receive acquired data from the WD, and a long-life battery (at least 8h).
The connection from the Patient System to the WFM is implemented by the exchange of XML-based CDA-2 structured documents optimized for the anonymous communication with mobile applications\(^4\), so that no identification data is sent through unsecure connections, or retained into unsafe environments.

The WFM communicates with the Patient System by exposing services that manage reminders and notifications to the mobile application.

**Workflow Manager**

The WFM is a system that provides the interoperability and electronic exchange of information between the Patient System and the WBB. This system offers to the Researcher the ability to model the patient protocol as a graphical flowchart in a workflow editor and to the Doctor the ability to associate each Patient to the specific protocol and execute such process in a workflow engine.

A proprietary workflow composer is used for viewing and creating patient protocols. Key components of each protocol definition are participants (i.e., patients, caregivers, doctors, researchers and inspectors), activities (e.g., data acquisition, filling patient diary, drug administration, …), transitions (e.g., end data acquisition and send the CDA-2 document), schedules (e.g., filling the patient diary each 30 minutes), and variables.

For patient protocol execution, the WFM extends the Mirth Connect health care integration engine\(^6\). Mirth Connect is an open source HL7 interface engine is rich in features as well, including filtering, validation, transformations and routing of documents through different kinds of information system.

Users with different privileges and roles will gain access to the WFM according to their job function and to the clinical center they belong to, according to each specific research protocol. User access is managed and tracked in the WBB and synchronized with the WFM access control.

**WebBioBank**

WBB (www.webbiobank.com) is a web-based platform that integrates clinical data collection with signal management and processing\(^5\). The system is based on the wHospital framework\(^7\) that is a commercial EHR system used in several healthcare institutions and Regional implementations. WBB includes dedicated functionalities to support multicenter clinical studies and an adjunctive module for biosignal storage, management, and analysis\(^5\). The system is accessed through a standard web browser, allowing users to perform various tasks for data management in an anonymous mode according to shared protocols, thus guaranteeing real time interaction between researchers and clinicians in different research centers. Clinicians can add patient’s clinical information using shared clinical forms specific for the clinical study, whereas researchers develop and use shared advanced algorithms for signal processing that can be combined in analysis chains, ensuring that the data processing and analysis are the same in all of the centers involved in the research study. To extend its use to clinical trials, WBB provides data de-identification, ensuring patient’s privacy also when involved in multi-center studies. To enable anonymous data collection, on the web-based platform, only unique patients’ IDs (IDBAC) are saved and records do not include identifying demographic information. The unique IDBAC ensures attributability of records to patients. Patients demographics are visible only to the users belonging to the clinical center (operative unit, OU) in charge of the patient. Each OU can therefore use WBB as an EHR. WBB implements a Role-Based Access Control ensuring that only authorized users, with pre-defined roles, will gain access according to their job function in the clinical center during each specific research protocol. Also, the system keeps track of logins and failed login attempts. Since WBB integrates the functionalities of traditional EHRs with those of research support systems, it implements a “research” EHR (rEHR)\(^5\).

**Structured documents templates**

Data reliability, integrity, and attributability was achieved by exchanging standard CDA-2 documents. The CDA-2 template used is a modified version of the Personal Healthcare Monitoring Report (PHMR) CDA2 template (CDAR2_IG_PHMRPTS_R1.1_DSTU_2010OCT) adapted to fulfill the requirements of the mHealth App/EHR data exchange as already described in \(^4\). We will refer to this template as mobile PHMR (mPHMR) The major changes introduced in mPHMR regard the possibility to recognize the patient as data author (and not only as <recording target>), and the use of de-identified patient’s information, to ensure security. In this implementation, the experimental session ID is also reported in the header, to identify the precise location of the data collected within the clinical study protocol. The <Custodian> is the OU in charge of the patient. The mobile app and device are described as equipment and participate to the data collection as data source. The body of the document is composed by four mandatory sections: Results (LOINC 30954-2), Medical Equipment (LOINC 46264-8), Medications (LOINC 10160-0), and Purpose (LOINC 48764-5)\(^4\).
Validation case study

Our first target for system validation is the telemonitoring of patients with DBS implant in order to obtain information on therapy optimization. Since our patients face a fragile stabilization period immediately after electrode placement, we decided to make the first system testing in a controlled environment, to keep the risks for patients as low as possible.

We hence used the implemented system to support a clinical trial ongoing at the Fondazione IRCCS Ca’ Granda Ospedale Maggiore Policlinico of Milan (Italy) on patients with Parkinson’s Disease implanted with DBS electrodes. The specific research aimed to test a newly developed CE-marked external prototype for closed-loop adaptive DBS (aDBS). The aDBS device automatically adapts stimulation parameters moment-by-moment to the patient’s clinical state, thus providing optimal stimulation parameters\(^8\). This external prototype we tested implements an aDBS approach based on the analysis of local neuronal activity (local field potentials, LFPs) captured from the DBS electrodes while stimulation is switched on\(^8\). In particular, the prototype adapts DBS parameters according using modulations of the LFP beta band (13-35 Hz). In this research study, aDBS was tested in freely moving PD patients for 8 consecutive hours, by continuously monitoring beta band modulations and by assessing aDBS ability to respond to changes in patient’s state (Figure 2). The data collection system we implemented was used to support the research in two ways: (1) collecting clinical data generated by the expert neurologist who assessed the patient during the 8-hours period; (2) collecting patient-generated data in an ecologic but controlled environment, while the patient was left alone doing his/her normal activities in his/her room with the aDBS prototype on.

Figure 2. 8-hours experimental protocol

The experimental protocol is depicted in Figure 2. The study was approved by the institutional review board and by the Italian Ministry of Health, and conformed with the Declaration of Helsinki. We enrolled 4 PD patients who underwent surgery for DBS electrode implant having externalized leads for a week to connect a wearable device for aDBS testing. Two perioperative sessions lasting from 7 to 8 hours were conducted the day 5 and 6 after surgery while the patient was doing his/her normal activities. In the first session, the beta band power was continuously recorded while the patient took its post-operative daily medication dose. In the second session, we added aDBS treatment to beta band power monitoring and daily medication. A neurologist assessed the clinical state and fluctuations at 5 time points (Figure 2) through the motor Unified Parkinson’s Disease Rating Scale part III (UPDRSIII) and the Unified Dyskinesia Rating Scale (UDysRS). During the entire duration of the experimental session, the patient filled in a diary (every 30 minutes) and wore a bracelet to assess his/her bradykinesia state.
Patient’s wearable device and mobile application

Patient’s generated data in the implemented system were of two kinds, the first one being a personal diary, collecting the patient’s state every 30 minutes, with scheduled alerts; the second one being accelerometer data acquired by a commercially available wearable device.

The device used was a Pebble Time smart-watch. It includes a three-axis accelerometer and a Bluetooth connection with a mobile device (Android Phone). A dedicated app was developed to both acquire and store data, and to provide a clinical diary to be filled in by the patient at predefined times. The patient has a personal ID and password to access to the app (enforced by an initial login screen). The mobile phone app implements an algorithm that finds the Bradykinesia Acceleration Scores (BAS) using the accelerometric values of the smart bracelet. The BAS algorithm was adapted from the patent of Griffiths & Horne9.

System testing

The system Validation test consisted into two experiments: the first one checked the functionalities of the WBB system and its integration with the WFM, and the second one verified the ability of the app to collect patient-generated data in an accurate and secure way. Tables 1 and 2 (columns 1 and 2) detail the test protocols of the two experiments and their expected results. Errors are detected when the test result differs from the expected result.

Results

System implementation

The system was fully implemented to be used in the validation case study. WBB was configured in terms of users, roles, and forms to support the 8-hours research study in the hospital-based ecologic but controlled environment. WBB fulfills the requirements for clinical study data collection: patients are de-identified to ensure security; the clinical forms are developed by the researcher (usually the principal investigator), filled in and signed by the author, reviewed by the principal investigator, and changes/modifications are tracked, time-stamped, and signed whenever they occur, thus guaranteeing integrity, attributability, and reliability. The definition of the “inspector” user role allowed auditability. Figure 3A shows the snapshots of the main rEHR forms created to collect data from PD patients undergoing the experiment.

<tr>
<td>1) A caregiver logs into the app with the patient ID and password, configures the timer of the app to acquire only accelerometric data from the Pebble Watch in an 8h session and press play to start the acquisition from the mobile phone.</td>
<td>At the end of the session, there will be a rEHR inside the WBB with the BAS data of the patient and another rEHR with the UPDRSIII scores compiled by the clinician. The mPHMR data on the mobile device must be absent at this time and the tables on the SQLite Database must be empty. The IDBAC of the two rEHR and the IDBAC into the mobile device must be the same.</td>
<td>There are two correct rEHR on the WBB. Some BAS data in particular timeframes are absent due to the distance of the mobile device from the patient caused by forgetfulness or special conditions (e.g. MRI or other exams). The correlation between UPDRSIII scores and the BAS is -0.582 (p-value&lt;0.009, Pearson) for 5 sessions regarding 4 different patients.</td>
</tr>
<tr>
<td>2) The patient wears the bracelet helped by the caregiver and starts the acquisition pressing the start button on the watch, at the end of the session the caregiver synchronizes the mobile device pressing “Send data” with the Workflow Manager.</td>
<td>At the end of the session, there will be a rEHR inside the WBB with the diary data of the patient. The mPHMR data on the mobile device must be absent at this time and the tables on the SQLite Database must be empty. The IDBAC of the rEHR and the IDBAC of the patient must be the same.</td>
<td>There is a correct rEHR on the WBB; the BAS score was not evaluated. One patient did not fill the diary; the rEHR data contains null values for every missing timeframe.</td>
</tr>
<tr>
<td>3) A doctor logs into the WBB and fills the clinical form of the patient with the UPDRSIII scores assessed during the session.</td>
<td>A caregiver logs into the app with the patient ID and secret password, configures the diary notifications interval of the app to 30 minutes and sets the session time to 8 hours to acquire the personal diary data. The patient, after the setup, fills the diary every half an hour, at the end of the session the caregiver synchronizes the mobile device with the Workflow Manager pressing “Send Data” on the mobile app.</td>
<td>Testing the range of the Bluetooth connection between mobile device and smartwatch. It must cover all the patient room including the bathroom and the nearby corridor (at least 8 meters with a wall in between, not RF shielded). Bluetooth Low Energy has &gt;100 m declared line-on-sight range with the on-chip antenna, in normal patient rooms the RF noise on the 2.4 GHz band is low and the walls are not RF shielded.</td>
</tr>
<tr>
<td>A caregiver logs into the app with the patient ID and password, configures the diary notifications interval of the app to 30 minutes and sets the session time to 8 hours to acquire the personal diary data. The patient, after the setup, fills the diary every half an hour, at the end of the session the caregiver synchronizes the mobile device with the Workflow Manager pressing “Send Data” on the mobile app.</td>
<td>Testing the battery life of both the pebble smartwatch and the mobile devices. The prerequisite states that the WiFi and Bluetooth connection must be always on, also the accelerometric acquisition must be always on in a daily living situation, for at least 8 hours.</td>
<td>The Pebble Smartwatch app acquires data with a sample rate of 100 Hz and sends packets every 5 seconds to save battery. The background service on the mobile device must be always on. It is a power consuming activity but it is expected at least 8 hour of operation.</td>
</tr>
</tbody>
</table>
Two web services were developed to support the communication and integration between the WBB and the WFM. The first one (wHvpc) is devoted to the integration of user roles and patients’ IDs: it allows the verification of the privacy criteria for doctors/researchers who access the WFM to create or assign the patient’s protocol and, once the doctor accesses to assign the study protocol, allows the exchange of patient’s ID and contact information from WBB to WFM. Then, when the protocol has been assigned and the patient is registered in WFM, the WFM deletes contact information and keeps only the patient’s ID. In this way, the synchronization between the two systems is guaranteed thus allowing attributability and integrity, and patient’s contact information do not reside on WFM, thus allowing security and privacy. The second one (wHcda) is devoted to the exchange of CDA-2 standard documents between the WFM and the WBB. Once the WFM receives patient-generated data from the mobile application, it creates and encodes the CDA-2 document according to the mPHMR template, and sends it to the WBB using the wHcda web service. Data reliability is therefore ensured by the use of standard documents that are accepted by the WBB platform and processed as clinical documents.

On the patient side, the WFM provides the functionalities for patient’s registration and protocol fulfillment. The WFM stores the patient data into the correct rEHR on the WBB by calling the wHcda service passing the identification numbers of the user (uID), the patient (IDBAC), and the custodian (ID OU). The patient data inside the database are anonymous for all users, and only the patient’s doctor can re-identify them by means of a local registry. De-identification is guaranteed also by the WFM registration process that does not require patient’s demographic information, but uses the contact information retrieved at the time of assignment that are then deleted when the patient is successfully registered. Thanks to the definition of the patient’s protocol, the WFM is able to send the activity program to the patient’s mobile app, and to provide remainders and alerts when a task is due (e.g., when the patient has to fill-in the diary). Also, in the case WFM does not receive the patient-generated data on time, according to the protocol, it sends new requests, and then notifies the WBB of the deviation from the protocol, sending a specific CDA-2 with the indication of the deviation using the wHcda web service.

Patient-generated data collection for the case study, including a patient’s diary to be filled in and a wearable bracelet for bradykinesia evaluation (Figure 3B), is shown in the sequence diagrams in Figure 4. The algorithm in the mobile app generates a BAS value every 4 minutes of data. BAS is lower when the patient is bradykinetic (Figure 3C). Bracelet data are preprocessed in the mobile app to retrieve the bradykinesia score (Figure 3C). The forms for the patient’s diary consists of a multiple-choice mutually exclusive list that asks the perceived motor status through 4 different answers: “OFF: Bradykinesia and rigidity”, “ST: Transition”, “ON: normal mobility”, and “ON: disabling dyskinesia”.

The diary and the accelerometer data is stored internally in a SQLite DBMS. When the device is synchronized with the WFM, a mPHMR document is generated with the all the BAS data compressed and encoded in MIME format in an observation of the CDA-2 document (content-type: application/x-compressed, Content-Transfer-Encoding: BASE64) and all the diary data on another plain text observation of the same document. If the mPHMR document is correctly stored and approved by the WFM, a positive feedback is sent back to the mobile device and the internal database is erased for security reason. This feedback and the other remainders are sent through a web-service exposed by the WFM. The use of standard CDA-2 documents between the App and the WFM ensures data integrity, attributability, and safety (in the CDA-2 the author is the patient, identified only by his/her ID). Also, the mobile app does not retrieve any clinical data, but deletes them when the WFM correctly receives the CDA-2 and validates the data.

System validation

In our experiment, we enrolled 4 patients, 2 doctors, and 1 researcher (the principal investigator). Also, a user with role “inspector” was created to test the audit functionalities. On WBB, the researcher created 7 forms, one for patient’s disease history, one for DBS surgery details (target position, electrodes implanted, intraoperative monitoring results), one for the details of the experimental setting (levodopa equivalent dose administered to the patient, neurophysiologic parameters retrieved to set the aDBS device), one for each clinical assessment including the UPDRSIII and the UDysRS scale, and one for the visualization of patient-generated data. The results of the planned validation testing are reported in Tables 1 and 2 (column 3).
Figure 3. System implementation for the validation case study. A) Snapshot of the WBB form for UPDRS III. B) Patient assessment and patient diary. C) Accelerometer exemplary data. D) Correlation between UPDRS III score and bradykinesia accelerometer score (BAS). Note that the system was implemented in Italian.

All the expected 128 diary recordings were received by the system. Of them, 105 were filled-in whereas 23 arrived with null values. The major reason was one poor compliant patient who lacked compiling the diary several times. There were no errors in the data transmission. A total of 40 hours of accelerometer data were recorded. The accelerometer data loss was due to a poor connection between the wearable device and the mobile app. Despite this, as shown in Figure 3D, there was a significant correlation (-0.582, p<0.009) between clinical assessments and patient-generated data, thus suggesting that the measures obtained by the wearable device are reliable for assessment purposes, even though data are incomplete.

Conclusion

We designed, implemented, and tested in a real clinical research study a system that allows integrating patient-generated data regarding clinical trial into rEHRs, using a standards based architecture that ensured the fulfillment of the major requirements.

Health information exchange between mHealth Apps (Patient Reported Outcomes, PRO), clinical research studies, and EHR systems is a recent challenge from the technological and regulatory point of view. Many example bi-directional health information exchange between mHealth Apps and EHR systems are available but they all differ from the architecture described in the present work, because they were all developed for the hospital environment and for the use by healthcare professionals. Other solutions provide the integration between clinical research studies and PRO without EHR support. Our web based solution provides the integration of all the three elements: PRO, EHR and clinical trials.
Moreover, the presented system architecture could be used in different healthcare domains. For instance, a similar architecture, still in a prototype stage, was developed to support longitudinal studies in nutrigenomics\textsuperscript{14}, including the management of behavioral and nutritional habits of patients with cardiovascular risk that was guaranteed by the integration of the patient reported meals, his/her EHR, and food dictionary.

It has been proposed that interoperability issues in health IT can be addressed by using web services\textsuperscript{15,16}. Our architecture, in agreement with this hypothesis, implements specific web services to ensure interoperability among the different systems (WebBioBank, Workflow manager, and mHealth App) and to enable the communication among patients/caregiver, researchers and doctors by using standards such as PHMR template compliant with RIM (CDA2) and dictionaries.

Considering that DBS patients after surgery for electrode implant face a fragile stabilization period, we expected poor compliance and increased risk. For this reason, we decided to make the first assessment of the mHealth App in a controlled hospital environment. However, the system requires, in the next future, a more focused testing procedure with the patients in their home environment to further verify usability and robustness in longitudinal studies.

The loss of data during the evaluation stage was mainly caused by the low available data storage memory in the bracelet, thus requiring a continuous connection with the mobile phone to transfer data and free the memory. This study shows how the capability of a device to collect data autonomously is critical during the daily living of these fragile patients who are not used to keep the mobile phone close to them but tend to wander off outside its range. This capability will be a major requirement for future implementations of the proposed architecture.

The validation showed that the implemented system and architecture were able to provide a reliable solution for including the patient as direct digital data source, ensuring ALCOA requirements for data generated either by the patient him/herself or by personal wearable device.

Fast and Accurate Metadata Authoring Using Ontology-Based Recommendations

Marcos Martínez-Romero, PhD, Martin J. O’Connor, MSc, Ravi D. Shankar, MS, Maryam Panahiazar, PhD, Debra Willrett, MS, Attila L. Egyedi, Olivier Gevaert, PhD, John Graybeal, and Mark A. Musen, MD, PhD

Abstract

In biomedicine, high-quality metadata are crucial for finding experimental datasets, for understanding how experiments were performed, and for reproducing those experiments. Despite the recent focus on metadata, the quality of metadata available in public repositories continues to be extremely poor. A key difficulty is that the typical metadata acquisition process is time-consuming and error prone, with weak or nonexistent support for linking metadata to ontologies. There is a pressing need for methods and tools to speed up the metadata acquisition process and to increase the quality of metadata that are entered. In this paper, we describe a methodology and set of associated tools that we developed to address this challenge. A core component of this approach is a value recommendation framework that uses analysis of previously entered metadata and ontology-based metadata specifications to help users rapidly and accurately enter their metadata. We performed an initial evaluation of this approach using metadata from a public metadata repository.

Introduction

Reproducibility of biomedical discoveries has become a major challenge in science. Investigations in a variety of fields have shown alarmingly high levels of failure when attempting to reproduce published studies.¹,² To help address this issue, many funding agencies and journals are now demanding that experimental data be made publicly available—and that those data have associated descriptive metadata.³ In the last few years, the biomedical community has met this challenge by driving the development of metadata standards, which scientists use to inform their annotation of experimental results. For example, the MIAME standard⁴ describes metadata about microarray experiments. The overarching goal when defining these standards is to provide sufficient metadata about experimental data to allow the described experiment to be reproduced. Community-based groups have defined an array of standards describing metadata for a variety of scientific experiment types. A large number of standards-conforming repositories have been built, greatly enhancing the ability of scientists to discover scientific knowledge.⁵

Despite the increasing use of these standards, the quality of metadata deposited in public metadata repositories is often very low.⁶ A central problem is that metadata authoring process itself can be extremely onerous for scientists.⁷ A typical submission requires spreadsheet-based entry of metadata—with metadata frequently spread over multiple spreadsheets—followed by manual assembly of multiple spreadsheets and raw data files into an overall submission package. Validation is often post-submission and weak. A secondary problem is that metadata standards are typically written at a high level of abstraction. For example, while a standard may require capturing the organism associated to a biological sample, it typically will not specify how the value of the organism must be supplied. Little use is made of the large number of controlled terminologies currently available in biomedicine. Submission repositories reflect this lack of precision and usually have weak or nonexistent mechanisms for linking terms from controlled terminologies to submissions. Faced with this lack of standardization, users often provide ad hoc values or simply omit many values. These difficulties combine to ensure that typical metadata submissions are sparsely populated and poorly described, and thus require significant post-processing to extract semantically useful content.

In this paper, we describe the development of a methodology and associated tools that aim to improve the metadata acquisition process. We outline a recommender framework that provides an intuitive and principled approach to metadata entry. The framework uses analyses of previously entered metadata combined with ontology-based metadata specifications to help guide users to rapidly and accurately enter their metadata. The recommender framework is part of the CEDAR Workbench (https://cedar.metadatcenter.net), an end-to-end metadata acquisition and management system under development by the Center for Expanded Data Annotation and Retrieval (CEDAR).⁸ The ultimate goal is to speed up the creation of metadata submitted to public repositories and to increase the quality of that metadata.
Related Work

Browser-based auto-fill and auto-complete functionality has a long history on the Web. Common auto-fill examples include the automatic population of address and payment fields by Web browsers in standard HTML forms. Auto-complete suggestions are commonly made for page URLs, where browsers typically maintain a history of visited pages and suggest likely pages based on a simple frequency analysis of previously visited pages. More advanced auto-complete functionality can be seen in search engines from major Web search vendors, where suggestions are based on analyses of both Web content and searches made by users.

A variety of auto-fill and auto-complete recommendation systems have been developed that perform more substantial analyses of previously entered content. A common approach is to process raw form content to extract high-level semantic concepts that drive the recommendation process. A system called Carbon⁹ presents auto-complete suggestions based on an analysis of Web forms previously filled in, combined with semantic information from those forms. The system uses this information to help users fill in structurally different forms. A related system called iForm¹⁰ was developed to assist form completion by analyzing both previously filled versions of a form and free text to extract likely values for fields. The approach focused on performing a semantic analysis of data-rich input text to automatically select text segments and then associating the text segments with fields in a form.

Several recommender systems that support auto-fill and auto-complete with ontology terms have been described in the literature. RightField,¹¹ which is distributed as an Excel plugin, provides mechanisms for embedding ontology-based value fields in spreadsheets. Users populating the resulting spreadsheets are presented in real time with suggestions restricted to terms from subsets of specified controlled vocabularies. Ontology-based systems that specifically address the metadata acquisition challenge include Annotare¹², which is used to submit experimental data to the ArrayExpress metadata repository,¹³ and ISA-Tools,¹⁴ which provides a generic spreadsheet-based tool chain for metadata authoring. Both systems provide strong support for using controlled terms and allow users to link metadata to controlled terminologies. None of them provides value-recommendation functionality, however.

By combining the analysis-driven and ontology-based recommendation strategies used by these systems, we can generate more powerful suggestions than is possible with each approach alone. We believe the combination of the two techniques can provide the speed of analysis-driven recommendations coupled with the added precision of ontology-based suggestions. This paper advances our preliminary work on metadata prediction¹⁵,¹⁶ by outlining the development of a methodology and associated tools that demonstrate this combination.

Methods

We designed an approach for metadata recommendation that simplifies the metadata authoring process in the CEDAR Workbench. The CEDAR Workbench is a suite of Web-based tools and REST APIs for metadata authoring and management, centered on the use of metadata-acquisition forms called metadata templates (or simply templates). In the CEDAR Workbench, templates are used to formally encode metadata standards and to create highly-interactive interfaces for acquiring metadata conforming to those standards. Templates define the data attributes (called template fields or fields) needed to describe experimental data. For example, an experiment template may have a disease field containing the name of the disease studied by a particular experiment. Our approach simplifies metadata authoring by suggesting the most appropriate values for template fields when acquiring metadata. We outline our approach and then explain how we implemented it in the CEDAR Workbench.

Description of the approach

Let \( t \) be a metadata template, which contains a set of template fields \( f_1...f_n \). Now suppose that a user is filling out the template \( t \) with metadata. Our approach generates a ranked list of suggested values for fields \( f_1...f_n \) based on: (1) the template instances previously authored for the template; and (2) the field values already entered by the user for the current template, which we call the recommendation context.

For a template field being filled out, our approach retrieves all values previously entered into that field and calculates a relevancy score in the interval \([0,1]\). This score represents the likelihood of the value occurring again based on previously created template instances and on the recommendation context. The relevancy score for a field-value pair \( p \) in a template instance \( s \), derived from a template \( t \), is calculated as:

\[
\text{score}(p, s) = \frac{|\text{matchingInstances}(W)|}{|\text{matchingInstances}(fv(s))|}, \text{with } W = \{p\} \cup \text{fv}(s)
\]
where instances(t) are all previously authored instances of the template t, and matchingInstances(A) returns the instances that contain all the field-value pairs in A. The matchingInstances(A) function is defined as:

\[ \text{matchingInstances}(A) = \{ x \in \text{instances}(t) \mid \forall a \in A, a \in f(v(x)) \} \]

Here, \( f(v(s) \) represents all the field-value pairs for an instance s:

\[ f(v) = \{ (f, v) \mid f \in \text{fields}(s) \land v \in \text{values}(s) \land \text{value}(f) = v \} \]

where fields(s) are the fields in the template t, from which s is derived, values(s) are all the values in the instance s, and value(f) is the value assigned to a field f in the instance s. While the instance is being created \( f(v(s) \) represents the recommendation context.

Example: Suppose we have a template t with disease and tissue fields and have four instances of t with values as shown in Table 1.

Table 1. Field names and values for four sample instances of a template with disease and tissue fields.

<table>
<thead>
<tr>
<th>Field</th>
<th>instance 1</th>
<th>instance 2</th>
<th>instance 3</th>
<th>instance 4</th>
</tr>
</thead>
<tbody>
<tr>
<td>Disease</td>
<td>liver cirrhosis</td>
<td>liver cirrhosis</td>
<td>liver cirrhosis</td>
<td>breast cancer</td>
</tr>
<tr>
<td>Tissue</td>
<td>liver</td>
<td>liver</td>
<td>blood</td>
<td>Breast</td>
</tr>
</tbody>
</table>

Suppose that the user is populating a new instance of t and has entered liver cirrhosis as a value for the disease field. The relevancy scores for the values liver, blood, and breast of the tissue field can be calculated as follows:

\[
\begin{align*}
\text{score}((\text{tissue}, \text{liver}), s) &= \frac{|\text{matchingInstances}(((\text{tissue}, \text{liver}), (\text{disease}, \text{liver cirrhosis})))|}{|\text{matchingInstances}(((\text{disease}, \text{liver cirrhosis})))|} = \frac{2}{3} = 0.67 \\
\text{score}((\text{tissue}, \text{blood}), s) &= \frac{|\text{matchingInstances}(((\text{tissue}, \text{blood}), (\text{disease}, \text{liver cirrhosis})))|}{|\text{matchingInstances}(((\text{disease}, \text{liver cirrhosis})))|} = \frac{1}{3} = 0.33 \\
\text{score}((\text{tissue}, \text{breast}), s) &= \frac{|\text{matchingInstances}(((\text{tissue}, \text{breast}), (\text{disease}, \text{liver cirrhosis})))|}{|\text{matchingInstances}(((\text{disease}, \text{liver cirrhosis})))|} = \frac{0}{3} = 0
\end{align*}
\]

Our method takes advantage of previously populated fields to generate a context-sensitive estimate of the values for an unpopulated field. When there is no context (i.e., when no other fields in a template have been filled out), it simply computes the frequencies of all the values found for the unpopulated field and ranks the values accordingly. The method does not impose any restriction on the order in which the fields must be filled out. The analysis for a field can be performed on all instances in the repository and using all the values previously entered for other fields, independently of the order they were filled out. This ability of the method to consider contextual information enables it to go beyond simple one-cause, one-effect relationships and to consider the combined effects that previously entered values may have on the target field.

The basic approach can be extended to deal with fields whose values have been constrained to particular ontologies, ontology branches, or lists of ontology terms (e.g., a disease field could be constrained to contain diseases from the Disease Ontology). When dealing with these ontology-based field values, our method calculates the frequencies of the underlying term identifiers independently of the display value used. For example, suppose that the repository contains template instances that refer to hypertension in different ways, such as HTN, increased blood pressure, and high blood pressure, and that those instances have been linked to the identifier of the term hypertension in the Disease Ontology (http://purl.obolibrary.org/obo/DOID_10763). In this case, our analysis approach would use the term identifier to calculate the frequency of the Disease Ontology term, effectively aggregating the frequencies of all synonyms of hypertension.

The generated recommendation scores can be used to produce a ranked list of suggested values for a target template field. Each recommendation consists of the suggested value and a number in the interval [0,1] that represents the frequency of the value in previously populated instances. For plain text metadata, the system suggests textual values. For ontology-based metadata, the system suggests ontology term identifiers. These recommendations can be
presented to the user using a user-friendly preferred label for the ontology term defined in its source ontology (e.g., hypertension is the preferred label for http://purl.obolibrary.org/obo/DOID_10763 in the Disease Ontology). The recommendations for a particular field can be calculated in real time as a template is being filled in. The metadata repository’s recommendation index can be updated whenever a template instance is saved, allowing other metadata instance creators to immediately use the updated recommendation values.

Implementation

We implemented our approach for metadata recommendation as a Web service called the Value Recommender, and integrated it into the CEDAR Workbench. The CEDAR Workbench provides two core tools that form a metadata authoring pipeline: the Template Designer and the Metadata Editor. The Template Designer allows users to interactively create metadata templates in much the same way as they would create survey forms. Using live lookup to BioPortal, the Template Designer allows template authors to find terms in ontologies to annotate their templates, and to constrain the values of template fields to specific ontology terms18. The Metadata Editor uses a template specification generated by the Template Designer to automatically generate a forms-based metadata acquisition interface for that template. The generated interfaces allow users to populate metadata templates with metadata.

We modified both tools and several other CEDAR components to work with the Value Recommender service (see Figure 1). We extended the Template Designer to allow users to specify the fields for which value recommendations are enabled. We enhanced CEDAR’s template specification model to store this preference. This preference is used to signal to CEDAR’s metadata indexing engine that field-level metadata in its metadata repository should have additional analysis steps applied to it. Fields marked for value recommendation are indexed by CEDAR’s Elasticsearch-based engine (https://www.elastic.co) such that their values can be compared with other value recommended fields. These statistics are used in real time by the newly developed Value Recommender component. Note that users can also use standard CEDAR functionality to constrain fields to contain values from controlled terminologies held in the BioPortal server. Both constraint types can be specified simultaneously for a field.

We extended the Metadata Editor to use the Value Recommender service to suggest appropriate values for metadata fields during field entry (see Figure 2). Users entering metadata using the Metadata Editor are prompted in real time.
with drop-down lists, auto-completion suggestions, and verification hints supplied by the Value Recommender service. Recommendations for unfilled fields are updated in real time as users incrementally complete metadata acquisition forms. The editor presents a drop-down list for value-recommended fields containing suggested values ranked in order of likelihood. The editor can also be configured to indicate whether suggested values are ontology terms, in which case it also shows the BioPortal acronym for that ontology.

Figure 2. Screen shot of the CEDAR Metadata Editor showing recommended values for a particular field. In this case the editor shows suggestions for disease values. It presents a drop-down list containing suggested values ranked in order of likelihood. Ontology-based terms are indicated with an ontology icon. The relevancy score for each suggested value is presented as a percentage.

Evaluation

We analyzed the performance of our framework when suggesting appropriate metadata values using both plain text metadata and metadata represented using ontology terms. We constructed an evaluation pipeline to drive the analysis workflow (see Figure 3). The main steps of our evaluation workflow are as follows.

1. Preprocessing and ingestion

We used the CEDAR Workbench to design a metadata template targeted to the BioSample metadata repository. This repository, which is provided by the National Center for Biotechnology Information (NCBI), captures descriptive information about biological materials used in scientific experiments. BioSample defines several packages that represent specific types of biological samples, and specifies the list of attributes by which each sample should be described. The BioSample Human package, for example, is designed to capture metadata from studies involving human subjects, and includes attributes such as tissue, disease, age, and treatment. We used this package specification to develop a BioSample template in CEDAR to describe human samples.

For the purpose of our evaluation, we populated BioSample template instances using metadata from the Gene Expression Omnibus (GEO), a database of gene expression data which contains experimental metadata largely authored by original data submitters. The GEO database currently contains over 2 million records, and includes over 80,000 studies, each of which contains metadata for related biological samples.

We downloaded metadata from the GEO repository using GEOmetadb, and extracted all corresponding metadata elements for all human samples. We chose the fields title, sample_id, series_id, status, submission_date, last_update, type, sources_name, organism, and characteristics (including disease and tissue). Then, we picked the human samples that contained both disease and tissue metadata (35,157 samples), and transformed them into BioSample template instances conforming to CEDAR's JSON-based model.
Figure 3. Evaluation workflow. (1) Design a template for the BioSample repository, and populate it with metadata from the Gene Expression Omnibus (GEO); (2) Annotate the template instances obtained with terms from biomedical ontologies; (3) Upload the training set to the CEDAR Workbench; (4) For each of the test instances, generate suggestions for the disease, sex, and tissue fields; (5) Compare the suggestions obtained using the Value Recommender with the suggestions obtained using the baseline method.

2. Semantic annotation

We define semantic annotation (or simply annotation) as the process of finding a correspondence or relationship between a term in plain text and an ontology term that specifies the semantics of the term in plain text. We used a component of the CEDAR system, called the Semantic Annotation Pipeline (SAP), to automatically annotate all the fields values in 35,157 BioSample instances using biomedical ontologies. Table 2 shows the BioSample fields used in our evaluation. It presents both the number of plain text values and the number of ontology terms resulting from the semantic annotation process. The annotation ratio represents the mean number of plain text values per ontology term. For instance, we observed that the concept female was represented in plain text using values such as female, Female, f, F, and FEMALE.

Table 2. Comparison between the number of plain text values for the fields disease, sex, and tissue, and the number of ontology terms resulting from applying our Semantic Annotation Pipeline (SAP) to the plain text values.

<tr>
<td>tissue</td>
<td>Type of tissue the sample was taken from</td>
<td>604</td>
<td>liver, Liver, liver tissue, liver biopsy, Liver biopsy tissue</td>
<td>171</td>
</tr>
</tbody>
</table>
3. Training

We partitioned the sample data—both for plain text values and for values annotated with ontology terms—into two sets. We used 80% (28,126 instances) of the sample data for training and 20% (7,031 instances) of the data for testing. We uploaded the training set to the CEDAR Workbench using the CEDAR API. We then indexed the training set with Elasticsearch.

4. Testing

For each of the test instances, we used the Value Recommender to generate value recommendations for the disease, sex, and tissue fields. The Value Recommender suggested values for each field based on the values of the other fields (e.g., suggestions for tissue were generated using the values for disease and sex). We used the majority vote as our baseline, which means picking the value with more occurrences in the training data. This process differs from the Value Recommender in that it ignores co-occurring values. For each field, we compared the suggestions provided by both the Value Recommender and the baseline with the expected value. We considered that the expected value for a field was the value for the field contained in the instance.

The Value Recommender produces a list of suggested values ranked by relevance. We assessed the performance of our method using the mean reciprocal rank (MRR) statistic. This statistic is commonly used for evaluating processes that produce a list of possible responses to a query, ordered by probability of correctness. We limited the output to the top three recommendations, and calculated the reciprocal rank (RR) as the multiplicative inverse of the rank of the first correct recommendation.

For example, if the correct value were ranked in the 3rd position, the reciprocal rank would be calculated as 1/3. Then, MRR was calculated as the mean of all RRs obtained. Table 3 shows the RR statistic for some example recommendation results. The MRR of the three values suggested in the table can be calculated as the mean of the RR value for all three rows: $(1 + 1/2 + 1/3) / 3 = 0.61$.

5. Analysis of results

Figure 4 compares the mean reciprocal ranks obtained using our recommendation framework with the majority value baseline. It shows results both for plain text values (left) and values annotated with ontology terms (right).

The results indicate that our framework performs considerably better than the baseline for the three fields. Our context-sensitive recommendation method obtained an average MRR of 0.78 for plain text values, and 0.77 for ontology terms, compared to the baseline method’s average MRR of 0.21 for plain text values and 0.41 for ontology terms. By examining the results we see that, for example, our method correctly suggested asthma as a value for the disease field when the tissue was epithelium of bronchus. However, the baseline method suggested hepatocellular carcinoma, a disease that is not related to that kind of tissue. Our approach performs consistently well both for plain text values (0.78) and for ontology-based metadata (0.77). The importance of contextual information is particularly evident when analyzing the results obtained for plain text values, where there are substantially more values for each field than for ontology terms (for example, as shown in Table 2, there are 1,064 plain values versus 261 ontology
terms for the disease field). The average MRRs of the baseline are considerably lower for plain text values (0.21) than for ontology terms (0.41).

![Figure 4](image)

**Figure 4.** Mean reciprocal rank for BioSample instances with plain text values (left) and with ontology-terms (right), both for the baseline and the Value Recommender (VR).

Finally, we investigated more closely the effect of the context on the recommendations. The best results were obtained for the tissue field, with MRRs of 0.88 for plain text and 0.86 for ontology terms, illustrating the strong influence of the context on that field. Once disease and sex field values are provided, our approach is able to identify the appropriate value for the tissue field in most cases. Figure 5 shows the top suggestions provided by the Value Recommender for the disease field, with increasing levels of context. The figure shows how lung cancer can be much more clearly suggested as a likely choice when sex and tissue have been specified. This example reflects the increase in discrimination that is possible when more contextual information is available.

![Figure 5](image)

**Figure 5.** Top 10 suggestions provided by the Value Recommender for the disease field of the BioSample template, with increasing levels of context. The last plot shows 6 different values because only 6 suggestions were returned.
Discussion

We developed and deployed a metadata recommender service as part of an end-to-end metadata management system called the CEDAR Workbench. We found significant improvements could be obtained by considering contextual information when making recommendations. Our evaluation suggests that, by adding our recommendation capabilities on top of already-offered user interface optimizations, the CEDAR Workbench can provide major enhancements in both speed of metadata creation, and accuracy of those metadata.

A limitation of our evaluation is that we did not use all values in GEO, restricting our analysis to human samples only. We plan to carry out further analyses using all samples in GEO to determine how our method generalizes to additional sample types. We also plan to perform similar analyses on data from the BioSample repository, which contains metadata on 2,787,750 public biological samples used in scientific experiments. Additionally, we plan to study how the metadata recommender service performs with templates that contain a greater number, and more diverse fields. While disease, sex, and tissue are relevant metadata for biological samples, they are a small and relatively simple set of fields and generalizability may be a challenge.

The Value Recommender system is the first of a planned set of intelligent authoring components in the CEDAR system. Future efforts will concentrate on deeper analyses of metadata to discover more complex relationships among metadata fields, which will then drive tools to assist users when entering metadata. As a first step, we plan to extend the recommender to derive and use more in-depth knowledge of correlations among values in the dataset. Specifically, we will apply our previous research on association rule mining to identify degrees of correlation among metadata items. This approach will strengthen the positive associations that our current recommendation engine provides, and will allow us to point out possible errors by identifying unlikely values. With sufficient levels of accuracy, our system may be used to automatically fill in missing values for a significant number of metadata fields.

Our work also has implications for scientists focused on retrospective augmentation of metadata. For example, the system could be used to interactively help curate previously submitted data by suggesting more specific values for populated fields, in addition to suggesting values for empty fields. It could also assist curators with suggestions for correcting incorrectly entered element values. In particular, the system could be targeted to both retrospective and real-time quality assurance by detecting unlikely field combinations. Strong discrepancies detected between the element value entered by a user and the predicted value could be highlighted to human curators for review. By rapidly providing highly interactive recommendation, the system could also help curators quickly deal with greater volumes of metadata submissions, and help address the problem of curation scalability faced by many repositories.

Conclusion

We have described the development of a recommendation framework that focuses on helping biomedical investigators annotate their experimental data with high quality metadata. The framework takes advantage of associations among the values of multiple fields in existing metadata to recommend context-sensitive metadata values. A key focus is on interoperation with ontologies. Using formal ontology-based specifications and interactive look-up services linked to the BioPortal ontology repository, the system tunes its recommendations to target controlled terminologies. We outlined an initial evaluation of the framework using metadata from the GEO repository, and provided an implementation of the system in a metadata management system called the CEDAR Workbench.

These tools aim to provide a series of intelligent authoring functions that lower the barrier to the creation and population of metadata templates, and help ensure that the resulting metadata acquired using these templates is of high quality. The ultimate goal is to provide the ability for investigators to easily create metadata that are comprehensive, standardized, and make the corresponding data sets conform to FAIR principles.

Abstract
Annually, 1.6-3.8 million concussions occur from sports in the United States, which account for 5-9% of all sports injuries. The dangers of concussions include prolonged post-concussive symptoms, increased risk of subsequent concussions, seizures, mental health issues, and in cases of second-impact syndrome (SIS), possible death. Certified Athletic Trainers (ATC) continue to serve an important role in providing assessment and treatments for athletes with sports-related injuries. They provide a critical safety net due to limited knowledge and misconceptions of concussion held by some youth sports coaches and athletes. However, availability of services from ATCs in rural areas is a challenge. In order to help extend coverage to more rural student athletes, we propose designing a telemedicine app following the mHealth development roadmap from the Center for eHealth Research (CeHRes). In this paper we will document contextual inquiry, user requirements capture, design phases, and app evaluation from the targeted user base.

Introduction
There are an estimated 1.6-3.8 million concussions that occur from sports and recreational activity in the United States annually¹. Board Certified Athletic Trainers (ATC) provide a critical safety net due to limited knowledge and misconceptions of concussions held by some coaches and athletes. Studies have shown schools with ATCs have lower overall injury rates, and higher rates of concussion diagnoses due to increased reporting and accurate assessment. However, only 55% of athletes in United States public secondary schools have access to a full-time ATC, and only 37% of schools employ a single ATC. Currently 30% of public secondary schools in the US lack an ATC, leading to 24% of sporting events that have no medical coverage². Due to budget restrictions, many schools resort to contracting an ATC from local physical therapy clinics or hospitals. This is an alternative to hiring a full time ATC, and often the ATC under contract will cover two or more schools. These ATCs have to select which school they will cover when events are held concurrently. This contributes to the overall medical coverage gap. Given the budgetary concerns in many schools, tools that facilitate remote diagnosis and/or treatment of patients by means of telecommunications technology may be one solution; specifically, an mHealth app may be ideal for many schools.

Concussions account for 5-9% of all sports injuries, which often translate into visits to the emergency room³. For most athletes (80-90%) concussions resolve in 7-10 days, however in some cases, symptoms can persist for months or even years⁴. The dangers of these injuries include prolonged post-concussive symptoms, increased risk of subsequent concussions, seizures, mental health issues including depression, and in rare cases, death. Of particular concern is second-impact syndrome (SIS), which may occur if an athlete returns to activity while still exhibiting concussion symptoms. SIS can cause a rapid increase in intracranial pressure, brain stem herniation, and often death. The most worrying aspect is while still recovering from the initial concussion, an additional impact of lower severity can lead to the onset of SIS. Chronic traumatic encephalopathy (CTE) is emerging as a long-term health concern that may be linked to concussions. The key to minimizing these dangers involves timely diagnosis, comprehensive treatment and rehabilitation plans, and return-to-play guidance from trained medical professionals like ATCs. In the absence of medical professionals on the field, the ER is often the only outlet for athletes with suspected concussions. When reviewing reports from ER visits, a 62% increase in non-fatal traumatic brain injuries occurred between 2001-2009⁵, indicating that ER visits for concussions have been on the rise. It is estimated that 12% of ER visits are non-urgent, and studies have shown that overuse of ER detrimentally impacts the entire hospital⁶. Unnecessary visits to the ER for non-urgent conditions also carry a risk of nosocomial infections, overtreatment, and lack of continuity of care. Hence, there is an incentive to provide these injured athletes access to medical care without having to escalate that care into a trip to the ER.

For concussions, the standard of care when evaluating concussions is by a physician or licensed healthcare provider who are specifically trained. Diagnosis of a concussion involves identifying one or more of the following clinical
domains: somatic symptoms, cognitive impairment (e.g., slow reaction times), behavioral changes (e.g., irritability), sleep disturbance (e.g., insomnia), and physical symptoms (e.g., balance, amnesia, loss of consciousness)\(^5\). To assist with the diagnosis of sports concussions, there are several technological approaches available. Functional neuroimaging is the most popular approach; there is also qualitative EEG, and impact sensors. A computer-based neuropsychological testing tools has been developed called the Immediate Post-Concussion Assessment and Cognitive Testing (ImPACT)\(^6\) which is also very popular. Telemedicine and mobile devices are options that have been relatively unexplored as potential tools\(^7\). Work by Vargas et al. has proposed a wheel and spoke telehealth approach, centralizing specialists who are available via a telemedicine robot\(^8\), but the utilization of an mHealth app solution is largely untapped. There are over 20 mobile concussion assessment apps available on the market, but none of these are part of a telehealth system. Most of these existing apps only assist the user in detecting if a trained healthcare provider should evaluate the individual. A recent systematic review of smartphone and tablet concussion apps raises concerns about the appropriateness of these tools for different groups of end users, and they also found that the apps were not always in compliance with testing guidelines\(^9\). There are some validated tools used by medical professionals for concussion evaluations, like the Sport Concussion Assessment Tool 3 (SCAT3)\(^10\). When used by a non-medical layperson, the SCAT3 test can be used to help identify signs of concussions, but diagnosis should remain a task left to medical professionals. A less technical sport concussion recognition method, like the Pocket Concussion Recognition\(^11\) tool is recommended for anyone without a medical background. This is where we would distinguish our proposed telehealth app. With a user-centric development path, and using ATCs as members of the focus group, the intent is to ensure ATCs remain the nexus of the medical evaluation process. Many of the available apps aim to place the coaches, parents, or athletes into the drivers seat for these decisions. This can be problematic due to biases (an athlete trying to “tough it out” on an injury) or possible conflicts of interest (placing winning over the health of the athlete).

Visual examination during concussion testing is a key component, which is what led us to pursue a telehealth model. There are sections in the SCAT3 test that rely on observing the athlete, like the balance test. It is also important to watch facial expressions to ensure the subject comprehends the question. For example, the ATC will want to make sure they understand all the questions being asked, such as if they are experiencing nausea. Does the athlete know what nausea is, or is there any attempt at evasion during the questions? This begs the question, why not just have the ATC complete the SCAT3 test via Skype, FaceTime, or other similar video conferencing tools? It is possible to do, but not practical. Usability and secure storage of health information are two major obstacles encountered with this approach. An ad hoc solution of conducting the SCAT3 over a conferencing app still would still rely on using paper records. If the video conferencing was integrated into a single app, there are inherent advantages. Currently, the SCAT3 is principally designed to be paper-based tool, where sections of the test are completed via print outs of the test. Any paper based data storage approach is faced with major concerns about issues with readability, data entry errors, retrieval, and backup\(^12, 13\). Many of these problems can be avoided by performing data collection into a secure HIPAA compliant database, following guided data entry steps with error checking, all into a file attached to a particular individual. These paper files also would have a high likelihood of being stored under lock and key in the ATC’s office in addition with any other medical files. Retrieval is not a problem if both the athlete and the ATC are in that office, but in the rural environment, the ATC is often working remotely. Secure logins and file encryption would ensure the data would be accessible to the ATC as long as they were able to connect online. Using alternate video conferencing tools is a shortcut that would solve the access to medical professionals temporarily, but we feel the complications associated with it would discourage repeat use. Initial conceptualization of the

The primary aim of this paper is to detail the development of this proposed mHealth app following the protocol recommended by the Center for eHealth Research (CeHRes)\(^14\), presenting a prototype version of the app, and reviewing its reception by ATCs. Specifically, four primary components of the five stages of the CeHRes roadmap will be conducted: contextual inquiry, value specification, design, and operationalization.

**Importance of Research**

Telemedicine is an established tool for extending medical coverage to underserved and rural areas\(^15, 16\). Telestroke\(^17\) is one example of a successful telehealth tool that has been able to provide cost-effective\(^18\) coverage to rural areas where stroke specialists are lacking\(^19\). However, there is a lack of work in developing a telehealth solution for assessing concussions and helping to extend care and treatment options for rural high school athletes\(^7\). When looking into application options for this technology, there is a distinct opportunity for rural Nebraska. The distance between rural high schools is a factor impacting the availability of full time ATCs to provide medical coverage. The

\(^{1276}\)
Nebraska School Activities Association (NSAA) is the organizing body that oversees all interscholastic activity for the state. Table 1 highlights sports in NSAA’s seasonal schedule with increased risk and the number of rural participants in those highlighted sports for that season. The tally was taken from NSAA’s 2014-2015 statewide report of participants per school. Each school was identified as rural or urban by using the Economic Research Service Rural-Urban Commuting Areas (RUCA) for counties with codes 4-10, codes 1-3 were designated as urban. Detailed statistics on the exact number of ATCs covering these athletes in Nebraska is difficult to find. There is a lack of standard reporting to indicate the number of staff ATCs employed by high schools, as discovered by Schwaderer and Unruh. Some schools administrators recorded full time ATCs in the same fashion as ATCs that were contracted out to multiple schools, making it challenging to identify exact coverage gaps. They were able to build a general ATC coverage map that depicts the disparity of ATC availability between rural and urban areas in Nebraska (Figure 1). The numbers of rural participants at risk for concussion and the large areas of Nebraska with coverage gaps lend itself to exploring a solution through mHealth.

Roadmap

The Center for eHealth Research roadmap was selected as the template for developing this project. One of the primary goals of this app is to make it appealing to the audience we are trying to reach, primarily ATCs and their student athletes. The human-centered design of the CeHRes road map helps to achieve this aim.

There are five phases of the road map, with iterative elements to help ensure that improvement is occurring through each stage of the mHealth app development.

1. **Contextual inquiry** – the app’s target user perspective is evaluated and the current standard of care is considered.
2. **Value specification** – Stakeholders and values are identified and translated into user requirements.
3. **Design** – taking the user requirements, developers, stakeholders, and targeted user collaborate in building the app.
4. **Operationalization** – once the technology has been built, steps are taken to market the product and integrate it into practice.
5. **Summative evaluation** – the final stage is a review of the product, how is it being used and what kind of impact is it having on healthcare.

**Research Approach or Methodology**

In following the CeHRes roadmap, the first step is to identify key stakeholders and explore the relevance of the idea in the contextual inquiry phase. A focus group comprised of these stakeholders was held as a part of the value specification phase. The output from the focus group helped to guide the development of the app in the design phase of the CeHRes roadmap. The target market for this app is aimed at high school level athletics (grades 9-12). High schools often are faced with restrictive budgets that contribute to the previously described ATC shortages, in comparison to college and university athletics, which have more robust budgets. At this point, the contextual inquiry, and value specification, and design phases have been completed. The Operationlization stage has started, being with revisiting the requirements captured at the beginning of the process with the focus group and conducting an End-User Computing Satisfaction (EUCS) survey. For the focus group component of the study and the EUCS survey, IRB 206-16-EX was submitted as an exempt educational, behavioral, and social science research review, and was accepted by the UNMC IRB board. The last two components of the CeHRes roadmap, operationalization and summative evaluation will be presented when those stages are complete and field-testing has been completed. These final two stages focus on marketing and market impact once the app has been released. Completion of the design phase provided a tangible product, which we felt presented a natural break in the process that could be shared. Additional details on these plans will be explained later in this paper.

**Research question**

There are three principal research questions that will be investigated in this paper:

1. **Who has a stake in addressing the healthcare problem of concussions?**
2. **How can technologies contribute to a better quality of care, and in what manifestation can technology contribute?**
3. **Was the design process able to meet user requirements established by the stakeholders and targeted users?**

**Results**

**Contextual inquiry phase: Stakeholder and targeted users**

After a literature review and market examination was completed, the authors of this paper conducted a brainstorming session to identify all stakeholders and targeted users. The results from that session generated the following list:

1. **Patients** – the student athletes participating in the sporting event, and are suspected of suffering from a concussion.
2. **Certified Athletic Trainers** – medical providers assigned to provide coverage for the sporting events. Typically assigned to a particular team or school, for the purpose of this app, these ATCs would be at a different location than the patient.
3. **Emergency Medical Technician (EMT)** – EMTs occasionally have been hired to provide medical coverage for these sporting events.
4. **School nurses** – school provided medical professional.
5. **Parents & Guardians** – due to the targeted patients for this app are high school aged athletes, many would be considered minors, and thus require their involvement for this mHealth app.
6. **Coaches, Staff, and Game Officials** – individuals that are involved with the patient’s sports team, or are involved with the officiating of the match.
7. **Principals, Athletic Directors, High School administration** – many of the matches and practice sessions where a potential concussion could occur happen on school property.
The primary user base was designated as ATCs who work with rural athletes, and the coaches of those rural athletes, and thus were critical to the design stage. Other stakeholders could be approached once the app was developed.

**Value specification phase: focus group**

The focus group was conducted on May 25th, 2016 for 90 minutes. Five members were included in this interview session. Four of the members are certified athletic trainers with various backgrounds and levels of experience, and one member was a developer with medical software applications experience. The first ATC is practicing at a local high school in the Omaha metropolitan area. The second ATC is employed at the University and is involved in an athletic training education program. This program offers both undergraduate and graduate degrees in athletic training. The third ATC previously worked at the collegiate level, and now works at a medical center as director for sports medicine in addition to being member of the national certification board for athletic training. The fourth ATC is a director of operations for a clinic that subcontracts out ATCs and holds an executive role in the Nebraska State Athletic Trainers’ Association (NSATA), part of the National Athletic Trainers’ Association (NATA). This provided a wide range of views and perspectives to draw from.

The focus group was recorded and transcribed into a word document to serve as input for app requirements. The transcripts and artifacts generated by the focus group were used to guide efforts in the design stage. The paper versions of the definitions of the "10 E’s in e-health" and a print out version of the preliminary app mock-up (Fig. 2) were collected after the session was complete.

![App mock-up screens depicting data entry and data retrieval screens](image)

**Figure 2.** App mock-up screens depicting data entry and data retrieval screens

Eysenbach’s “10 E’s” are used to help establish a clear vision for the mHealth app. They are values that encompass what e-Health should aim for:

- Efficiency
- Enhancing quality
- Evidence based
- Empowerment

In Eysenbach’s paper, each of these terms is explained in more depth. However, having the focus group define these values in context of the mHealth app helped to identify what elements are most desired from the final product. Following up and having the group pick the top three after the definitions are complete provided insight to what was desired the most from the mHealth app. These documents were treated as additional research artifacts, which contained notes, and questions that the participants had during the focus group interview.

**Guidelines for designing a telehealth concussion app**

To help elucidate the design guidelines, there needs to be a clear directive captured from the stakeholders in the focus group. These were specified as values, and helps to establish the boundaries and directions our development work should take when building the app. To help identify the key values for this project, the focus group reviewed Eysenbach’s list of “10 E’s”. From the list, three stood apart from the rest: *enhancing quality of care, efficiency, and extending the scope of care.*
The focus group was encouraged to define what these terms mean, ‘in their own words’, when discussing how an mHealth app could aid in remote concussion assessment. For enhancing quality of care, the emphasis was more on follow up care over the initial assessment. As one member stated: “There is value for using this tool on the sidelines, but I think it would be more helpful when we check up on them later.” The consensus of the group was that this would not be a tool that they would expect either athletes or coaches to pull out and use in the middle of a match. After the match or practice was seen as the more likely opportunity for the mHealth app to come into play. This also was reflected in how the group defined efficiency. Eysenbach states that efficiency decreases cost, by either cutting unnecessary or duplicate diagnostic interventions. The focus group felt that efficiency was more along terms of time saved. By allowing ATCs to follow up with athletes across town, or in another town entirely, the time spent traveling to those locations could be reduced. Often, when ATCs are contracted out to multiple locations, they spread their visits out across the week. It is possible that an athlete may have to wait a few days before the ATC is scheduled to visit their location. This exchange was particularly enlightening because our initial vision for the app was a real time assessment tool. However, these stakeholders helped us refine the vision for the app to more of a post match assessment tool. As they explained, it is not uncommon for athletes to shake off signs of concussions as just wear and tear of the sporting event, only to notify ATCs when they haven’t fully recovered over the next 24-48 hours.

The third major value was extending the scope of care. Both the focus group and Eysenbach frame this value in terms of overcoming geographic barriers. Finding times to be available for a teleconference using the mHealth app would be much easier than trying to plan actual trips to each location. Following this path would also help to overcome potential technical hurdles, such as wireless signal strength. If the app helps the health care provider with their scheduling, it would be possible for both the athlete and the ATC to meet at a time where both can ensure strong Internet connections.

The focus group also discussed requirements that they would like to see for how the app operated. The SCAT3 exam is a validated tool, but only when used by properly trained individuals. In order to help keep the evaluation under the control of the medical professionals, it was suggested that the app have different tiers of access. Some of the more technical questions that move beyond the basic capture of the mechanism of injury and who was involved should be handled by the ATC. To accomplish this request, the idea was to have initial screening data that could be entered by a layman (another athlete, a parent, or a coach). That data would be forwarded on to the ATC for them to make the call if the evaluation should continue. These additional conversations helped to outline key values for the end-user of this application. 1) Ease of use. 2) Confidentiality of athlete records. 3) Timely notifications and information retrieval.

The focus group established that the mHealth app should be defined as a success or failure if it could measurably increase the detection of concussions in comparison to events where medical supervision was absent. Although beyond the current scope of the project, the intent is to continue development to reach a point where clinical data can be captured with the app in order to measure this metric.

App concept

The app was built using agile development methods with student developers from the University of Nebraska at Omaha. Agile development cycles were tracked using the web collaboration tool Trello. The initial vision for this app centers on converting the SCAT3 test to a mobile platform. The process flow (Fig. 3) was an output from the focus group session.

![Figure 3. ATC telehealth mHealth app process flow](image-url)
Player information can be captured prior to participation in a sporting event, helping expedite the submission process. The SCAT3 has eight primary sections, with additional data entry for mechanisms of injury, athlete background, and signs of concussions. Accessing the system does require log in for any user. Two primary accounts types will be available, a limited access account restricted to data entry and review of their own submitted reports (coach view), and an account with both submission and retrieval access to complete the report reserved for medical professionals (trainer view). A third account type (administrator), will be used to create new users and maintain the system. Once logged in, the layperson can complete three initial sections of the SCAT3. The first section is titled “Potential signs of concussion”, which ask simple yes/no questions for the observer of the injury (e.g., “Any loss of consciousness?”). The second section is the Maddocks Score test $^{25}$, which helps to identify situational awareness by asking the athlete simply memory tests like “What team did you play last week?”. The final section includes the injured athlete’s background (demographics, any history of concussions, etc.). This data capture is consistent with what information is collected in the Pocket Concussion recognition tool, and this does not require medical expertise.

When complete, a report would then be sent to the database, and notification will be forwarded on to an ATC of its entry. The ATC would then log into the system via the website, retrieve and review the report, and make a decision. At this point, if they decide no further intervention is needed, they can log the report for follow up later and clear the athlete to return to play. Alternatively, they can decide to continue the evaluation, and complete the additional six elements remaining on the SCAT3 test in order to generate a score. Return to play decisions are on a 6-point graduated scale ranging from abstaining from all activity, to allowing light aerobic exercise and incrementally increasing activity levels until culminating at clearance for normal game play$^{3}$.

The database for the app was developed in PostgreSQL and is currently not HIPAA compliant. Postgres can easily be converted into a MySQL or Microsoft SQL database if needed. Before any real patient data can be entered, the app will need to be ported to a more secure platform. Details about this task are addressed in the future work section of the paper. As suggested by the developers, this project was broken in three phases. The first phase was building the core elements of the app for data capture, storage and retrieval between multiple users, which is now complete. The next phase would be porting it over to a secure, HIPAA compliant platform, and the final piece would be the video feed integration, since it would be the most technically challenging, and expensive component.

**Figure 4.** App data capture (via an app on a smart phone) and retrieval screens (via website on a tablet)

**Evaluation phase**

With a useable prototype complete, the app could be shared for feedback from ATCs and athletic training students (individuals who have not yet taken the certification exam). The focus group was invited to review the app and see if it met the three initial key metrics: 1) the app’s ease of use 2) maintaining confidentiality of athlete records 3) timely
notifications and information retrieval. Additional users were encouraged to download either an Android or iOS version of the app, build their own test cases, and provide feedback and complete an End-User Computing Satisfaction (EUCS) survey. EUCS is a validated tool designed to evaluate factors impacting user satisfaction, content, format, accuracy, timeliness, and ease of use\(^6\). The tool has also been used to evaluate other medical systems\(^{26, 27}\).

**Conclusions**

At this current phase of this project, we have a functional Android, iOS, and web based version of the app. We were able to define the requirements with the insight from the focus group. In addition, the process helped to construct answers to our primary research questions. Funds were not sufficient at this time to construct the videoconferencing element as originally proposed. This was a disappointing development, but as this was our first effort in mHealth app development, learning about cost limitations was an important takeaway. Pricing out bids for app development prior to the focus group session would have avoided this setback. Grant funding will be pursued to cover the additional costs associated with the development of the video component at a later date.

- **Who has a stake in addressing the healthcare problem of concussions?**
  
  We were able to provide a detailed list of stakeholders in the results section who have a vested interest in improving detection of concussions. From this list, we identified a primary user base of ATCs working with rural athletes and the coaches of those athletes. Success or failure of this mHealth app would depend on our ability to properly deliver a tool that meets the needs for this group.

- **How can technology contribute to better quality of care and in what manifestation can technology contribute?**
  
  By offering a solution that integrates telehealth and mHealth into an already accepted and validated concussion tool, we don’t have to worry about re-inventing the wheel. The augmentation of the SCAT3 will require testing to ensure that the mHealth app works to the same degree as its paper based iteration, but this change offers many advantages. Data capture and retrieval would be improved over the paper versions of the tests. Follow-up on athletes suspected or verified to have a concussion can be simplified and can occur more frequently.

- **Was the design process able to meet user requirements established by the stakeholders and targeted users?**
  
  The focus group was satisfied with the progress of the project so far. All three key metrics were deemed satisfactory, although there are noted points for improvement on some “ease of use” elements. This feedback will be incorporated into the next version of the app, which will be shared again with the focus group. Additional data was planned based off the results from the EUCS survey, but delays due to launching the app on Google Play and Apple iTunes prevented us from reaching our goal of 20+ completed surveys. Participation in the survey is still being solicited, and additional iterations of the app will use EUCS to measure progress.

One of the big lessons learned from this project so far has been the transition away from a concept of immediate access to a healthcare professional, toward more of a tool that can facilitate increased contact between the athlete and ATC. By following the CeHRes roadmap, there have been structured guidelines that helped us reach these new insights. Without taking the time to work through these stages, the app development would have most assuredly been built with the focus on sideline interventions. While the tool built with these specifications may have been effective in it is aims and deliver on its goals, adoption of the tool may have never taken off. It is not uncommon for an athlete to suspect something is wrong the day after a concussion, when symptoms have still persisted. As highlighted by the focus group, this app would be beneficial to extend care to those athletes too. There are two suggestions we would provide for enhancing the CeHRes roadmap, an emphasis on budget building/cost analysis and guidance for launching an app on either an Android or iOS platform. Overall, it is a very effective tool, and one recommend by us to others, with the caveat for these two areas. We would emphasize on having a clear handle on building costs before entering the value specification phase of CeHRes. Also, launching our app in beta proved to be a significant hurdle, one that should not be overlooked in planning for a successful mHealth app. The certificate, keys, and profile generation steps required for launching the app on the Apple iTunes store and Google’s Play store has a sizeable learning curve if it is the first time a user is publishing their app. Developer accounts also are required by the user (at the time of publication, $25 for a lifetime license on Android, and $99 per year for Apple’s iOS).
Both the Google Play store and Apple iTunes have mechanisms to run closed and open beta tests. Beta testing via the Google Play store is fairly simple, it is managed from the Google Play Console and only requires users to have a Gmail account to participate. Apple beta testing follows a different framework, which should be accounted for in planning for testing phases. Apple uses a program called Testflight for beta tests. Before beginning the beta testing program, the app needs to pass evaluation from Apple, and reviews are targeted to be complete 24-48 hours after submission. Once the app has passed review, beta testers can be added via their Apple ID. Users first need to download the Testflight app. Once their account has been added to the beta testing list, the app will appear inside of the Testflight app. Additional time should be budgeted for this overall process on top of helping beta testers who might not be familiar with the process themselves.

Future work

In April of 2017, the group in charge of SCAT skipped over SCAT4 and released the latest version, SCAT5\textsuperscript{28}. We plan on reviewing this latest version and adjusting our app as needed. Additional EUCS survey results will continue to be collected for further feedback on the app. There are three major goals remaining for this project: converting it over to a HIPAA-compliant environments for secure patient data storage (most likely using REDCap\textsuperscript{29}), building the video conferencing component of the app and eventually conducting a randomized control trial study to test the app in the field. Using FaceTime or Skype APIs are the most likely solution, since they offer encryption and security options needed for medical consultations. The purpose would be to evaluate the app’s effectiveness in detecting concussions in practice. We are excited by the stakeholder’s interest when discussing this project and plan on using our prototype to secure additional funding to support future development.

Does a Community-Engaged Health Informatics Platform Facilitate Resource Connectivity? An Evaluation Framework

Mari Millery, PhD¹, Alejandra N. Aguirre, MPH² & Rita Kukafka, DrPH, MA, FACMI¹
¹Columbia University Department of Biomedical Informatics, New York, NY
²Irving Institute for Clinical and Translational Research, Columbia University Medical Center, New York, NY

Abstract
Community-engaged health informatics (CEHI) integrates informatics with community-based participatory public health. Addressing social determinants and population health requires mobilization of health-related resources in communities. We present a framework for evaluating the process and outcomes of a CEHI platform designed to improve connectivity among community health resources.

The GetHealthyHeights.org CEHI platform was implemented in an urban low-income community. It was designed to facilitate connectivity among health-related community-based organizations (CBOs). To evaluate the process towards and the achievement of connectivity, a conceptual framework, methodology, and operational measures were defined.

A system-level approach, such as social network analysis, is required to capture the community as one dynamic unit. The evaluation framework specifies network connectivity metrics based on a social network survey. A network survey of CBOs (n=35) at baseline demonstrates utility of social network data for characterizing connectivity among community resources. The evaluation framework models how informatics and community resources improve population health.

Introduction
Evidence indicates that zip code rivals genetic code as a determinant of overall health, urging more interventions on the “zip code level”¹. Accordingly, there is increasing demand for an ecological systems paradigm for community interventions, with focus on: community capacity; problem identification through community engagement; empowerment of the community; and the permeating role of culture². As the importance of social determinants of health is increasingly recognized, health systems must seek collaborations with community-based partners that are equipped to meet diverse social service needs of patients ³. From the healthcare financing perspective, population-based accountable care models provide additional incentives for health systems to address social determinants through community-based services⁴.

Community-engaged health informatics (CEHI) is an emerging field with many opportunities for novel discoveries, as it combines concepts and methods from biomedical informatics⁵, community-based public health approaches⁶, as well as other fields such as community informatics⁷. CEHI takes an ecological systems approach to community health². It extends the notion of Learning Health System to the community-level, and investigates the ecology of community health information in a “cyber-social ecosystem”⁸.

We applied community-based participatory research (CBPR)⁶ to design a CEHI platform GetHealthyHeights.org (GHH) for the medically underserved, urban, largely Latino community of Washington Heights-Inwood (WAHI)⁹. GHH features an innovative participatory architecture with functionality for facilitating community stakeholder interactions. In addition to community residents, and a range of other community stakeholders, GHH specifically serves health-oriented CBOs, as they are viewed as essential assets for building community health interventions¹⁰. As an intervention, GHH was designed to facilitate connectivity among stakeholders in the community.

The design of GHH builds on the lessons learned from GetHealthyHarlem.org¹¹, ¹². While the Harlem portal was designed primarily for community member participation, the GHH team decided to primarily focus on community-based organizations and other groups and agencies that care about health of WAHI. GHH is intended to be a CEHI platform that allows exploration of novel functionalities that promote community engagement and community health. The mission of GHH was collectively defined by the GHH Steering Committee as “an online community that engages people and organizations in Washington Heights-Inwood to discover, connect, and share resources to get healthy”¹³.
Selected functions include a community calendar, a local service directory, posting of multiple types of content (e.g., articles, videos, and links), the ability to comment and rate content, integration of social media for content sharing, use of Google Translate (especially for Spanish translation of content), creation of pages for local organizations and the ability to form groups that other users can join. Community organizations have an essential role in creating and disseminating content through GHH. Figure 1 shows an illustrative screen shot of GHH. An initial version of GHH was launched to the public in April 2015. As of February 2016 (23 months of public use), the website had 43,990 page views, 16,860 use sessions (average 733 per month), 39 partner organizations, and 286 registered users.

Figure 1: Screenshot of GetHealthyHeights.org

GHH seeks to include and engage all health-related resources in the community. A comprehensive resource mapping was conducted and is described elsewhere. Resources encompass public, non-profit, private, and informal sectors, and range from large organizations (e.g., universities, hospitals) to small informal entities (e.g., bulletin board, walking group). The GHH team is currently in the process of defining a taxonomy to better classify types of health-related community resources, organizations, and services. CBOs are an important sub-type of resource and play a central role in GHH. The evaluation approach described in this paper specifically focuses on detecting change over time in network connectivity among CBOs, and attributing the change to GHH.

CBOs play an important role in networks of community health resources and services but they have poor capacity for processing, using, and exchanging information. Care coordination is a well-documented problem within the health care system generally, suggesting similar challenges with coordination of community-based services and resources. Emerging literature in the area of knowledge translation is beginning to highlight the potential of CBOs in translating evidence into the community. But many barriers hinder evidence use and evidence-based practices of CBOs. Research has consistently identified that CBOs struggle with: access to evidence; time to process evidence; skills to review, summarize, and synthesize evidence; research terminology; and local applicability and acceptability of evidence. Strategies are needed to address these barriers in order to realize the potential of CBOs as important agents of improving population health. The GHH CEHI platform targets these challenges through a set of online functionalities specifically designed to facilitate connectivity and information access among CBOs in the WAHI community. Enhanced connectivity of a community health resources network may provide positive synergistic effects, and has a large potential pay-off in terms of health-related social capital, and resulting benefits to community wellness.

Network connectivity means that local community-based organizations (CBOs) are sharing information, collaborating, and cross-refering clients. Paarlberg and Varda argue that network exchanges are the most essential driver of capacity in the non-profit sector. Connectivity is an important outcome because it is expected to make delivery of programs and services more efficient, and to facilitate health-related social capital, contributing to improved community wellness and reduction in health disparities. In the context of health informatics, there is a vision of seamless exchange of health data across organizations, and CBOs are increasingly considered part of the...
health data exchange network. For this future vision of sharing data among CBOs to become reality, trust among organizations becomes a critically important intermediate connectivity construct. Broad-based data sharing will require trust as a quality of organizational linkages.

A system-level approach is required to study connectivity on the community level. Social network analysis provides such approach. Some prior research has used social network analysis to demonstrate outcomes of community-level interventions. For example, Ramanadhan and colleagues 24 used network analysis to show that a cancer prevention coalition building intervention increased the connectivity among members of an intersectoral agency network in Massachusetts. The PARTNERtool has been used in several studies to measure social networks of community partnerships26. It provides an established instrument for operationalizing the kinds of linkages and exchanges that constitute network connectivity.

The overall rationale of the GHH CEHI platform as an intervention and its impact on health draws from several theoretical influences, including literature on community engagement, social networks, and social capital27. Based on literature, our conceptual model postulates that network connectivity contributes to social capital22, and social capital contributes to community health23.

The GHH CEHI platform is purposefully designed to facilitate health resource network connectivity. The architecture of participation in GHH9 mediates connections and interactions among community stakeholders. The evaluation framework we present here seeks to specify some of the processes by which functionality in GHH, and participation in GHH, are expected to lead to more resource connectivity.

Prior research has not investigated the impact of a comprehensive CEHI intervention such as GHH. Studies are starting to explore ways of applying informatics methods in the context of community engagement28-32. Compared to other applications of health informatics in the community engagement context, GHH is unique in its focus on CBOs as the primary community partners. One reason why GHH partners closely with CBOs is the desire to enhance sustainability of GHH by building it in partnership with stable local community assets33. Lack of sustained use is a known challenge for information technology (IT) interventions that rely on voluntary motivation of users34, and is potentially addressed through a community-level approach that engages CBOs to champion the IT system.

This paper presents a conceptual model and describes how it is operationalized. Our view of operationalization comes from the social science research perspective35. We describe the conceptual underpinnings and the design of the evaluation framework. We also present baseline data for the network survey to substantiate how key outcome constructs in the framework were operationalized and measured.

Methods

Community Setting of Evaluation Study

The Washington Heights-Inwood (WAHI) neighborhood is located in upper Manhattan within New York City (NYC), north of Harlem and directly south and west of the Bronx. It is a densely populated urban area of 2.8 square miles and four zip codes with approximately 200,000 residents36. A large proportion of WAHI residents are Hispanic (71%), and 93% belong to a racial/ethnic minority group. African Americans represent 7% of the population37. Almost half (48%) of residents are foreign-born, mainly from Latin America, with 2/3 from the Dominican Republic. Many ethnic groups are represented as foreign-born residents come from a total of 55 countries38. A large proportion (39%) of residents have limited English proficiency37. The median household income was $37,460 in 2013, and 27% lived below the federal poverty level38. A large percentage (30%) of adults did not graduate from high school. The most common sources of employment are services and sales industries39. Housing quality is rated among the lowest in NYC37. Health concerns in the community are significant compared to NYC as a whole. Among WAHI residents, 27% rate their health as fair or poor, compared to 22% citywide, and 16% reported that they went without needed medical care. Obesity rate is 22%, and 22% of residents report they had no physical activity in the past month. Only 36% had influenza vaccinations37.

Approach to Defining Evaluation Framework

The overall approach includes three major components: (1) conceptual modeling, (2) selection of evaluation design and methodology, and (3) definition of operationalized measures.
The plan to evaluate process and outcomes of GHH evolved during the design stage of the project and was based on conceptual modeling of relevant constructs. Important key constructs included: “engagement” to capture active participation of users with GHH, “network connectivity” to capture a system level outcome on the level of the community as a whole, and “health-related social capital” as a construct that bridges network connectivity to community health outcomes. Detailed conceptual analysis was conducted to further break down components of each of the key constructs. Several iterations of logic models and conceptual diagrams were developed to capture the conceptual framework. Community stakeholders were engaged and provided input into the models, primarily through the GHH Steering Committee.

An evaluation design and methodology were developed based on the conceptual modeling and considerations of feasible data collection options. While recognizing the limitations of a pre-post design, an outcome evaluation design was selected to capture change in network connectivity over time in the target community. Consistent with GHH focus on CBOs, the team decided to primarily focus the evaluation on network connectivity among CBOs. Baseline data collection was conducted during early implementation of GHH, with a plan to collect similar data at later time points.

The PARTNERtool was selected as an established measure of network interactions among community agencies. It was adaptable for the purposes of the GHH evaluation. The PARTNERtool provided a foundation for defining operationalized measures of constructs that constitute “network connectivity”, as further described in the Results section below.

The process evaluation was designed to document and measure how organizations and individuals engage in GHH. Process evaluation data sources included Google Analytics for GHH, system back-end data from GHH use logs, and records of participation in GHH governance and other GHH-related activities. In the outcome evaluation design, the process measures also serve as independent variables, with the plan of measuring associations between GHH engagement and network connectivity outcomes for individual CBOs.

**Baseline Network Survey Methodology**

The primary inclusion criteria for the network survey was: non-profit organization that provides health-related services to the WAHI community and has a physical office location within the four targeted zip codes. The research team went through a systematic process of identifying the list of CBOs. This process involved decisions about what kinds of organizations to include as “health related”. The initial list of organizations was based on the researchers’ prior experience of working in the community, complimented with results from a systematic community resource mapping. The resource mapping was based on five data sources on community resources, including most recent files from the Internal Review Service listing all organizations with 501(c)(3) non-profit status within the four zip codes. We have described the resource mapping process elsewhere.

The team identified 25 qualifying non-profit organizations, including 8 multi-service CBOs, 6 senior centers, 2 nursing homes, 2 health centers/health center networks, 2 behavioral health providers, 3 child/youth service providers, 1 free-standing food pantry, and 1 HIV/AIDS service provider. The team also decided to invite three local city-government organizations to participate in the survey: local Community Board (part of city government), and 2 recreation centers (operated by city). In addition, the team decided it was important to represent the following seven entities in the survey to capture a more comprehensive picture of the community’s network: city government (libraries, health department, police department, etc.); Columbia University; Yeshiva University; K-12 public, private, and parochial schools; New York Presbyterian Hospital community programs; New York State Psychiatric Institute (located within the community); and faith-based organizations. The 25 non-profits and the three city government entities constitute the pool of 28 organizations invited to complete the survey. The 28 organizations and the seven additional entities constitute the set of 35 entities listed on the survey. Each survey respondent was asked about their connections to all other 34 entities.

We used an adapted version of the validated PARTNERtool. The PARTNERtool was designed to collect network interaction data from public health collaborations. It includes a section where the respondent is asked to indicate relationships and interactions with all listed agencies. Organizational leaders were recruited to respond to the surveys. The instructions stated that the Executive Director (or equivalent, or someone he or she designates) should fill out the survey as a representative of the organizational perspective. The survey administration was managed through the PARTER tool website.
The survey protocol was approved by the Columbia University Medical Center Institutional Review Board. The survey data were collected in summer and fall of 2016. It should be noted that GHH was already open to the public at that time, and many of the organizations in the survey already began initial use of GHH before they were recruited to participate in the survey. Thus, the baseline survey was collected during early stage implementation of GHH.

**Results**

**Evaluation Framework**

Figure 2 depicts the conceptual logic of the causal chain of outcomes we theorize for the evaluation framework. The evaluation focuses on measuring engagement in GHH as the primary independent variable and connectivity in the community resource network as the primary outcome variable. The other outcome constructs are specified to create a full picture of how and why we think GHH contributes to community wellness. In particular, the logic model defines health-related social capital as the construct that links resource network connectivity to health outcomes. Even though we do not measure them in the current evaluation, we postulate several components of social capital that the GHH intervention can improve. For example, we argue that improved connectivity will lead to efficiency in the way the community as a whole is able to deliver health programs and services.

**Figure 2:** Logic model of outcome constructs

Further conceptual analysis was conducted to elaborate on the two constructs the evaluation is designed to measure, namely, *engagement in GHH* and *connectivity*. This step is grounded in a more concrete level, looking at the actual functionality built into GHH and the actual activities of connecting among CBOs. The two bottom boxes of Figure 3 represent these two domains. The model suggests that the GHH system functionality (and participation in GHH governance) facilitate specific ways in which CBOs connect among one another. The top two boxes of Figure 3 represent how the evaluation measures the constructs in the bottom boxes. The top section of the figure captures the essential elements of the evaluation plan. Measures of the processes (and independent variable) of GHH use and participation are described on the top left, and specific network connectivity measures are described in the top right. The study design examines change in network metrics over time, but in addition, as indicated in the figure, we plan to measure associations between GHH use/participation and connectivity indicators for individual organizations.

It should be noted that the engagement of CBOs occurs within and outside of the actual online platform. In fact, in-person meetings related to governance of GHH appear to be a powerful mechanism for engaging organizations around GHH. Other engagement processes, such as sharing content or finding resources, reside more directly on the GHH website.

**Baseline Network Results**

The baseline network survey was sent to 28 organizations; with a 61% response rate. The survey listed 35 total organizations; 28 that received surveys and seven that were listed to represent selected groups or entities (e.g., faith-based organizations) that were not recruited to respond to the survey.
Organizations that responded reported that they collectively had 273 connections with other entities. The average number of connections per organization was 13 (out of a possible 34). The top seven most connected had an average of 25 connections per partner, leaving the remaining 28 organizations averaging 10 connections per partner. Table 2 shows selected network metrics for the entire network, along with the definitions of the metrics.

**Figure 3:** Key constructs and evaluation measures

**Table 1:** Selected network metrics for whole network

<table>
<thead>
<tr>
<th>Network Metric</th>
<th>Baseline Survey Score</th>
<th>Definition of Metric</th>
</tr>
</thead>
<tbody>
<tr>
<td>Density</td>
<td>39%</td>
<td>Percentage of ties present in the network in relation to the total number of possible ties in the entire network.</td>
</tr>
<tr>
<td>Degree Centralization</td>
<td>56%</td>
<td>The lower the centralization score, the more similar the members are in terms of their number of connections to others (e.g. more decentralized).</td>
</tr>
<tr>
<td>Trust</td>
<td>64%</td>
<td>The percentage of how much members trust one another. A 100% occurs when all members trust others at the highest level.</td>
</tr>
</tbody>
</table>

Figures 4 and 5 show network diagrams depicting types and frequencies of baseline connections among the entities. As shown in Figure 4, about one-third (32%) indicated that they only had awareness of one another, while 47% indicated cooperative activity connections, 14% indicated coordinated activity connections, and 7% indicated integrated activity connections with one another.
Discussion

Our evaluation framework offers a conceptual and methodological map for measuring the impact of a community-level informatics intervention on network connectivity among community organizations. We trace conceptual and operationalized definitions from engagement with functionality of the information system (GHH) to different dimensions of interactions and exchanges that constitute network connectivity. We also discuss the intervention change model that postulates that network connectivity translates to health-related social capital\textsuperscript{22}, which, in turn, is expected to contribute to positive population health outcomes\textsuperscript{23}.

The baseline results of the social network survey of CBOs, using the PARTNERtool\textsuperscript{26}, demonstrate that the survey methodology produces a rich set of network metrics for describing the state of the CBO network at baseline. Among the many available metrics are density of connections, and different types and frequencies of connections. “Trust” is an important example of a specific quality of a connection that provides a conceptually meaningful outcome in the context of our evaluation. With “Trust” at 64%, density at 39%, the community appears to have many positive connections, but with ample room for increase from baseline. Examination of the baseline visualizations shows that many of the possible binary connections are not in place at baseline, and suggests that any new edge that is added to the network in the future can be examined as evidence of change, and potentially characterized resulting from GHH facilitation. The social network methodology allows analyses of the entire network as a whole system, as well as drilling down to the level of individual organizations. Having both levels is extremely useful for an evaluation framework in a transactional context such as CBOs connecting in a community and engaging with a system designed to facilitate such connections.
Engagement is a central construct within CEHI. The design of GHH with an architecture of participation is an operationalized instance of engagement processes. In the evaluation framework, use of GHH functionality becomes not only a process evaluation metric, but also means of measuring engagement as an independent variable. An association between use of GHH and improvement over time in network connectivity measures serves as evidence that GHH has its intended impact.

The GHH evaluation highlights the role of CBOs as special kind of health-related resource. Collectively, CBOs can establish a backbone of network exchanges that translates into community-level benefits that are more than the sum of its parts. CBO networks are a natural mechanism for addressing social determinants of health. In the future, medical care systems should pursue closer connections with CBO networks and other community resources. This will be a starting point for a Learning Health System that includes community services and resources. The future vision of such Learning Health System includes sharing and flow of data across medical care and community entities.

The construct of “trust”, which we examine in our evaluation as a component of inter-organizational connectivity, will be a critical pre-requisite for data sharing and exchange to ever become reality.

**Limitations**

We only present a preliminary stage of work that needs to be supported by further data collection and analysis. However, we believe it is valuable to present a focused conceptual analysis that constructs a coherent and organized model of the phenomenon under evaluation and an operationalized way of measuring it. Our initial analysis shows that much more can be done, even within the realm of operationalizing the measures. For example, internal correlations within the baseline network survey dataset can be used to further examine validity of sub-constructs of connectivity.
The baseline dataset can also yield numerous additional network metrics both for the entire network and for its sub-units. For example, we plan to examine measures of strong ties (bonding social capital) and weak ties (bridging social capital) within the network\(^\text{40}\). We can also further specify the statistical analyses approaches to be used to measure change in network metrics over time.

A pre-post evaluation design implemented in only one community has obvious limitations, but is a valid starting point for further work. It was feasible to collect baseline data only after implementation of GHH had already begun. At present time we observe community organizations increasingly engaging around GHH. Once we collect systematic data over time we will be able to further describe mechanisms by with GHH functionality facilitates the engagement.

Operationalizing valid constructs and study designs in the context of a complex information technology poses special challenges and limitations\(^\text{41}\). It is a limitation of validity if only one system is built to “instatiate” the constructs. It should be recognized that the specific and idiosyncratic ways in which this system gets designed may account for the evaluation results.

**Conclusion**

We argue that mobilizing community-based resources through informatics is an important strategy that should be leveraged to improve population health. GHH is an instance of such strategy, linking engagement in a CEHI technology to network connectivity among entities in a geographic community.

Distinction between medical and non-medical usages of short forms in clinical narratives

Sungrim Moon, PhD, Donna Ihrke, Yuqun Zeng, MD, PhD, Hongfang Liu, PhD
Department of Health Sciences Research, Mayo Clinic, Rochester, Minnesota, USA

Abstract

The short forms of medical concepts or expressions (i.e., acronyms/abbreviations) are prevalent in clinical documentation. Given the limited number of potential short forms, they are also highly ambiguous. Resolving the ambiguity of short forms is essential in clinical natural language processing (NLP). However, one prerequisite for resolving ambiguity of short forms is to have a sense inventory. This paper outlines our process of identifying 141 potential short forms with randomly sampled phrases from a large clinical corpus. We assessed various features in their ability to disambiguate medical and non-medical usages. We identified 68% of our short forms as primarily serving medical usages, whereas 12% had non-medical usages. The remaining 19% showed alternating usage based upon case form. Our short forms had an average of 3.58 senses. Usages could be distinguished using basic trigram/bigram/line information. Our initial findings will be applicable for automatic usage/sense resolution.

Introduction

The short forms of medical concepts or expressions (i.e., acronyms/abbreviations) are prevalent in clinical documentation. Given the limited number of potential short forms, one short form can have multiple senses. Resolving the high ambiguity of short forms, a special case of word sense disambiguation (WSD), is essential in clinical natural language processing (NLP) systems. There are some unique characteristics of short forms in the clinical domain. First, the appearance of short forms in clinical documents is very different from other domains (1). They are seldom defined in the text but can have diverse meanings at different settings. For example, “CA” can mean “California”, “Cancer”, and “Calcium” without any clear definition in clinical narratives. “DT” can be frequently used as “Discharge time” in Discharge summaries and “Diptheria-tetanus double vaccination” in Immunization reports. Second, “one sense per discourse” (2), a common understanding in the general English WSD community, may not hold here (3). For example, “PT” can stand for “Patient” in the subjective section and it can mean “Prothrombin time” in the assessment section. Additionally, besides multiple clinical meanings, short forms in clinical texts can also have non-medical English usages. For instance, the short form “US” in “The US shows a lesion” and “The patient retired from US army in 2011” has two different meanings where the first one means “Ultrasound”, and the second one means “United States”.

WSD in the clinical domain has been studied including the use of rules or machine learning (ML) approaches (1, 4, 5). Various textual features (such as POS tags or n-grams) have been inspected (5, 6). However, those textual features may not perform well in documents that are semi-structured (e.g., containing tables) or not grammatically well formed (7) such as Emergency Department (ED) notes. Document metadata features are also crucial but they vary across different EHR systems or institutions. Additionally, expert or distributed semantic (e.g., SNOMED concepts or topic models) features have also been utilized but they highly depend on the comprehensiveness of knowledge resources (8) and the availability of a large collection of documents in the corresponding domain. Research (5, 9) has been focused to develop individual classifier per short form to achieve reasonable performance rather than one generalized classifier for all.

However, the prerequisite towards WSD is the creation of a sense inventory which catalogs the associated meanings of those ambiguous words (10). As described, short forms can have both medical and non-medical usages in clinical documents. Existing clinical terminology resources may not capture their non-medical usages. For example, the non-medical usage of “ICE” in “ICE number” as “In Case of an Emergency phone number” is not included in existing clinical terminology resources. Additionally, some short forms have localized usages. For example, “MEA” stands for “MayoExpertAdvisor”, a short form for a decision support system at Mayo Clinic or “Minnesota Education Assembly”.

In this paper, leveraging a large collection of clinical notes in our clinical data warehouse, we investigated the usages of short forms in clinical documents, assessed potential features which can be utilized for identifying varying usages, and assembled high frequent usage patterns towards WSD tasks.
Method

Dataset and resources

For this study, we used a corpus consisting of 40 million clinical notes from 1995 to 2011 retrieved from the Mayo clinical data warehouse. The corpus includes all notes generated from a diverse range of medical specialties. The total number of our word tokens in the corpus was 13.9 billion corresponding to 61.8 million unique word tokens. For each word token, we extracted all corresponding text lines.

We used multiple publicly available resources to aggressively identify medical and non-medical usages. Specifically, we leveraged the Unified Medical Language System (UMLS)\textsuperscript{(11)} of the National Library of Medicine (NLM) as the source for concepts. The UMLS integrates various controlled vocabularies pertaining to biomedicine by assigning a concept unique identifier (CUI) to link all clinical term variants with the same meaning together. Based on our prior work\textsuperscript{(8)}, we derived an short form list, 7,092 entries, from the UMLS. Another resource is allacronyms.com\textsuperscript{(12)}(data: Aug 18~19, 2016), which is a comprehensive resource for short forms with over 3 million entries across all domains. The website offers user-driven and topic oriented short forms using online search. We also utilized the following resources: titles of Wikipedia (date: July 20, 2016), unigram tokens in the Brown corpus\textsuperscript{(13)}, and the Kunth list of American English words\textsuperscript{(14)}.

Identification of short form candidates

Since short forms can appear in diverse forms as described in our prior work\textsuperscript{(8)}, to simplify our study we used the following criteria to identify potential short forms from the word tokens gathered from the corpus:

1. The number of characters needs to be at least 2 and at most 7. For example, a word token, “NA” is one of our candidates because its length is two with all capital alphabet letters. In addition, a length of “N.A.” is four according to our criteria.
2. The token contains all capital alphabet letters with or without numbers/special symbols taking its diverse expressions into account in clinical narrative notes. We consider special symbols as “+”, “-”, “/”, “&”, and “.”. Additionally, the token has at least one capital alphabet letter. E.g., we include “N+A”, “N-A”, “N/A”, “N&A”, and “N.A.” for a short form “NA”.
3. The token may contain special symbols in the middle but not consecutively occurring. Taking as an example for a short form “NA”, we exclude “N++A” or “N+/A-”.
4. The token may end with “+”, “++” and “.”. For instance, we regard “NA+”, “NA++”, “N.A+”, and “N.A.” as valid tokens.

We used the following heuristics to identify a subset of short form candidates for our study stratified to those with both medical and non-medical usages as shown in the left side of Figure 1. Specifically, we considered those short form candidates appearing in the short form list derived from the UMLS (i.e., they have medical usages) and at the same time occurring with multiple prevalent lexical variations (i.e., potentially have non-medical usages). For a word token, if after ignoring special symbols and capitalization, it appears in the short form list derived from the UMLS, we consider it a lexical variation of that candidate. To take example on one token “(n/a)” in our clinical notes, we stripped non-alphanumeric characters in the front/end of token as “n/a” at first. Next, we removed “/” in “n/a”, and then disregard the capitals. Therefore this “(n/a)” is a lexical variation of short form “NA”.

We counted two types of frequencies for each candidate in the right side of Figure 1. One is the number of occurrences containing of all lexical variations (loose form) and one is limited to those lexical variations without lower case letters (strict form). This case-sensitive distinction was examined because the lexical forms of medical usages (specially, medical abbreviations) have a tendency to consist of capital cases (strict form) compared with those of non-medical usages. We limited to candidates with the strict form frequency of at least 100. After logarithm transformation, we computed the difference between the two frequencies. For example, we counted 705,472 occurrences of “NA” as loose form and 158,348 occurrences of “NA” as strict form. After logarithm transformation, the difference is 2 (i.e., 19 minus 17). We then randomly selected five to six short form candidates from each frequency difference.
Manual review of the selected set

For each short form candidate, we extracted 100 unique lines containing the candidate in loose form and another 100 unique lines containing the candidate in strict form after removing those capitalized lines. We asked two experts to manually annotate the following usages and the specific meaning for the candidate in the context:

- **Medical Abbreviation**: the candidate is used as a short form for a medical concept. In a sentence, “Abdominal ultrasounds to check patency of TIPS performed on 09/10/03.”, the “TIPS” is abbreviation for “Transjugular intrahepatic portosystemic shunt procedure” as medical usage.

- **Medical Concept**: the candidate itself is used for a medical concept. For example, “tips” in “She’s had some surgeries on the finger tips for wound care and ulceration and a hysterectomy.” indicates “Body Regions”.

- **Non-medical Usage**: the candidate is used as a non-medical term. For instance, “tips” represents “Advice” in the sentence, “I gave her a brochure of tips on healthy brain aging.” with regards to non-medical usage.

- **Others**: the meaning of the candidate is unknown or potential typo. For example, “IBC” was frequently used as a typo of “inferior vena cava (IVC)”. e.g., “He is status-post IBC filter”. On top of it, we counted unknown meaning for human experts in this category. We also included “Spanish” and “Template limitation” in this category.

Following the above-mentioned guideline, the export annotated “FL” as (1) “Medical abbreviation” and (2) “Full liquid diet” for the sentence “Pt is tolerating diet adv to FL.” whereas (1) “Non-medical term” and (2) “Florida” for the second sentence “Pt had the follow-up at Mayo Clinic in Jacksonville, FL.”. All annotations were validated by terms in The UMLS Terminology Services (UTS) Metathesaurus (ver. 2016AA). The inter-annotator reliability of the annotated senses was calculated with percentage agreement based on 5% of total 28,200 instances. The usage agreement of short forms was also measured based on all identified senses.
Exploratory analysis of features for usage disambiguation

In this step, we performed an exploratory analysis of features with potential of disambiguating medical usages from non-medical usages. To identify representative variations of short forms, we stripped non-alphanumeric characters in the front/end of token in our clinical documents. Specifically, we investigated the following features:

- **The number of unique lines in strict and loose form**: For instance, “OR” appeared in 581,807 unique lines as strict form and 49,908,734 as loose form in our clinical lines. If the candidate appears in loose form relatively more frequently than in strict form, it implies that the candidate has a high chance to have a non-medical usage. Oppositely, the candidate is primarily used as a short form with medical usage.

- **The number of unique lexical variations in strict and loose form**: We assume that tokens with medical usages tend to have fewer non-strict variations. For example, “CPD” always appears as one lexical variation in strict form (i.e., “CPD”), so the number of unique strict lexical variations is 1. However, it has five unique lexicon variations, “CPD”, “CPd”, “Cpd”, “cpd” and “c.p.d.” in loose form, so the number of unique loose forms is 5.

- **The number of the candidate appearing as the signal word of a sentence (in loose form)**: The first letter of the first word in a sentence is usually capitalized. We consider a lexical variation is used as the signal word if the first letter is capitalized and the remaining letters are in low case. It implies the candidate has non-abbreviation usages.

- **The number of distinct normalized bigrams and trigrams when candidate appearing in strict and loose form**: For each candidate, we obtained all the occurrences of the trigram (left word, candidate, right word) with the candidate or its variation appearing in the middle. After converting all digits to “9”, ignoring cases of the left and right words, and removing punctuations, we counted the number of distinct normalized trigrams. For instance, one phrase for “PLAT” appeared as “9 PLAT 9”, which implies a “Blood Platelets” value in Laboratory Test. (This pattern has 80% of frequency over the total frequency of twenty-seven patterns in strict forms.) We calculated the number of distinct normalized bigrams taking a phrase as a left word and target word form into account as well. Our assumption was the proximal words (especially next left word) conserved the meaning/sense.

- **Existence in well-known dictionaries and resources**: We leveraged multiple medical and non-medical resources to identify the existence in those resources. We assumed if any short form frequently appeared in non-medical or medical resources, there is a high possibility to serve as the particular usage of that domain. We explored common medical usages using [www.allacronyms.com](http://www.allacronyms.com) limited to the medical field. For non-medical usages, we used [www.allacronyms.com](http://www.allacronyms.com) limited to non-medical fields and the following general resources: Wikipedia, Brown corpus, and the Knuth’s list. We ignored case information when checking the existence in those resources. Additionally, we took case information into consideration for Wikipedia, Brown corpus and the Knuth’s list. We used the binary representation (1= existence, otherwise 0) for our features.

We used Pearson product-moment correlation coefficient to assess the predictability of the usages of those features. Each value (except the binary representation of the existence in resources) was logarithmically transformed and the differences between strict and loose forms were used to compute the correlation against usages.

**Result**

Overall, the total number of short form candidates was 297 million (2.14%) corresponding to 0.53 million unique tokens in Mayo clinical corpus. Table 1 shows the set of 141 our randomly selected candidates after the process in Figure 1. Based on line samples of these selective short forms, we collected 518 senses over medical, non-medical and other usages with 89% of them normalized to UMLS concepts. 69% of our total senses served as medical (medical abbreviations and medical concept) usages, whereas 30% of them used as non-medical usages. Also, Our short forms have the average 3.58 senses. There were total 258 typos (178 and 80 case in loose and strict form, respectively) and 337 unknown senses (134 and 203 cases in loose and strict form, respectively) over all 28,200 random instances. Table 2 represents the details of our annotation senses per domain and form. The inter-annotator agreement is 95% when assigning senses to individual instances and 97% on usages (base on total 518 senses) of short forms.

Table 2 represents prevalent medical usages and low non-medical usages as strict form (75% and 25% of sense ratios respectively) compared to loose form (68% and 31%). However, both forms primarily have senses (about 67% in strict form and 59% in loose form) serving as medical abbreviations.

Table 3 summarized our selected short forms according to dominant sense ratio and relevant usages. For example, “TEA”, this short form belonged to non-medical class if “Beverages” was the prime sense (96%) among 100 random unique lines as loose form. However, if dominant usage (75%) in strict form for “TEA” was “Arthroplasty, Replacement, Elbow”, it classified as “Medical usage (Medical Abbreviation)”. According to Table 3, 86% and 72% of our short forms were medical usages as strict and loose form respectively. This prevalence of medical terminologies is unsurprising given our input corpus of clinical documents. Furthermore, 78% (strict form) and 62% (loose form) of our short forms were clinical acronyms and abbreviations. Additionally, 80% and 77% of the selected short forms have high major senses ratio (over 90% of sense dominant) in strict and loose forms respectively, which reflects the general tendency for short forms to have a dominant tendency to serve a particular domain. Sets in strict form have a tendency served as medical usages as those most likely are commonly used short forms in the medical domain.

* SF = short form

We categorized those 27 short forms with different usages into the following:

- Medical Abbreviation to Non-medical usage (18 cases): Majority of usage change belongs to this category. For “APR”, the major sense is “Abdominoperineal resection” in strict form. However, it changed to “April” in loose form.
- Medical Abbreviation to Medical Concept (3 cases): This category has three short forms “AIDS”, “CHI”, and “TIPS”. For “AIDS”, “Acquired Immunodeficiency Syndrome” in strict form is the major sense whereas “Hearing Aids” is the major sense in loose form.
- Medical Abbreviation to Others (3 cases): There are “AME”, “MAS”, and “SOM”. These short forms contain “Unknown” or “Typo” senses as majority senses in loose form (see discussion later).
- Medical Concept to Non-medical usage: (1 case): A short form “CUP” changes the major sense from “Acetabular Cup Prostheses” (strict from) to “Measurement” (loose form)
- Non-medical usage to Medical Abbreviation: (2 cases): We have two cases, “UNC” and “NA”. “UNC” has the major senses as “University of North Carolina” in strict form and “Intravesical reimplantation of ureter” in loose form. In case of “NA”, it changes the major sense from “Not applicable” (strict form) to “Sodium” (loose form).
Table 5 and Figure 2 illustrate the ambiguity and sense distribution in strict or loose forms. Among 141 short forms, the majority have senses as medical abbreviations (124 in strict and 118 in loose forms). The number of short forms that are ambiguous is 94 and 92 in strict and loose form respectively with 70% of them having senses from both medical and non-medical domains. The short form with the highest number of sense is “MAS” which has sixteen and eight different senses in strict and loose form, respectively. For example, “MAS” has medical abbreviations such as “Macrophage Activation Syndrome”, “Meconium Aspiration Syndrome”, “Multiple autoimmune syndrome”, “Marlo Anatomical Socket”, etc., as well as non-medical usages such as “Medical assistant”, “Initial (abbreviation)”, and “Academic degree”.

Results of Feature Investigation and Analysis

The number of unique lines in strict and loose form: Among our short forms, “FIND”, “CUP”, “BICARB”, “DROWSY”, “PER”, “DRY”, “ON”, “HOT”, “PHOS”, “DIZZY”, “ACHE”, “NO”, and “AS” have a high difference in frequencies (logarithm difference ≥ 7) between strict and loose forms. Most of these short forms (ten of thirteen) are belonged into medical concept or non-medical usage. Besides, short forms, having identical frequency in both forms such as "OHI", "PVRI", "RVOT", "MPV", and "MCHC", classify into medical abbreviation.

The number of unique lexical variations in strict and loose form: This feature primarily indicates the degree of diverse representations per short form in the clinical corpus. In our investigation, short forms consist of only two (or three) characters have high variations, which may imply the high sense ambiguities. For examples, “BS”, “OP”, “PO”, “US”, “IV”, “NA”, and “ST” have more than twenty lexical variations as loose form. Besides, the short form having exactly same numbers of lexical variants in both forms with low frequency (< 3) tends to have only single sense (i.e., “OHI”, “PVRI”, and “RVOT”). However, this feature may not a key factor to determine the domain usage of short forms.

The number of the candidate appearing as the signal word of a sentence (in loose form): In our sets, “NO” presents the highest frequency (63% of total) as the signal word (the major sense is “Negation” as non-medical usages). Furthermore, the words with high frequency (more than 1.7M) such as “ON”, “AS”, “PER”, and “ST” are classified into non-medical category. On the contrary, short forms which never appear as signal word, such as “AAV”, “CPVT”, “EAA”, “MHR”, “OAG”, “OHI”, “OPV”, “PVRI”, “RVOT”, “SMP”, and “TMB”, serve as medical abbreviations.

The number of distinct normalized bigrams or trigrams when candidate appearing in strict and loose form: If the short forms have the similar frequency of trigrams (or bigrams) in both forms, it serves as medical abbreviation. Our representative short forms are “AAV”, “CPVT”, “EAA”, “IBC”, “MCHC”, “MHR”, “MPV”, “OHI”, “OPV”, “PVRI”, “RVOT”, and “TSR” with less than 10 differences in our corpus. Oppositely, the short forms with the substantial difference may have a high possibility as non-medical usage (i.e., “NO”, “ON”, “OR”, and “AS” have more than 100K difference between two forms). We also find very similar phenomena in bigrams (proceeding word token with short form).

Existence in well-known dictionaries and resources: Table 6 represented the size of lexical forms and coverage of our short forms per resource. Higher numbers of lexicons and coverage ratios of available corpus may not strictly guarantee to distinguish domain usages, since the resources (Allacronyms or Wikipedia) tend to cover both domains.
extensively. As an opposite perspective, Brown and Knuth corpus have low coverage on our short forms in our clinical corpus, but contain well-known lexicons in each domain. For instance, Brown and Knuth cover “CT”, “DIZZY”, “DROWSY”, “LIP”, “LYMPH” (we categorized them as medical usages) as well as “DIET”, “FIND”, “OK”, “PER” (as non-medical usages).

We selected features with any significant correlation (p < 0.05) to the usages of short forms in Table 7. Taking the difference of logarithmic transformation regarding trigram, bigram, and unique line between two forms have moderate correlations (r > 0.4). Brown/Knuths corpus, logarithmic transformations of signal word and bigram in loose form also have weak correlation (r > 0.3 and r < 0.4) Additionally, logarithmic transformations of trigram and unique lines (loose form) have weak correlations.

Discussion

In this study, we described the process to identify short forms from a large collection of clinical documents and investigated the usages of a randomly sampled subset of those short forms with the goal of creating a clinical sense inventory for short forms. Our analysis indicates that the majority of our short forms (68% of our 141 short forms) served as medical abbreviations or medical concepts with about 19% of them having non-medical usage. The majority of our short forms have multiple meanings. Feature analysis identifies the difference of logarithmic information regarding trigram, bigram, and unique lines between strict and loose forms can differentiate short forms primarily with medical usages from those that are not. It implies that statistical information about local context and word form obtained from a large corpus is useful in disambiguating the usages.

Note that, our institution has been governed the use of approved abbreviations, resulting in relatively low ambiguity. Therefore, 50% of ambiguous short forms have only two or three senses. According to Figure 2, 30% of our ambiguous short forms have two senses, and 20% of them have three senses. This distribution is very similar in both strict and loose forms, but short forms in upper case are frequently represented as medical abbreviation in our corpus. This implies that resolving ambiguity associated with abbreviations is relatively easier for our data.

It is important to note that the quality of our clinical notes is high with low errors or unknown senses given 95% of our clinical notes were generated through dictation followed by manual validation, so our findings may not directly applied to other health institutions. However, we identify the tendency that short forms in loose form format contains twice as many errors but fewer unknown senses compared to those in strict form format. As our samples are extracted to cover as many contextual variations as possible, for high frequent words (e.g., “has”, “some”), their misspellings (e.g., “mas” or “som”) tend to dominate our samples for the corresponding short forms (e.g., “MAS” or “SOM”) where most of those are errors introduced when transforming documents in rich text format (RTF) into plain text format (e.g., “MASS” is inserted with a line break between “MAS” and “S”).

We examined 57 senses that were not covered by the UMLS including 30 medical usages and 27 non-medical usages. Those medical usages include clinical abbreviations (e.g., “Problem-Intervention-Evaluation” for “PIE”, “Maximum Access Surgery” for “MAS”, “Anterior Posterior Repair” for “APR”, “Inversion and Eversion” for “IE”, “cycles per degree” for “CPD”, and “per patient” for “PPT”). Medical devices were also frequently abbreviated (5 cases; e.g., “Intubation Macintosh (curved) blade” for “MAC” and “Intravenous bird cage (filter type)” for “IBC”). There were also some localized medical usages (3 cases; e.g., “Mayo Age Standard” for “MAS”). Additionally, many of the non-medical usages can be localized abbreviations. For example, we have “St Mary’s” for “SM” which is the name of a hospital.

There are some limitations in our study. First, we assumed a short form served as medical usages if it has numerous occurrences with any medical sense in our random 200 samples at Mayo Clinic repository. However, the majority of our short forms were fundamentally used as medical usages since we extracted them from clinical notes. Additionally, we investigated only 200 random unique lines for one short form that may not represent the complete usages distribution of the short form. Secondly, we took the simplest way to acquire our features for exploratory analysis. Therefore, we focused on unique lines without considering any sentence detection. It significantly affected the validation of our signal words in new lines as well as normalized n-grams. Also, we disregarded syntactic or part of speech (PoS) information because we might use the fragments of clinical sentences rather than compete sentences.

In the future, we will further explore those features to achieve automatic distinction between medical and non-medical usages with the large size of short forms. As feature refinements, we will use our resources in divergent views. For example, we identified title pages of Wikipedia covered 91% of our short forms but was not useful for our usage resolutions. However, 57% (80 cases) of them represented as “Categories: Disambiguation” and 17% of them (24 cases) showed “Redirect -> Categories: Disambiguation pages”. This information can be useful to indicate the level of ambiguity for the short form. We will leverage additional well-known resources such as Corpus of Contemporary American English (COCA) and the British National (BNC) corpus. We will also consider the term frequency-inverse document frequency (TF-IDF) scores of short forms on different corpora to weight the token information for distinguishing medical and non-medical usages.
Conclusion

We have investigated the usage information of short forms mined from a large clinical corpus and discovered the prevalent use of short forms as medical abbreviations, but with a high degree of ambiguity and also including both medical and non-medical usages. The study also assessed a set of features to distinguish medical and non-medical usages. The work provides an initial feasibility assessment of creating a sense inventory of short forms and patterns for usage disambiguation.

Supervised Learning Methods for Predicting Healthcare Costs: 
Systematic Literature Review and Empirical Evaluation

Abstract
An important informatics tool for controlling healthcare costs is accurately predicting the likely future healthcare costs of individuals. To address this important need, we conducted a systematic literature review and identified five methods for predicting healthcare costs. To enable a direct comparison of these different approaches, we empirically evaluated the predictive performance of each reported approach, as well as other state-of-the-art supervised learning methods, using data from University of Utah Health Plans for October 2013 through October 2016. The data set consisted of approximately 90,000 individuals, 6.3 million medical claims and 1.2 million pharmacy claims. In this comparative analysis, gradient boosting had the best predictive performance overall and for low to medium cost individuals. For high cost individuals, Artificial Neural Network (ANN) and the Ridge regression model, which have not been previously reported for use in healthcare cost prediction, had the highest performance.

Introduction
The United States’ national health expenditure (NHE) grew 5.8% to $3.2 trillion in 2015 (i.e., $9,990 per person), which accounted for 17.8% of the nation’s gross domestic product (GDP). In seeking to control these unsustainable increases in healthcare costs, it is imperative that healthcare organizations can predict the likely future costs of individuals, so that care management resources can be efficiently targeted to those individuals at highest risk of incurring significant costs. Key stakeholders in these efforts to manage healthcare costs include health insurers, employers, society, and increasingly healthcare delivery organizations due to the transition from fee-for-service payment models to value-based payment models. For any given individual, insurers generally have the most comprehensive information on healthcare costs as they pay for care delivered across various healthcare delivery organizations.

Predicting healthcare costs for individuals using accurate prediction models is important for various stakeholders beyond health insurers, and for various purposes. For health insurers and increasingly healthcare delivery systems, accurate forecasts of likely costs can help with general business planning in addition to prioritizing the allocation of scarce care management resources. Moreover, for patients, knowing in advance their likely expenditures for the next year could potentially allow them to choose insurance plans with appropriate deductibles and premiums.

Despite the importance of healthcare cost prediction, to our knowledge there has been no review of the literature on this important topic. Therefore, we conducted a systematic literature review. Moreover, in order to enable a direct comparison of approaches on a common data set, we evaluated each of the identified approaches on a health insurance data set from the University of Utah Health Plans. We also evaluated additional state-of-the-art methods not previously evaluated in the literature.

Methods

Literature Review
Adapting a search strategy from a previous systematic review, we searched Google Scholar and MEDLINE. The latest search was performed on February 21, 2017. We used a combination of the following search terms: healthcare cost prediction, medical claim cost, pharmacy claim cost; healthcare expenditure prediction; healthcare risk score prediction; and patient cost prediction.
In conducting the systematic literature review, we sought to answer the following questions. Because the answer to the first question identified that using features of prior costs to predict future costs performed as well as or better than approaches that also used clinical data for cost prediction purposes, all subsequent questions were focused on approaches that used prior cost features to predict future costs (referred to henceforth as “cost on cost prediction”).

1. What are the types of healthcare cost prediction approaches reported in the literature?
2. What are the input features that have been used for cost on cost prediction?
3. What are the supervised learning methods that have been used for cost on cost prediction?
4. What are the performance measures and evaluation results for cost on cost prediction?

**Direct Comparison of Alternative Cost Prediction Methods using a Health Insurer Data Set**

**Approach.** This study was approved by the University of Utah Institutional Review Board (Protocol # 00094358). We used a health insurance data set to directly compare the performance of cost on cost prediction approaches identified in the literature, as well as other state-of-the-art supervised learning techniques.

**Data.** Our data set consisted of 6.3 million medical claims and 1.2 million pharmacy claims from approximately 91,000 distinct individuals covered by University of Utah Health Plans from October 2013 to October 2016. Available data included demographic information (e.g., age, gender, age), clinical encounter information (e.g., place and date of service, provider information), diagnosis and procedure codes, pharmacy dispense information, and cost information (e.g., paid, allowed and billed amount). This data was filtered to individuals with insurance membership for the whole three years period, which resulted in approximately 3.8 million medical claims and 780,000 pharmacy claims from 24,000 patients.

The data set was divided into two time periods: an observation period and a result period. The former time period was from October 2013 to September 2015 (i.e., two years), which was used to predict individuals’ cost in the result period ranging from October 2015 to October 2016 (i.e., one year). Table 1 shows all input features used in this study. All features used in this study were cost related features extracted from Bertsimas et al.6, which had the largest and most complete set of cost related features among the reviewed manuscripts. If a member did not have any cost for a specific month it was considered as zero; therefore, there are no missing values in this dataset.

The range of paid amounts in the result period showed that 80% of the overall cost of the population came from only 15% of the members. Therefore, aligned with the literature on cost bucketing, to reduce the effects of extremely expensive members, the data set was partitioned into five different cost buckets. This partitioning was done so that the sum of members' costs in each bucket was approximately the same in the observation period (i.e., the total dollar amount in each bucket was the same). For instance, 84% of members are in bucket 1 with the same total cost amount as the members in bucket 5, which contains about 2% of the population.

**Classifier.** Classifiers evaluated included Linear Regression, Lasso7, Ridge8, Elastic Net9, CART10, M511, Random Forest12, Bagging13, Gradient Boosting13, SVM14, and ANN15. Except for CART, the other classifiers had not been previously evaluated for cost on cost prediction. All models were optimized on their parameters to get their best parameter setting on 30 percent of the data set. Models were evaluated with the following parameter settings: number of hidden layers, number of nodes in each layer, learning rate, and momentum were varied for the Neural Network; kernel type along with the corresponding parameters of each kernel type were varied for the Support Vector Machine; minimum split and minimum number of sample in each leaf were varied for the M5 and CART; learning rate and loss function for the Gradient Boosting; and alpha was varied for the Lasso, Ridge and Elastic Net.

A brief description of all the models used in this study (except linear regression) is provided below.

**Lasso:** This is a linear regression model enhanced with variable selection and regularization, which is given by the L1-norm (the loss function is the linear least squares error)7.

**Ridge:** This is a linear regression model where the regularization is given by the L2-norm (the loss function is the linear least squares error). L2-norm equips the model to have non-sparse coefficients, which means many coefficients with zero values or very small values with few large coefficients8.

**Elastic Net:** This is linear regression model that linearly combines the L1-norm and L2-norm penalties of the Lasso and Ridge models9.

**CART:** This is a regression decision tree, where on each node the algorithm chooses the split that minimizes the sum of squared errors for regression of the node. The important quality is that the algorithm uses the sample mean of the instances in each node for regression10.

M5: Similar to CART, this algorithm is also a regression tree, where a linear regression model is used for building the model and calculating the sum of error as opposed to the mean.  

Random Forest: This is an ensemble learning algorithm that fits a number of regression decision trees on several subsamples of the data. The mean value of the outcomes of the regression tree is generated as the final prediction of the algorithm.  

Support Vector Machine: This is a support vector regression model implemented based on libsvm which uses kernels to find the regression lines.  

Bagging: This is an ensemble learning algorithm that fits each base regression model on random subsets of the data that are generated by a bootstrapping sample method. Aggregation of the individual predictors is performed by averaging to form the final prediction.  

Gradient Boosting: This is an ensemble learning algorithm, where the final model is an ensemble of weak regression decision tree models, which are built in a forward stage-wise fashion. The most important attribute of the algorithm is that it ensembles the models by allowing optimization of an arbitrary loss function. In other words, each regression tree is fitted on the negative gradient of the given loss function, which is set to the least absolute deviation.  

Artificial Neural Network (ANN): This is a large collection of processing units (i.e., neurons), where each unit is connected with many others. Neural networks typically consist of multiple layers and the goal is to solve problems in the same way that the human brain would.  

20-fold cross validation was employed as the evaluation method on 70% of the data set. For statistical significance, we first applied the Friedman’s test to verify differences among multiple classifiers. If significant at an alpha level of 0.05, pairwise comparisons were made with the Wilcoxon Signed-Rank test. This statistical approach was aligned with the method recommended by Demsar.
Results

Literature Review

1. What are the types of healthcare cost prediction approaches reported in the literature?

There are three kinds of methods that have been reported for cost prediction: rule-based, statistical and supervised learning. The disadvantage of the rule based methods (e.g. Kronick et al.15) is that they require a lot of domain knowledge, which is not easily available and is often expensive16. Although statistical models, mainly multiple regression models, are powerful tools for capturing the relationships between the predictors and the dependent variable, they have two important challenges 18. One is that working with several independent variables often causes multicollinearity, which is caused by the presence of significant correlations among predictors. Moreover, their performance is challenged by the skewed nature of healthcare data, where cost data typically feature a spike at zero, distributions are strongly skewed with a heavy right-hand tail19, and extreme values can be present, all of which make them inefficient in small to medium sample sizes if the underlying distribution is not normal. Although several advanced statistical methods have been proposed to accommodate the skewness observed in healthcare data, this type of prediction method is not able to outperform supervised learning methods20. Therefore, this paper is devoted to the use of supervised learning methods for cost prediction, and the remainder of the literature review excludes other types of prediction methods.

There are generally three types of literature that use supervised learning for cost prediction. In the first type, the goal is to predict cost using medical predictors. In this type of literature, the main goal is to show the effect of medical factors such as chronic disease score on cost prediction21. In the second type of literature (which is limited), cost predictors with or without medical predictors are used to predict cost. In the last type of literature, researchers bucket individuals’ costs and predict an individual’s cost bucket rather than his or her actual costs. This last type of research applies nominal predictive models rather than numerical predictive models.

Cost prediction using non-cost predictors. Lee et al.22 provided one of the earliest works on predicting cost by using non-cost predictors. They selected a small sample of 492 patients from a hospital in Korea and compared the performance of ANN and a classification and regression tree for cost prediction. Demographic information, diagnosis codes, number of laboratory tests, the number of admissions and number of operations were the predictors of their analysis. The results showed the superiority of ANN.

Powers et al.23 evaluated several regression statistical modeling approaches for predicting prospective total annual health costs (medical plus pharmacy) of health plan participants using Pharmacy Health Dimensions (PHD), a pharmacy claims-based risk index. Their models included ordinary least squares (OLS) regression, log-transformed OLS regression with smearing estimator, and 3 two-part models using OLS regression, log-OLS regression with smearing estimator, and generalized linear modeling (GLM), respectively. The results showed that most PHD drug categories were significant independent predictors of total costs. The OLS model had the lowest mean absolute prediction error and highest R². The main conclusion was that the PHD system derived solely from pharmacy claims data can be used to predict future total health costs.

Analyzing the impact of multimorbidity (i.e., co-occurrence of more than three chronic disease conditions) on healthcare costs, König et al.21 interviewed 1,050 randomly selected primary care patients aged 65 to 85 years suffering from multimorbidity in Germany. A conditional inference tree algorithm was used as the classifier. The results showed that Parkinson’s disease and cardiac insufficiency were the most influential predictors for total costs, and that the high total costs of Parkinson’s disease were largely due to costs of nursing care.

Cost bucket prediction. Lahiri et al.4 predicted the rise in patient care costs as a binary classification problem. They used a data set with more than 114,000 patients for a span of three years (2008-2010) to investigate which patients experienced increases in inpatient expenditures between 2008 and 2009. Using stacked generalization, they ensembled six classifications algorithms including gradient boosting machine, conditional inference tree, neural networks, SVM, logistic regression and Naive Bayes. This achieved 80% recall, 78% accuracy and 76% precision. One of the contributions of the paper was that they initially had 12,400 features, most of them arising out of diagnosed conditions and drugs taken, and selected 44 of them according to their information gain. This helped the authors to identify major factors which were crucial in determining whether an individual was going to incur higher healthcare expenditure going forward. In a similar study, Guo et al.24 tried to predict patients’ transition from one cost bucket to another bucket in the following year. To do so, they applied multiple methods (each for a single type of transition) to improve the prediction performance. The results showed that they could improve the performance for 21% comparing to baselines. Moreover, they found that the proposed method can help health care entities
achieve efficient resource allocation while improving care quality. Reviewing all papers in this category, we found no studies on categorical cost prediction that used cost-based features as the input.

Cost prediction using cost predictors (cost on cost prediction). Bertsimas et al.\textsuperscript{6} provided one of the first evaluations in the area of health cost prediction using supervised learning techniques. They used a combination of medical, demographic and cost related features from August 2004 to July 2006 as the input and applied regression decision tree and clustering to predict total patient costs in 2007, as measured by insurance payments including medical and pharmacy payments. The results showed that utilizing just 22 cost related features as input and a CART regression decision tree as the classifier gave almost the same performance as adding the medical and demographic information (total of around 1500 features) or applying clustering techniques. Performance was reported in terms of Mean Absolute Error, Hit Ratio, $R^2$ and a penalty based evaluation designed by the authors. Bucketing was also used to evaluate the prediction results to assess the accuracy. This evaluation showed that while the method is strong at predicting low cost buckets, it had a weak performance on higher cost buckets.

Following the above study, Sushmita et al.\textsuperscript{18} evaluated the use of a regression tree, M5 model tree and random forest for cost prediction and showed that M5 had the best performance. The results also confirmed that prior healthcare costs alone can serve as a good indicator for future healthcare costs. To predict patients’ cost for the next year, they used the Medical Expenditure Panel Survey (MEPS) data set coming from responses to panel surveys given to households and their employers, medical providers, and insurance providers over two year periods.

Duncan et al.\textsuperscript{2} compared several different supervised learning and statistical models to predict patients’ cost including M5, Lasso and boosted trees. They applied their experiments on 30,000 patients where the information from 2008 was used for training and the total allowed amounts in the claims from 2009 were used for testing. They involved a variety of predictors as input including the previous year’s total cost, total medical cost, total pharmacy cost, demographic information, total visits and chronic conditions (83 different conditions). The results showed that boosted trees and M5 were the most effective classifier in terms of $R^2$ and Mean Absolute Error (MAE) respectively, and that cost predictors were the strongest predictors. Moreover, confirming previous literature results, this paper showed that statistical methods are not as good as supervised learning techniques.

Kuo et al.\textsuperscript{25} attempted to show the significance of pharmacy-based metrics as opposed to diagnosis-based morbidity measures in predicting patients’ costs and outpatient visits. They used data from 2006 to predict patients’ billed costs in 2007. To achieve this, they applied linear regression on the data set. Evaluation was done based on Mean Absolute Error and $R^2$. Although the purpose of the study was to explore the capability of the pharmacy-based metric in cost prediction, the results confirmed that using cost based features for cost prediction has almost the same accuracy as adding other types of features to the input. This paper did not incorporate sophisticated cost features and just used a single cost feature from 2006. Frees et al.\textsuperscript{26} studied the ability of linear regression to predict individuals’ costs in terms of healthcare insurance payments. They used self-rated physical health and self-rated mental health, provided by participants, using demographic and survey-based information as their input. Getting a reasonable performance (i.e., $R^2=0.27$), they found that cost, self-rated mental health and self-rated physical health are the most important predictors.

Collectively, and in particular in the study by Bertsimas et al.\textsuperscript{6}, these studies found that cost on cost prediction can match the performance of predictions made using clinical input factors or clinical plus cost input factors.

2. What are the input features that have been used for cost on cost prediction?

Input features are one of the essential parts of a supervised learning task. Numeric cost prediction studies have benefited from a variety of features as input, which are summarized in Table 2. As seen, Bertsimas et al.\textsuperscript{6} evaluated a wide range of cost inputs and reported the performance of cost inputs separately. Their results showed that prediction using a superset of 1542 features, including clinical features, had the same performance as using just the 21 cost predictors. This finding was confirmed by other researchers in subsequent work.\textsuperscript{5,18}

3. What are the supervised learning methods that have been used for cost on cost prediction?

There are a variety of supervised learning methods that have been used in this area. Table 3 summarizes all different methods that have been reported as successful methods for cost on cost prediction. These methods include Lasso, which is a type of linear regression, gradient boosting on regression decision trees, M5 regression decision tree, random forest, linear regression and CART regression tree. Table 3 also shows the target type of the cost that was studied in each paper. Billed amount is the total amount that is charged by the health care provider and the paid amount is the amount that is paid by the insurance company.

4. What are the performance measures and evaluation results for cost on cost prediction?

**MAE:** This shows the average error of the model on prediction of the actual cost values and is calculated as follows:

$$MAE = \frac{\sum |a_i - p_i|}{n}$$

where $a_i$ and $p_i$ are the actual and predicted costs of member $i$ in the result period respectively.

**Mean absolute percentage error (MAPE)**: This is a modified version of absolute error in which the MAE is divided by the mean of the cost, so that the MAE could be compared across the models with different means of cost:

$$MAPE = \frac{\sum |a_i - p_i|}{\frac{n}{\bar{a}}}$$
MAE is dependent on the data set, such that different models from different studies cannot be directly compared using that measure. MAPE is a relative measure and does not have this limitation.

$R^2$: This shows the Pearson correlation between the actual and predicted cost values:

$$R^2 = 1 - \frac{\sum_i(a_i - p_i)^2}{\sum_i(a_i - \bar{a})^2}.$$  

*Hit Ratio*: This measure shows the percentage of the members for whom a model forecasts the correct cost bucket:

$$\text{Hit Ratio} = \frac{\text{Number of members with correct predicted bucket}}{\text{Total number of members}}$$

*Penalty Error*: This is a performance measure for cost prediction based on domain knowledge. Penalty error penalizes models for underestimating high cost members more than overestimating low cost members, which is motivated by the estimated opportunity loss. Table 4 shows the penalty table for the five-cost-bucket scheme. The final value of the penalty error is calculated from the average forecast penalty per member of a given sample.

Table 5 summarizes the evaluation measures used in different papers. The reported performance measures in this table correspond to the whole data set used in each study. This study reports the experimental results in terms of all five performance measures except MAE, which is not reported given the sensitivity of absolute cost data.

**Direct Comparison of Alternative Cost Prediction Methods using a Health Insurer Data Set**

Tables 6 to 9 show the performance comparison between different supervised learning models on training and validation data sets. As seen, Gradient Boosting had the highest performance in terms of all measures in all buckets except bucket five. Here, ANN was superior. Also, the Ridge model showed a comparable performance compared to ANN, especially for low cost buckets.

Discussion

Summary of findings. This study reviewed the literature of healthcare cost prediction and found that cost on cost prediction performs as well or better than cost prediction using clinical data or clinical data plus cost data. Moreover, supervised learning methods were found to be superior in predictive ability. Moreover, we found that gradient boosting provides the best cost on cost prediction models in general, with ANN providing superior performance for higher cost patients. The evaluations show consistency between training and validation results.

Strengths. An important strength of this study is that we combined both a systematic literature review and a head-to-head empirical evaluation of different supervised learning methods reported in the literature. An additional strength is that we evaluated state-of-the-art supervised learning methods not previously evaluated in the literature for cost on cost prediction in health care.

Limitations. The main limitation of this study is that we used one data set. More experiments on different data sets from different institutions and regions could provide more solid evidence on the comparative performance of different algorithms. The second limitation of this study is that we used cost features. Although previous studies showed that medical features did not improve the performance of the cost models, we could potentially still benefit from such features for two reasons. One is that the new supervised machine learning methods may benefit from the medical features. Second is that the medical features have more explanatory power that may help decision makers understand the root causes of members’ costs.

Future studies. This study was devoted to the paid amount of the medical claims. An interesting venue of research would be analyzing the billed amount as well as the out-of-pocket amount paid by patients to see which approaches work best for each type of cost metric. Another future research direction would be to explore the use of more advanced supervised learning methods such as deep learning and structure analysis to improve the performance of cost prediction methods. Finally, adding medical features and benefiting from their predictive and explanatory power can be another future research direction, which has already been started in our team.

Conclusion

The literature indicates that the preferred approach to healthcare cost prediction is cost on cost prediction using supervised learning methods. Empirical analysis of alternate approaches using data from a single health insurer found that gradient boosting provides the best cost on cost prediction models in general, with ANN providing superior performance for higher cost patients.

The Role of Surface, Semantic and Grammatical Features on Simplification of Spanish Medical Texts: A User Study

Partha Mukherjee, Ph.D1, Gondy Leroy, Ph.D1, David Kauchak, Ph.D2, Brianda Armenta Navarrete, BS1, Damian Y. Diaz, MA1, Sonia Colina, Ph.D1
1University of Arizona, Tucson, AZ; 2Pomona College, Claremont, CA

Abstract

Simplifying medical texts facilitates readability and comprehension. While most simplification work focuses on English, we investigate whether features important for simplifying English text are similarly helpful for simplifying Spanish text. We conducted a user study on 15 Spanish medical texts using Amazon Mechanical Turk and measured perceived and actual difficulty. Using the median of the difficulty scores, we split the texts into easy and difficult groups and extracted 10 surface, 2 semantic and 4 grammatical features. Using t-tests, we identified those features that significantly distinguish easy text from difficult text in Spanish and compare with prior work in English. We found that easy Spanish texts use more repeated words and adverbs, less negations and more familiar words, similar to English. Also like English, difficult Spanish texts use more nouns and adjectives. However in contrast to English, easier Spanish texts contained longer sentences and used grammatical structures that were more varied.

Introduction

Providing simplified text to patients and health information consumers facilitates understanding. Using clear and understandable language is especially relevant in the medical domain as better text comprehension helps create a health-literate patient group. Easier texts help patients remember medical information1 and motivates them to read and understand the text2. Well informed patients can manage their conditions better.

Readers’ education level, language skills and reasoning abilities play a role in their ability to understand, digest and act on information3. Studies that evaluated readability grade levels, presentation and format, and education levels4, 5 show that the education level influences understanding. Demographic differences also impact patient understanding of health education and instructions6; there are significant differences in health literacy with respect to age, gender, academic background and household income, with higher educational attainment and higher household income associated with more adequate health literacy. Advanced age had a negative correlation with adequate health literacy.

There exist several approaches for improving patient health literacy7, however, providing text-based materials is one of the most cost- and time-efficient solutions. Albright et al.8 recommend providing patients and caretakers with written information as it is vital in reinforcing verbal communication between patients and doctors. However, written materials for patient education must be carefully matched to patient reading levels9. Different text features affect text difficulty10 and different approaches have been suggested to increase comprehension. For example, studies advise replacing technical jargon with more common terms or improving the organization of the text11: avoiding long sentences, keeping length to no more than eight to ten words12; organizing the content in question and answer format; and creating a logical flow of information13. Interdisciplinary team collaboration to write and provide information for patients in plain language has also been suggested14. Finally, the use of information technology tools has been advocated to assist with this process and improve the understanding of clinical information and data15, 16.

In this study, we examine how different text features interact with text difficulty in Spanish medical texts. Most previous studies have focused on English texts, even though Spanish is the second most used language in the United States17. We leverage our previous work on English features to motivate our feature selection and to help understand how Spanish text simplification might differ from English simplification. Identifying parallel simplification approaches is important for our final goal, which is the development of a multi-lingual text simplification toolkit. To evaluate our set of potentially interesting features, we conducted a user study to estimate the difficulty of texts. We separated the texts into ‘easy’ and ‘difficult’ based on perceived and actual difficulty scores. We then examined feature occurrence in the texts and report on those that were significantly different between the easy and difficult texts. We also compare the Spanish text features with those found important for English text simplification.
Literature Review

Text Simplification

Text simplification is a procedure that transforms text into a clearer and more understandable version while preserving the meaning of the text\(^8\). Simplifying texts can facilitate readability for people with disabilities\(^9,10,11\), low literacy\(^12,13\), non-native backgrounds\(^14,15\) or non-expert knowledge\(^16,17\). Text simplification may also help improve the performance of many natural language processing (NLP) tasks, such as parsing\(^18\), summarization\(^19,20\), semantic role labeling\(^21\) and machine translation\(^22\).

Formulas to measure text readability include Reading Ease Score (RES), SMOG (Simple Measure of Gobbledygook), Flesh-Kincaid score and Gunning Fog index\(^23\). However, these formulas rely on simple, surface-level features such as sentence length, percentage of familiar words and word length and, although they have been used in readability research over the past two decades\(^24\), there is little evidence that there is a relationship with actual text difficulty.

We have developed a new feature to measure text difficulty, term familiarity\(^2\), which can be used to both measure text difficulty and guide text simplification. Term familiarity is measured based on a term/word’s frequency in a large corpus, with low frequency terms being more difficult. A text can be simplified by replacing difficult words with synonyms that are less difficult, as measured by term familiarity\(^25,26\). Similar to term familiarity, we developed grammar familiarity as a new feature, measured by the frequency of the parse tree structure of the sentence in a large corpus. Grammar familiarity has a similar effect to term familiarity: more commonly used grammatical structures (i.e. higher frequency in the corpus) are considered more familiar and have been shown to be easier to understand\(^27\).

We have also demonstrated that different types of negation are used in easy and difficult texts: morphological negation is used more frequently in difficult text\(^28\). Furthermore, we have shown that splitting long noun phrases is beneficial for improving perceived difficulty, but only affects actual difficulty when it can be done while maintaining the natural flow of the sentence\(^29\).

Even though Spanish is one of the most common languages in the US, there is little information about how to determine text difficulty and simplify text in Spanish. Even traditional readability formulas do not entirely fit Spanish text\(^30\). Some previous Spanish studies have focused on structural simplification such as sentence splitting, lexical substitution of functional multi-word units\(^31\) and re-ordering of syntactic units\(^32\). For example, the Simplext project focuses on simplifying vocabulary and syntactic structures\(^33\) for people with cognitive disabilities. Others focus on different aspects of the text such as the treatment of idioms and collocations\(^34\), the way that the syntactic structure looks\(^35\), and the font and colors\(^36\).

Actual and Perceived Difficulty

Two components play a role in the difficulty of a text: 1) whether the text looks easy for readers (perceived difficulty) and 2) whether the reader can understand it (actual difficulty). Perceived and actual difficulty independently influence intention to read and the comprehension of materials\(^37\). Perceived difficulty is often measured on a 5-point Likert scale by asking participants how difficult the text ‘looks’. Actual difficulty requires measuring understanding and has been accomplished with cloze tests, multiple-choice tests and other measures of comprehension\(^38\). A text conveys information effectively when people both want to read it and can understand the content. The willingness to read is related to a text’s perceived difficulty, while comprehension is related to its actual difficulty and specific characteristics. Previously we showed that lexical simplification reduces perceived difficulty, while coherence enrichment reduces actual difficulty\(^39\).

Evidence for distinguishing between perceived and actual difficulty comes from two research models. The Health Belief Model (HBM) explains and predicts health-related behaviors. It is defined in terms of perception of four constructs: 1) perceived susceptibility, 2) perceived severity, 3) perceived benefits, and 4) perceived barriers. These concepts were proposed to account for people’s ‘readiness to act’\(^40\). It was assumed that diverse demographic, sociopsychological and structural variables might, in any given instance, affect an individual’s perception and thus indirectly influence health-related behavior. The second model is the Theory of Planned Behavior (TPB), which is an extension of the Theory of Reasoned Action (TRA)\(^41\). TPB is used to explain deliberate and planned behavior. According to this theory, human action is guided by three kinds of considerations: 1) behavioral beliefs, 2) normative beliefs and 3) control beliefs. Human actions are guided by three concepts that particularly impact willingness to change behavior. The general rule is that the greater the perceived control, the stronger a person’s intention to perform the behavior in question.
Both models highlight the importance of perceived text difficulty. Many readers do not read a text if they feel that it is difficult\textsuperscript{48}. Naturally, perceived difficulty does not tell the entire story. It is insufficient for a text to be perceived as easy; actual difficulty plays a major role in the resulting comprehension of information. We want to both reduce the perceived difficulty and increase text comprehension. Adjusting text based on reading levels will encourage people to read more\textsuperscript{45}.

**Methods**

To evaluate which text features are important for simplifying Spanish text, we conducted a user study to measure both perceived and actual difficulty of the texts. We then split the texts into easy and difficult based on the perceived and actual difficulty scores and evaluated which text features are indicative of difficult and easy texts.

**Text and Content Questions**

To analyze the characteristics of medical texts, we created a corpus with 15 texts. The texts are paragraphs from abstracts of scientific articles related to seven different diseases that are the most frequent causes of death in the world\textsuperscript{49}: asthma, cancer, diabetes, hepatitis, hypertension, influenza, leukemia. We chose scientific articles since the content is more difficult to understand\textsuperscript{50}. Each disease was discussed in at least one text, with some diseases represented in as many as six.

For each text, we generated four multiple-choice questions. The first three multiple-choice questions tested content knowledge in the article and participants had to select from four answer options. The fourth multiple-choice question is a conclusion question that asked participants to select the sentence that would best finish the text. We removed the actual last sentence of the text and included this as an option, along with three other incorrect options. We used Amazon Mechanical Turk (MTurk) to recruit participants, with the restrictions that they were US residents and had a 95% approval rate on tasks previously performed for other requesters.

After the study, we pre-processed the text and extracted the different features. The word parts-of-speech (POS) were identified using the Freeling parser\textsuperscript{51} and the full parse trees were generated using the Stanford parser\textsuperscript{52}. Word frequencies were looked up in the LEXESP\textsuperscript{53} corpus which contains approximately 120,000 words. The frequency of words not found in LEXESP was assumed to be zero.

**Metrics**

To measure perceived difficulty, we used a 5-point Likert scale and asked people “How difficult is the text to read?” The answers were quantified using a 0-4 range, with 0 representing the most difficult and 4 representing the least difficult.

To measure actual difficulty, we calculated the average accuracy of the answers to the multiple-choice questions.

**Features**

We identified surface, semantic and grammatical features motivated by prior work in English\textsuperscript{37, 54}. The surface and semantic features are averaged over the number of words per text, while the grammatical features are aggregated over the number of sentences per text. “Proportion” below denotes the number of words that have that feature (e.g. words that are nouns) divided by the total number of words in a text.

- **Surface features** (10):
  - Number of sentences.
  - Average words per sentence.
  - Function word ratio: proportion of words in the text that are function words (determiners, prepositions and conjunctions).
  - Punctuation ratio: proportion of words in the text that are punctuation characters.
  - Number ratio: proportion of words in the text that are numerals.
  - Negation ratio: proportion of words in the text that are negation words. The negation words are identified by the Freeling parser.
  - Noun/adjective/verb/adverb ratio: proportion of words in the text that are nouns/adjectives/verbs/adverbs in the text, each as a separate feature.

- **Semantic features** (2):
  - Repeated words ratio: proportion of the words in the text that are repeated.
  - Term familiarity: We use the frequency of content bearing terms (i.e., nouns, adjectives, verbs, adverbs) in the LEXESP\textsuperscript{53} database as an approximation of term familiarity.
Grammatical features (4): We denote the “grammar structure” of the sentence as the top two levels of the parse tree of a sentence.37

- Average grammar frequency: Number of different sentence grammar structures in a text, averaged over the texts.
- Average grammar question frequency: Average number of different grammar structures for the multiple-choice question per text.
- Average minimum edit distance: Edit distance is the minimum number of edit operations (deletions, substitutions and insertions) to transform one grammar structure into another. We calculate the edit distances of the grammar structures for all adjacent sentence pairs in the text and calculate the average of these values. This measure quantifies how dissimilar (i.e., distant) two grammar strings are, so lower values indicate more similarity. We consider this measure complementary to the average grammar frequency since it also measures grammatical diversity in a text.
- Average cosine similarity: We created frequency vectors for each of the constituents in a grammar structure. We then calculated the cosine similarity between these vectors for all adjacent sentences and averaged these values per text.

Participants

A total of 66 workers participated in our study with 12 participants per text on average. They were paid $1.50 for completing each text and the associated questions. As is customary with MTurk studies, each participant could choose to complete from 1 to all 15 texts. Overall, an average of 3.9 minutes was needed to read the texts and answer the associated questions. The shortest time spent to complete reading the text and answering the questions was 1.4 minutes and the longest was 14 minutes.

Table 1 provides the participants’ demographic information as self-identified by the participants. Most participants (95%) were less than 50 years old. The majority were with 1) gender: female (52%), 2) race: white (80%), and 3) ethnicity: Hispanic or Latino (70%). Most had moderate education: 20% have a high school diploma, 26% an associate’s degree and 36% a bachelor’s degree. Thirty-nine percent of the participants spoke half Spanish at home and 35% mostly Spanish.

Results

Perceived and Actual Difficulty

To analyze the text features, the 15 texts were classified into three categories, easy, middle, and difficult using the median perceived and actual difficulty scores which are calculated based on the participant responses to the questions. Texts with scores higher than the median are considered easy; texts with scores less than the median are difficult. The texts with scores that were nearly the same as the median (i.e., median ± 0.05) were considered in the middle category. To get a clear distinction between ‘easy’ and ‘difficult’ texts, we excluded the middle category from our analysis, which included two texts. Table 2 shows the descriptive statistics for the easy and difficult texts: 6 texts were easy and 7 texts were difficult based on perceived difficulty and 7 texts were easy and 6 texts difficult based on actual difficulty. A t-test confirmed that the easy and difficult splits were significantly different. For the perceived difficulty split, the easy texts had significantly lower perceived difficulty scores with an average difference of almost a full point (p < 0.001). For the actual difficulty split, the easy texts had significantly better accuracy with the easy text resulting in question scores that were 23% (absolute) better (p < 0.001).

Example of sentences from easy and difficult texts are:

1. Perceived difficulty
   - Easy: “El manejo de la diabetes tipo 1 en la infancia y adolescencia ha evolucionado en los últimos años, como consecuencia de la intensificación del tratamiento insulínico y la aceptación de nuevos objetivos en el tratamiento.”
   - Difficult: “La primeroinfección por los virus herpes simple (VHS), varicela-zóster (VVZ), citomegalovirus (CMV), herpesvirus humano 6 y virus de Epstein-Barr (VEB) ocasiona hepatitis generalmente leve y autolimitada en pacientes inmunocompetentes.”

2. Actual difficulty

---

• Easy: “Aproximadamente el 75% de las mujeres con cáncer de mama avanzado presenta metástasis óseas, lo que les ocasiona una importante morbilidad y deterioro en su calidad de vida.”
• Difficult: “Con la creciente posibilidad de ocurrencia de una pandemia de influenza en las próximas décadas, es necesario que los niveles subnacionales de gobierno (estados, provincias, municipios) estén adecuadamente preparados con planes operativos basados en los lineamientos generales establecidos por organizaciones multinacionales o gobiernos nacionales.”

**Feature Comparison**

**Features that impact perceived difficulty**

To evaluate the differences in feature occurrences between easy and difficult texts, we carried out t-tests for all features. Since the easy/difficult document sets were different for perceived and actual difficulty, we conducted a separate analysis for each. The t-test results for the perceived difficulty partitioning are shown in Table 3. We used Bonferroni correction with significance level ($\alpha = 0.05$) to reduce Type 1 errors. With 17 features, the level required for statistical significance then becomes $0.05/17 = 0.003$.

Table 3 shows that there are several significant differences between the perceived easy and difficult texts. For surface features, we show, as has been seen in English text, that easy documents contain more adverbs while difficult documents contain more adjectives$^{11}$. Interestingly, unlike in English text, we did not see any significant differences between the use of function words, nouns and verbs. We also saw similarities with English text for the semantic and grammatical features, with easy documents containing more frequent words and using fewer unique
grammatical structures. We also saw more repeated words, punctuation and numbers in easy texts, while difficult texts had more negations.

Features that impact actual difficulty

Table 4 shows the analysis when splitting the text based on actual difficulty. Many of the same patterns appear, with numbers and adjectives occurring more in easy texts and negations more frequently in difficult texts, though a number of the features are not significant in this split. Difficult texts do use more nouns, though, which has been seen in English as well\textsuperscript{11}. Interestingly, while the easy texts had fewer structures (not significant), the structures were more similar in the difficult texts.

Discussion

Many features are significantly different between easy and difficult texts, particularly when perceived difficulty is used to make the distinction. The surface features such as the proportions of numerals, negations and adjectives are significant for both the perceived and actual difficulty and follow the same direction in terms of high and low between easy and difficult text, while average words per sentence follows the opposite direction. Relating to perceived difficulty, the easy texts are shorter in length but have longer sentences and difficult texts have more different grammar structures. Surprisingly, for actual difficulty, sentences in the easy texts have more dissimilar grammar structures. This means the sentences of difficult texts have more similar grammar structures. Neither of the
similarity measures plays an important role in identifying difficulty of Spanish texts from the perceived difficulty perspective.

Comparing these findings with those for English texts\(^7\), we see that from the perceived difficulty perspective easier Spanish texts have more punctuation and longer sentences. Similar to English, difficult Spanish texts contain more negations\(^8\). In English more nouns are seen in difficult texts\(^5\), but the proportion of adjectives is significantly higher in difficult Spanish texts. Surprisingly, function word use is not significantly different between easy and difficult text. In contrast, in English texts the higher frequency of function words identifies the text as easy\(^9\). Furthermore, easy texts in Spanish contain more adverbs, while easier English texts have more verbs\(^5\). Regarding semantic features, easy Spanish texts have a higher term familiarity, which is similar to easier English texts. Unlike English, for Spanish texts the grammar frequency does not have any effect on evaluating how easy a sentence is to understand (i.e., actual difficulty)\(^37\).

Some of these features differences between Spanish and English can be partially accounted for because of language differences. Though Spanish word order is similar to English (Subject-Verb-Object), Spanish generally places words that are emphasized at the end of the sentence. This may result in more grammatical variation. Long noun groups (modifier-noun-qualifier) are commonly used in English text, but are troublesome in Spanish\(^5\). To express the same meaning, Spanish sentences use prepositions or other avenues instead that may partially account for longer sentences.

Although preliminary, some initial practical observations can be made. Many of the practices used already in English can be continued in Spanish, e.g. use repetition, avoid negations and use familiar words. However, not all practices can be directly followed. For example, it is common in English to shorten sentence (e.g. by splitting long sentences) when simplifying text. In Spanish, we find that longer sentences are easier. Relatedly, extra caution should be used when using readability metrics, since they often incorporate sentence length, with a bias towards shorter sentences.

Looking forward, we plan to incorporate our findings into a tool to assist writers. Directly, the features above can be measured before and after manual simplification to help the writer understand the changes they’ve made and how the changes correlate with these findings. Additionally, suggestions can be made such as identifying more familiar (i.e. higher frequency) synonyms.

Conclusion

We measured perceived and actual difficulty separately in our study and evaluated the effect of different linguistic features that are indicative of easy and difficult Spanish text. Difficult texts have more nouns and adjectives, while easy texts have more adverbs and longer sentences. A Spanish text perceived as less difficult has higher term familiarity. Features identifying difficult texts exhibit somewhat similar behavior for both Spanish and English texts.

Identification of Clinically Meaningful Plasma Transfusion Subgroups Using Unsupervised Random Forest Clustering

Abstract

Statistical techniques such as propensity score matching and instrumental variable are commonly employed to “simulate” randomization and adjust for measured confounders in comparative effectiveness research. Despite such adjustments, the results of these methods apply essentially to an “average” patient. However, as patients show significant heterogeneity in their responses to treatments, this average effect is of limited value. It does not account for individual level variabilities, which can deviate substantially from the population average. To address this critical problem, we present a framework that allows the discovery of clinically meaningful homogeneous subgroups with differential effects of plasma transfusion using unsupervised random forest clustering. Subgroup analysis using two blood transfusion datasets show that considerable variablilities exist between the subgroups and population in both the treatment effect of plasma transfusion on bleeding and mortality and risk factors for these outcomes. These results support the customization of blood transfusion therapy for the individual patient.

Keywords: Plasma transfusion, bleeding, unsupervised learning, subgroup analysis.

Introduction

Numerous studies and published guidelines encourage the appropriate use of fresh frozen plasma (FFP) and recommend specific circumstances for FFP transfusions. Although there is some variation about the definition of appropriate FFP transfusion, most guidelines suggest a cutoff in the international normalized ratio (INR) of 1.5 (i.e. Prothrombin time > 1.5 × normal).1 However, the documented compliance to these guidelines is poor.2–4 Data suggest that inappropriate FFP transfusion varies from institution to institution and ranges from about 10% to 83%.5 6 Moreover, FFP transfusion puts the patient at risk of a variety of outcomes. FFP transfusion is associated with high risk of transfusion-associated circulatory overload (TACO),7 transfusion-associated lung injury (TRALI),8 perioperative bleeding,8–10 multi-organ failure,7 infectious complications, and increase in health resource utilization. Therefore, strategies that can safely reduce the need for FFP transfusion bear high potential for improving patient outcomes. Recognizing that inappropriate plasma transfusions should be avoided, the literature is however not clear about the remaining percentage for which it might be beneficial. Currently, no study or best-practice guidelines exist regarding either patient subpopulation or specific characteristics of those patients who might benefit from FFP transfusion. Identifying the subgroup(s) with the most beneficial; wasteful; harmful, or futile prospect of FFP transfusion can provide an efficient means to improve patient outcomes, reduce unnecessary exposure to treatment adverse effects, and save resources.

Subgroup analysis is an important task in comparative effectiveness research where assessing the effect of a treatment on an outcome is of critical interest. Large observational health care databases provide potentially rich sources of information for data mining and machine learning methods to help research on heterogeneity in patient response to treatments and to guide care-givers’ decisions. Because of the large sample sizes, heterogeneous patient population, and real-world settings, they are suitable for studying either patient-specific or group-specific characteristics with respect to a clinical measure. However, comparative effectiveness research based on observational data is challenged by both selection bias and potential for unmeasured confounding. In usual care settings, many patient and physician factors influence whether a patient is selected for a treatment or not, thus any comparison between treatment groups is subject to bias. Through classical statistical methods such as propensity score matching and instrumental variables, it is possible to adjust for measured confounding and obtain unbiased estimates of treatment effects. These methods however suffer from several known weaknesses described below.

Traditionally, treatment effect is commonly estimated by a regression model where the outcome is regressed against patient covariates and the treatment. The effect is then read off as the corresponding regression coefficient of the treatment variable. However, as patients can show significant heterogeneity in response to a treatment, this “average” effect is not appropriate for describing individual level differential effects. Average superiority of one treatment
over another does not necessarily mean the treatment will remain superior for each patient. As a result of heterogeneity in patient characteristics such as genetics, phenotypic, pharmacokinetic, environmental, and socio-economic factors, clinical outcomes for some patients may deviate considerably from the population average. The important relationship between treatment effect and patient heterogeneity has been well investigated; however, comparative effectiveness researchers still rely on inefficient and non-robust classical regression and propensity score methods for estimation of treatment effects in observational studies.

In this study, we provide a three stage framework that allows the discovery of stable, robust and clinically meaningful homogeneous subgroups with differential effects of plasma transfusion on important patient outcomes. In the first step, our proposed framework makes use of the unsupervised random forest (URF) algorithm to derive a “proximity” or dissimilarity matrix between data points in a mixed-type (continuous and categorical) high dimensional covariate space. In the second step, we use the dissimilarity matrix in a hierarchical clustering algorithm to identify highly similar patient subgroups. Compared to classical parametrically derived propensity scores, the URF subgroup membership represents a more robust covariate balancing score. Thus, treatment effect estimates within subgroups of well-matched clinically homogeneous patients are then conditionally unbiased. In the final step, we applied the doubly robust targeted maximum likelihood estimation (TMLE) method to estimate the effect of FFP transfusion on bleeding and mortality in each subgroup. The TMLE further insures against any potential confounding that may still exist in the subgroups.

The framework was applied to two datasets from a single academic institutional blood transfusion datamart to discover subgroups of patients with differential responses to pre-operative or pre-procedural plasma transfusion (PPT) on two important patient outcomes: intra-operative or intra-procedural bleeding and mortality. Using only pre-operative or pre-procedural patient information, a cluster validation technique based on the predictive strength of cluster memberships and treatment assignment indicated that the first dataset consisting of patients undergoing non-cardiac surgery (NCS) can be clustered into six homogeneous subgroups while the second dataset consisting of patients undergoing interventional radiology (IR) procedures can be clustered into five subgroups. With respect to clustering the NCS data set, we found two clusters with harmful effect, two clusters with beneficial effect, and a cluster with no effect of PPT on bleeding. Three clusters showed no effect of PPT on mortality and two clusters showed harmful effects. Similar results were obtained for the IR data set. Compared to previous studies that have shown the population wide harmful effects of plasma transfusion, the findings in this study suggest the need to consider individualized and/or subgroup effects of plasma transfusion.

To further characterize phenotypes of patients within these subgroups, we applied a random forest feature contribution technique to determine which patient characteristics most strongly predict bleeding or mortality at both the population and individual levels. The feature contributions showed that considerable variabilities exist between population level risk factors and individual/subgroup level risk factors.

Method

Study Population

This is a retrospective observational cohort study conducted under the approval of the Mayo Clinic Institutional Review Board (Rochester, MN) before initiation. The protocol was reviewed and approved by institutional review board as a minimal risk study and informed consent was not required. Screening for potential study participants was performed using the perioperative datamart, an institutional resource that captures clinical and procedural data for all patients who are admitted to an acute care environment including procedural suites, operating rooms, ICUs, and progressive care units at the study’s participating institution. This robust data warehouse also contains information on baseline demographic and clinical characteristics, fluid and transfusion therapies, perioperative/periprocedural medications and laboratory values, postoperative/postprocedural outcomes, and lengths of stay. Two different cohorts of patients were extracted from the datamart: the first comprising patients undergoing non-cardiac surgery and the second made up of patients undergoing percutaneous invasive image-guided intervention (i.e., inpatient or outpatient procedures performed by the Division of Vascular and Interventional Radiology).

Non-Cardiac Surgery Data

The non-cardiac surgery data (NCS) was originally extracted to study the association between preoperative plasma transfusion and perioperative bleeding complications for patients with elevated INR. To be considered for study
participation, patients must meet the following criteria: age $\geq 18$ years, non-cardiac surgery and an INR $\geq 1.5$ in the 30 days preceding surgery. Between January 1, 2008 and December 31, 2011, a total of 1,233 patients were identified and comprised the study population. Plasma transfusion was offered to 139 patients. To expand the work in\(^9\) that was based on traditional propensity score and matching techniques, we used the same data set and kept the same exclusion and inclusion criterion.

**Baseline Variables.** Baseline patient demographics include age, height, weight, gender and the ASA physical status classification. Disease conditions included myocardial infarction, congestive heart failure, cerebrovascular disease, dementia, chronic pulmonary disease, diabetes mellitus, etc. Preoperative laboratory values included INR, hemoglobin, platelet counts, creatinine, albumin, and APTT (activated partial thromboplastin time). A total of 51 predictors were considered for inclusion in the analyses.

**Outcomes and Treatment.** Two main outcomes were considered: perioperative bleeding and mortality. Bleeding was taken as the World Health Organization (WHO) grade 3 bleeding events, defined as the need for early perioperative red blood cell (RBC) transfusion.\(^9\) Mortality was death during surgery or death within 30 days post-surgery (typically in the ICU). The treatment variable PPT indicates if a patient was offered plasma transfusion after INR test and 24 hours before surgery. As a guard against residual confounding, all RBC transfusions cases within this interval were dropped.

**Interventional Radiology Data**

The interventional radiology (IR) data set has been used in\(^{10}\) to study the association between prophylactic plasma transfusion and periprocedural RBC transfusion rates (or bleeding) in patients with elevated INR (INR $\geq 1.5$ ). Similar to the NCS study, the IR study was based on traditional propensity and matching methods and this study seeks to expand those results through application of advanced machine learning methods. As with the NCS study, the same inclusion and exclusion criteria were used. Between January 1, 2009 and December 31, a total of 1,902 patients met the inclusion criterion with 190 receiving plasma transfusion. Similar groups of baseline predictors as for the NCS data were used for the analysis.

To handle missing values in both data sets, we applied the random forest imputation method *missForest*\(^{20}\) implemented in the R statistical programming language to impute variables with less than 35% missing observations. Predictors with greater missingness were removed from the data.

**Unsupervised Random Forest**

The goal of clustering the blood transfusion data is to discover internal structure in the data by breaking it down into groups without any prior knowledge about the groupings. The idea is that once these groups are identified and proven robust, the clusters can aid in the determination of the effects of plasma transfusion. Not only are the clusters expected to balance the covariates (mitigate confounding) and account for patient heterogeneity, we also expect them to be clinically meaningful. A clustering technique known to be able to produce accurate and clinically meaningful clusters is the unsupervised random forest (URF) clustering.\(^{13;21}\) URF clustering has the additional attractive property that it can handle mixed type of variables. The NCS and IR data sets contain both continuous (e.g. age) and categorical (e.g. race) variables making the use of classical clustering methods such as hierarchical or k-means clustering based on Euclidean or binary type distance measures inappropriate. While many researchers in health sciences have mainly used the random forest\(^{13}\) method for supervised learning in the context of classification, regression, or feature selection, many are unaware of its utility in unsupervised learning.\(^{22}\)

*Random Forest (RF):* RF is an ensemble learning method where multiple decision trees are constructed on a bootstrap sample of the training data and the predictions combined by averaging or majority vote. The left-out cases of the bootstrap also called out-of-bag (OOB) sample and consisting of around 37% of the data, are not used for tree construction but are used to validate the performance of the tree. The splitting criterion in RF is based on selecting a random subset of predictors or *mtry* and the predictor yielding the best split within this set is chosen to perform the split. An important output of a RF analysis is the “proximity” matrix, a similarity matrix of size $n \times n$, where $n$ is the number of observations. This matrix constitutes the fraction of times in which two observations are placed in the same terminal node of a tree. The intuition is, if two observations end up in the same terminal node, then they are naturally similar and their proximity or similarity score is increased by one. This is done for all observations and trees in the forest and the proximities are normalized by dividing by the number of trees. Computation of the proximity matrix is not
required for classification or regression problems, but crucial for URF. The proximity matrix can be easily transformed into a dissimilarity matrix: if $s_{ij} \in [0,1]$ is the proximity of the $i$ and $j$ observations, then the distance between them is given by $d_{ij} = \sqrt{1 - s_{ij}}$. The dissimilarity matrix can then be used for unsupervised learning such as clustering and multidimensional scaling.

**URF Clustering:** URF clustering consists of two steps. In the first step, a RF classification model is generated to distinguish between the original data labeled as class 1 and a synthetic data of the same size as the original data and labeled as class 0. One way to generate the synthetic data is to take independent random samples from each dimension according to the empirical distribution of the corresponding dimension of the true data and a second approach is to simply permute each dimension. The supervised learning step attempts to distinguish the true data from a random version of the data, thus if there exists any underlying structure in the true data, the OOB error will be small, showing that the synthetic data destroyed that structure. An OOB error of about 50% indicates the original data is not very different from the synthetic data and possibly contains no informative structure. Thus the OOB error provides a natural data driven way to determine if interesting patterns exist in the data. In the second step, the proximity matrix between the true data points is extracted and passed to a clustering algorithm such as hierarchical clustering. For clustering the NCS and IR data, we use the permutation strategy to generate synthetic data and used the agglomerative hierarchical clustering method with the Ward’s minimum variance criterion to identify clinically relevant subgroups with differential effects of plasma transfusion.

**Cluster Validation:** Cluster validation is the process of evaluating the quality of a clustering result, and is vital to the success of clustering applications. The robustness or stability of the clustering as well as the optimal number of clusters can be determined using “internal” or “external” validation measures.23 Internal measures used only information available to the data without reference to any external information. As our goal is to generate homogeneous clusters with respect the treatment a patient receives and an outcome, we evaluated the homogeneity of the clustering using an external validation technique that make use of the treatment and outcome not used to generate the clusters. Our external measure is based on the assumption that similar patients receiving the same type of treatment are expected to experience the same outcome. Thus, clusters are validated by measuring the area under the ROC curve (AUC) for a logistic regression model that predicts the true outcome (Bleeding and Mortality) based on cluster memberships and treatment (PPT). For a stable clustering application, the more homogeneous the clusters, the higher the AUCs, which implies that the AUC increases with the number of clusters. We select the optimal number of clusters by plotting the AUC by the number of clusters and apply the “elbow criterion”. The elbow is the point on the graph where addition of a cluster does not lead to a significant gain in AUC and corresponds to the optimal number of clusters (see Figure 1 (a) and (b)). As the elbow method can be ambiguous, we also apply principle of parsimony when selecting the number of clusters.

**Random Forest Feature Contributions**

An important component of the RF algorithm is its capability to produce a variable ranking score or variable importance based on association of a given predictor with other predictors and with the outcome variable. This score can help in interpretation of the model or for dimension reduction. The variable importance is a population measure, and as an average score, it does not indicate the relative influence of each patients’ feature value in predicting the outcome. A variable might be an important risk factor for the overall population, but not a risk factor for a given individual or subgroup of patients. Recently, the RF variable importance measure has been extended to an importance score or feature contribution19 for each individual patient in the training set. The feature contributions characterize the relative contribution of a patient’s baseline variables towards predicting an outcome value or class. Another attractive property of the feature contribution method is that it can be predicted for new patients. This offers a way to further validate the random forest model: when the average feature contributions of the training and test set matches, then the model can generalize well. For classification problems, a zero value for feature contribution indicates that the variable is irrelevant with respect to assigning a patient to a given class. Positive values indicate that the variable is influential towards classifying the patient to a reference class.

**Treatment Effect of Plasma Transfusion**

The standard approach to investigate the causal relationship between a treatment or exposure and an outcome is to construct statistical regression models in which the outcome is regressed against baseline covariates and the treatment variable. The attributable effect of the treatment is then read off as the corresponding regression coefficient. This
study takes a different approach and estimates the treatment effect through application of machine learning methods. The theory of causal inference or technical details of the considered estimation procedure are beyond the scope of this study. The interested reader is referred to\textsuperscript{16,24,25} for more details. However, for the purposes of this study, a brief discussion of the data structure required to compute these estimators is presented next.

\textit{Data structure and likelihood.} The observations for each patient in the data set can be written as $O = (X, Y, Z)$ where $Z \in \{0, 1\}$ is the treatment indicator with $Z = 1$ if patient was treated and $Z = 0$ if patient was not treated. $X$ is a vector of baseline covariates that records information specific to each patient prior to treatment. $Y$ is the outcome such as bleeding or mortality. The relationship between the observed variables in $O$ can be written in a factorize data likelihood as

$$
Pr(X, Y, Z) = Pr(Z|X) Pr(Y|Z, X) Pr(X).
$$

Pr$(X)$ and Pr$(Y|X, Z)$ are referred to as the $Q$ component of the likelihood while Pr$(Z|X)$ is the $g$ component. $g(Z|X)$ represents the propensity or the causal disposition of the treatment to produce some outcome. Let $Q_0(Z, X) = E[Y|Z, X]$ be the true potential outcome conditional on the observed characteristics. Estimates of $g$ and $Q_0$ can be obtained by standard regression or machine learning methods.

For a binary outcome and in the presence of no confounding variables, the treatment effect can be easily computed by taking the expectations $\psi_1 = E[Y_{Z=1}]$ and $\psi_0 = E[Y_{Z=0}]$: where $E[Y_{Z=1}]$ is the mean of $Y$ assuming every patient in the population was exposed at level $Z = 1$. These two statistics can then be combined in useful ways to assess the effect of different levels of the treatment. Two commonly reported summary statistics include the Additive Treatment Effect : $ATE = \psi_1 - \psi_0$ and the Risk Ratio : $RR = \psi_1 / \psi_0$.

The $ATE$ quantifies the additive effect of every patient being exposed to the event versus not being exposed. Thus, a meaningful interpretation of $ATE = 0.05$ could read: “offering a patient plasma transfusion versus not increases the risk of bleeding/mortality by 5%”.\textsuperscript{16} The $RR$ quantifies the multiplicative effect of being exposed versus not. A $RR$ of 5 can be interpreted as: “offering a patient plasma transfusion versus not would lead to a 5 times increase in the risk of bleeding/mortality”.

\textit{Targeted maximum likelihood estimation.} In observational studies, estimators of treatment effect need to account for possible confounding, i.e situations where the (apparent) effect of the treatment is actually the effect of another characteristic that is associated with both the treatment and the outcome. Several methods have been proposed for the estimation of $ATE$ and $RR$ in a way that can mitigate the effects of confounding (and model misspecification), e.g. G-computation formula, propensity score matching, inverse probability of treatment weighting (IPTW), and doubly-robust estimation. See\textsuperscript{24,25} for more in-depth discussion of these estimators. In this study, the targeted maximum likelihood estimation (TMLE)\textsuperscript{16,17} method is considered because of its double robustness and bias reduction properties. TMLE is a two stage doubly robust semi-parametric estimation methodology designed to minimize the bias of the parameters of interest. The first stage of the method estimates the density of the data generating distribution (specifically $Q_0$) while the second stage solves an efficient influence curve estimating equation. The influence curve describes the behavior of the target parameter under slight changes of the initial density estimates.

In TMLE, if either $g$ or $Q_0$ are consistently estimated, then the TMLE estimator is guaranteed to be asymptotically unbiased. However, TMLE will not return consistent estimates of the parameter of interest when both $g$ and $Q_0$ are misspecified. Thus it is important to avoid overfitting these measures.

As discussed above, estimating the two statistics $\psi_1$ and $\psi_0$ allows for calculating any of the causal effects $ATE$ and $RR$. The TMLE estimate of $\psi_z (z \in \{0, 1\})$ is given by

$$
\hat{\psi}_z = \frac{1}{n} \sum_{i=1}^{n} \hat{Q}_0^*(z, x_i)
$$

where $\hat{Q}_0^*(z, x_i)$ is an update of $\hat{Q}_0(z, x_i)$. The targeting step for updating $\hat{Q}_0(z, x_i)$ is done by fluctuating $\hat{Q}_0(z, x_i)$ through a parametric sub-model of the form: $logit(\hat{Q}_0^*(z, x)) = logit(\hat{Q}_0(z, x)) + \varepsilon \hat{H}(z, x)$, where $\varepsilon$ is the fluctuation parameter, $\hat{H}(z, x) = I(Z = z)/(\hat{g}(z, x))$ is the efficient influence curve equations, and $I$ is the indicator function. The MLE of $\varepsilon$ is obtained by a logistic regression of $Y$ on $\hat{H}(z, x)$ with offset logit$(\hat{Q}_0(z, x))$. Confidence intervals and p-value for TMLE can be obtained through the variance of the influence curve.
TMLE can use initial estimates of $Q_0$ and $g$ from any fixed parametric model such as generalized linear models (GLM) (e.g., logistic regression). However, most parametric models require a functional form for the predictors, and some assume distributions for the outcome and predictors variables, which are often not realistic such that model misspecification is difficult to avoid. It is therefore recommended to use machine learning methods that make little or no assumptions and are able to estimate complex relationships between the outcome and observed variables.

Results

This section presents the main results: estimates of treatment effect of PPT on bleeding and mortality for the complete data and for each subgroup. For the calculations of ATE and RR, we estimate $Q_0$ and $g$ using five models: generalized boosting machine (GBM), random forest, support vector machine (SVM), logistic regression, and extreme logistic regression (ELR) and select the best model through 5-fold cross-validation. First, we present the cluster validation analysis, then the treatment effect analysis, and end the section with analysis of the population or median feature contributions over all patients in the cohort and the individual feature contributions for two random patients.

Cluster validation and selection of optimal number of clusters

A robust and stable clustering procedure generates homogeneous clusters such that patients within clusters are similar with respect to baseline characteristics. This implies the procedure has identified hidden structure in the data. A way to determine if the URF method identified underlying structure in the NCS and IR datasets is to look at the OOB error rates. Specifically, the OOB error rate for the NCS and IR data clustering problems were 11.95% and 1.20% respectively, indicating that the synthetic data destroyed existing structure in the data and the RF model was able to capture this information with high accuracy.

Ward’s Minimum Variance: URF can identify structure in the data, but obtaining good clusters crucially depends on the clustering algorithm. We employ the agglomerative hierarchical clustering algorithm with the Ward’s minimum variance criterion. Figure 1 (c) and (d) shows the dendrogram of the algorithm for the NCS and IR data sets respectively. The dendrogram represents the similarity relationships between patients in a tree-like form. Agglomerative hierarchical clustering starts by assuming that each patient is a cluster, and successively merges similar clusters to form larger clusters. Because of the hierarchical structure, different number of clusters can be obtained by cutting the tree at different heights. We used the Ward’s method, which minimizes the sums of squares between clusters to merge similar clusters together. However, we also tried other merging algorithms such as the single, complete, and average linkage methods, but all produced unstable and sparse clusters. In contrast, the Ward’s method produced stable and equal sized clusters.

Predictive Ability of Cluster Memberships: The clustering partitioned the data space into non-overlapping regions, where each region is associated to a given level of the treatment and outcome. In other words, if the regions are sufficiently homogeneous, then similar outcomes are expected for patients if offered the same treatment. As a consequence, a classification model can efficiently discriminate between the classes based on treatment status and subgroup allocations, and the discriminative power increases the more homogeneous the groups become.

Figure 1 (a) and (b) shows AUCs (averaged over 5-fold cross-validation) of a logistic regression model predicting bleeding (red curve) and mortality (blue curve) based on cluster memberships and plasma transfusion plotted against the number of clusters. Clearly, the cluster memberships are predictive as can be seen by the rise in AUC as the number of clusters increases (solid lines) compared to the poor and unstable performance of a randomly generated clusters (dotted lines). There is a big jump in performance from 2, 3 and 4 clusters to 5 or 6 clusters. After the 5'th or 6'th cluster, the relative increase in AUC reduces and becomes somewhat stable. We choose the number of clusters as that corresponding to the elbow or turning point of the curve. At the elbow, adding another cluster to the logistic regression model does not lead to any appreciable performance gain. Thus, 6 clusters are optimal for the NCS data and 5 for IR. Close observation of the curves will indicate that 7 or 8 clusters can equally be selected. However, these higher cluster numbers produced very sparse distributions of the observed treatment and outcome events in some of the clusters. In our implementation, we set the minimum number of events observed in each cluster to 10.

Effect of Plasma Transfusion on Bleeding and Mortality

Population Effect: Table 1 presents the ATE and RR quantifying the population effect of PPT on bleeding and mortality for the NCS and IR datasets. The GBM algorithm performed best for the NCS data, while the ELR offered the best
performance for the IR data. To save on space, discussions will be restricted to the ATE summary statistics; interpretations for RR can be similarly made. Overall, the estimates from TMLE confirmed previous findings that population wise, PPT increases the risk of bleeding. Specifically, for the population of NCS and IR patients considered in this study, PPT significantly increases the risk of bleeding by 14% (p-value = 0.00) and 12% (p-value = 0.00) respectively (95% confidence intervals are shown in brackets). With respect to mortality, PPT marginally increases risk by 4% for NCS and has no effect for IR populations.

Subgroup Effect: Table 2 presents estimates of ATE and RR within each cluster identified for the NCS and IR data sets. With respect to the NCS clusters, we found: (a) One cluster with 551 patients where PPT increases the risk of bleeding and mortality by 32% and 6% (p-value = 0.00 and 0.05) respectively. (b) One cluster where PPT has no effect on bleeding and mortality. This cluster may represent patients where the administration of prophylactic plasma
transfusion is wasteful. (c) Two clusters of sizes 150 and 127, where PPT reduces the risk of bleeding by 9% in each
cluster. Correspondingly, PPT increases the risk of mortality in one cluster and has no effect in the second. (d) The
last cluster with 171 patients show harmful effect of PPT on bleeding and no effect on mortality.

Overall, the effect PPT on bleeding for the NCS data was beneficial in two subgroups and none showed any beneficial
effect with respect to mortality. It is therefore interesting to investigate the characteristics of patients in these sub-
groups. This information can help reduce the inappropriate use of plasma products as only the patients who will truly
benefit from plasma transfusion are considered for treatment.

For the IR data clustering, we found roughly similar results. One group with 187 patients having beneficial effect
of PPT on bleeding (11%. p-value=0.00). The IR data set however contains two subgroups with beneficial effect
of PPT on mortality. The NCS and IR clustering problems contain subgroups (n = 75 and 451 respectively) where
the observed number of patients with bleeding/mortality and PPT events was less than 10, and no treatment effect
estimates were computed for these groups.

Feature Contributions

We report only the results for the NCS complete data. Result for the IR data and all subgroups can be obtained by
contacting the authors. Figures 2 (a) and (b) shows the median feature contributions for all patients averaged over
five-fold cross-validation and the corresponding feature contributions for two random patients. The two patients (P1
and P2) were both offered plasma transfusion but experience different levels of the bleeding/mortality outcome: P1
bled/died and P2 did not bleed/die. Preoperative hemoglobin levels and PLT test value (platelet count) are the two
most contributing variables towards predicting bleeding and mortality. Though appearing in different order, the same
9 variables appear among the top 10 most predictive variables for all patients in the two models. Considering the
median feature contribution, these top 9 variables are somewhat equally contributive towards predicting whether a
patient will bleed or not. However, these variables contribute more towards predicting the death status of a patient
compared to predicting alive status.

The plots clearly show that significant variabilities exist between population level (median) feature contributions and
the individual level. For example, while plasma transfusion is a strong contributing factor towards predicting bleeding
for the random patients, the effect of the variable is almost zero when we consider the population level. Similarly, while
the population level contributing factor of connective tissue disease is almost zero, it however contributes significantly
towards predicting the death status of the random patient P1.
Conclusion

The most common reason cited for plasma transfusion is the correction of an elevated pre-operation/pre-procedural international normalized ratio (INR) for the prevention of bleeding complications, despite lack of evidence to support such practices. The decision to offer plasma transfusion to patients with abnormal coagulation factors still remains largely controversial. Current recommendations are mostly based on expert opinion and a precautionary approach to correct abnormal laboratory test results and there is widespread variation in the practice with respect to plasma transfusion. Many studies, including randomized control trials, have shown no significant benefit for prophylactic and therapeutic use of fresh frozen plasma (FFP) across a range of indications. Moreover, majority of these studies report the inappropriateness and harmful effect of prophylactic plasma transfusion. However, almost all the studies have evaluated the effect of plasma transfusion at the population level. Despite accounting for parameters such as treatment selection bias and potential confounding in observational studies, those results apply essentially to the average patient. Given that the critically ill patient population can be highly heterogeneous in their responses to treatments, the average effect of a treatment is of limited value, as it ignores individual patient level variabilities of the treatment, which often deviate substantially from the population average. Furthermore, except for the work in, most of the published work on the effect of plasma transfusion have traditionally used classical regression, propensity score, and matching methods, which often make unrealistic and difficult to satisfy assumptions about the patient population.

This study takes a different approach and applied subgroup analysis based on efficient and robust machine learning methods and identified several homogeneous subgroups exhibiting differential effects of plasma transfusion on bleeding and mortality. Specifically, using the unsupervised random forest (URF) clustering method and the doubly robust targeted maximum likelihood estimation (TMLE) method, we identified stabled and clinically meaningful subgroups with beneficial, harmful, and no effect of plasma transfusion on bleeding and mortality. Recognizing the widespread inappropriate use of FFP and the lack of evidence to support the use of plasma transfusion to prevent bleeding, the results from this study suggest that researchers should reconsider evaluation measures based on the overall population, and strongly support the fact that blood transfusion therapy should be customized for the individual patient. Further, analysis of the subgroup characteristics can help shed light on the much needed evidence to support the use of plasma transfusion to correct prolonged prothrombin time and prevention of bleeding complications.

Abstract

In order to better understand the potential value of genetics-informed drug dose guidance to obstetric healthcare providers at Johns Hopkins we administered a web-based needs assessment survey. The survey included questions about: 1) experience with adjusting drug doses during pregnancy; 2) comfort prescribing medications to pregnant women with chronic conditions; 3) awareness and use of genetics-informed dosing guidance; and 4) perceived value of access to services to provide genetics-informed dosing guidance. Among thirty-one respondents, 81% indicated an interest in access to genetics-informed drug dose guidance, particularly a mobile or electronic health record (EHR) application. It was indicated, however, that genetics is one of many characteristics that influence dose adjustments during pregnancy. This study motivates future research to help obstetric healthcare providers tailor drug dose to individual patients based upon models integrating multiple patient characteristics, including genetics.

Introduction

While obstetric healthcare providers counsel pregnant women to limit medication use during pregnancy unless clinical necessity warrants, prescription drug use during pregnancy is on the rise. Mitchell et al 1 conducted a 33-year study finding that nearly half of women between 1997 and 2003 used prescription medications and less than 5% took four or more. Use increased from 2003 to 70% of pregnant women using any medication, and the use of four or more medications rose to over 15%. Women today are delaying pregnancy 2 resulting in older women with higher rates of obesity and chronic medical conditions becoming pregnant. This increase in chronic medical conditions often requiring medications has highlighted the need for more research on medication use and safety in pregnancy 3.

Despite these challenges, there is a growing body of pharmacogenomics data on medications in general that can be used to find the most effective and safe doses for pregnant women. In addition, the Food and Drug Administration (FDA) has included pharmacogenomics information in the labeling of several medications that are commonly prescribed in pregnant women 4. Thus, the development of clinical dosing models that bring together clinical characteristics, physiologic parameters in pregnancy, and pharmacogenomics measures has been proposed as a way forward to eventually guide obstetric healthcare providers to individualize drug therapy in pregnant patients 5,6.

The first stage of designing a new software product is to specify the needs for a setting and the intended users of that product 7. One common way to complete this evaluation and to establish design requirements is to use a needs assessment survey. Given our interests in understanding the needs of obstetric health care providers, we conducted a needs assessment survey. The primary goal for this survey was to understand the value of genetics-informed dosing guidance to obstetric healthcare providers.

Methods

Recruitment

An initial recruitment email containing a link to a web-based survey was sent to approximately 80 obstetric healthcare providers associated with the Johns Hopkins Hospital (JHH). Two follow-up emails were sent to the distribution list in subsequent weeks. Survey responses were collected anonymously, and participants who agreed to be contacted about future research were entered into a contest to win $100 USD.

Survey development

Four co-authors developed a twenty-four-item survey instrument with the primary goal of understanding the potential value of genetics-informed drug dose guidance to obstetric healthcare providers (CO, HL, CC, JS). The survey included questions about: experiences with adjusting drug doses in pregnant women (five multiple choice, and one free response question, e.g., “How often do you have to seek consultation to confirm drug doses in pregnant women?”);
comfort in prescribing nine antiretroviral, four antihypertensive, and fourteen antidepressant drugs to pregnant women (Likert scale questions e.g., “How comfortable are you in treating pregnant women with the following antihypertensive medications?”); awareness and use of genetics-informed dosing guidance (five Likert scale and one free response questions, e.g., “Do you know of and use any resources for clinical guidance on genetics-informed dose use in pregnancy?”); perceived value of tools and consult services to provide genetics-informed drug dosing guidance for pregnant women (two multiple choice questions, e.g., “Would it be valuable to have access to a tool that considers genetics in drug dose use in pregnancy?”); and demographic information such as gender, years practicing, and clinical caregiver status (six questions) (see Appendix 1). For questions about comfort with prescribing, one co-author (CO) selected an initial list of medications used to treat HIV, hypertension, and depression for which drug exposure is known to be influenced by genetics according to PharmGKB8. Another co-author with expertise in obstetrics (JS), then narrowed down that list of medications to those prescribed in pregnant women.

Data analysis
Survey data was collected using Qualtrics (Qualtrics, Provo, UT) and analyzed using Stata (StataCorp, 2013. Stata Statistical Software: Release 13. College Station, TX: StataCorp LP). We estimated the proportion of respondents indicating that genetics-informed drug dose guidance was of high importance by gender, experience, specialty, and years since completing training. We then evaluated factors that may influence the perceived value of accessing guidance including experiences with adjusting drug dose in pregnant women, comfort with adjusting drug doses in pregnant women taking antiretroviral, antihypertensive and antidepressant medications, the perceived importance of genetics-informed dosing guidance in prescribing those medications, and awareness and access to existing guidance for genetics-informed drug dosing. Furthermore, we identified which modalities obstetric healthcare providers would like to use when seeking guidance in prescribing. Only descriptive statistics are reported given that our population is relatively small (obstetric healthcare providers from one institution).

Results
Data collection initiated on October 11, 2016 and concluded on December 23, 2016. Thirty-one out of 80 obstetric healthcare providers completed the survey for a response rate was 39%. The results of this survey are accurate at the 90% confidence level plus or minus 12%. All survey respondents were employed by Johns Hopkins University, Johns Hopkins Hospital, and/or Johns Hopkins Community Physicians. In response to questions about the value of accessing genetics-informed dosing guidance, with one exception, 50% or more of the respondents indicated that they would value access to genetics-informed drug dose guidance across all demographic categories (for more details see “Value of Genetics-Informed Dosing Guidance for Obstetric Healthcare Providers”). The one exception was that one male respondent indicated that it a consult service would be valuable. Table 1 summarizes the demographic data of our study sample.

Experiences with Adjusting Drug Dose in Pregnant Populations

Survey respondents indicated several patient characteristics that they have considered when making dose adjustments: twenty-six (81%) indicated that they use body weight, ten (31%) use height, fifteen (47%) use body surface area, twenty-seven (84%) use organ system function, five (16%) use genetics, and five (16%) indicated use of other characteristics. Among the twenty-seven respondents indicating that they use organ system function to adjust drug dose, free-text descriptions of specific organs included: kidney, liver, GI, respiratory (e.g., h/o asthma), blood volume, and brain/cognitive function. For the five respondents indicating that they have used other patient characteristics, free-text descriptions included: patient history, blood levels for some medications (e.g., anti-epileptics), medical co-morbidities and other medication use.

Dose adjustments are relatively common in pregnant women with nine (30%) of survey respondents indicating that dose adjustments occurred greater than or equal to 50% of the time when including changes due to pregnancy progression. When excluding dose changes due to pregnancy progression, only two (7%) indicated that that dose adjustments occurred greater than or equal to 50%. In instances where drug dose adjustments do occur, it is uncommon for drug doses to be modified beyond normal ranges, with twenty-three (74%) of respondents indicating that they modified drug dose beyond normal ranges less than 10% of the time (45%, or fourteen, indicated that they did so less than 1% of the time). However, in the instances where drug dose changes are made, seeking outside consultation is modest, with twenty-six (84%) of respondents indicating that they sought consultation less than 25% of the time (10%, or three, indicated that they never seek consultation).

Comfort in Prescribing Medications and Opinions about Using Genetics when Prescribing Medications

Obstetric healthcare providers were asked about their comfort in prescribing medications used to treat HIV, hypertension, and depression in pregnant women for which drug exposure is known to be influenced by genetics. For those who prescribe those medications, comfort in prescribing was split with more respondents indicating high comfort levels across all three categories of medications.

For nine antiretroviral medications, 35-45% do not prescribe, 26-29% are very uncomfortable or uncomfortable prescribing, and 26-39% are very comfortable, comfortable, or neither comfortable or uncomfortable with prescribing those medications (See Figure 1). The majority of survey respondents (58%, eighteen) also indicated a belief that genetics-informed dose adjustments was important or very important to achieve good outcomes when treating pregnant women with HIV. Thirteen (42%) respondents indicated that genetics-informed dose adjustments were moderately important, slightly important or not at all important.

Figure 1. Comfort in Prescribing Antiretroviral Drugs
For four antihypertensive medications, survey respondents indicated that 3-23% do not prescribe, 6-16% are very uncomfortable or uncomfortable prescribing, and 68-90% are very comfortable, comfortable, or neither comfortable or uncomfortable with prescribing those medications (See Figure 2). Slightly fewer than half of survey respondents (48%, fifteen) indicated a belief that genetics-informed dose adjustments was important or very important to achieve good outcomes when treating pregnant women with hypertension. Sixteen (52%) respondents indicated that genetics-informed dose adjustments were moderately important, slightly important or not at all important.

Figure 2. Comfort in Prescribing Antihypertensive Drugs

For fourteen antidepressant medications, among obstetric healthcare provider survey respondents 10-41% do not prescribe, 6-30% are very uncomfortable or uncomfortable prescribing, and 31-84% are very comfortable, comfortable, or neither comfortable or uncomfortable with prescribing those medications (See Figure 3). Slightly fewer than half of survey respondents (48%, fifteen) indicated a belief that genetics-informed dose adjustments was important or very important to achieve good outcomes when treating pregnant women with depression. Sixteen (52%) respondents indicated that genetics-informed dose adjustments were moderately important, slightly important or not at all important.

Figure 3. Comfort in Prescribing Antidepressant Drugs
**Awareness of and Access to Genetics-Informed Dosing Guidance**

Few survey respondents, ten (37%), were aware of any existing resources for clinical guidance on genetics-informed drug dosing. Of those indicating an awareness of any existing resources, only four indicated that they had used any. One respondent indicated as a free-text response that they had used FDA resources. For the six respondents indicating that they were aware of resources for guidance on genetics-informed dosing guidance, but that they had not used any, the following resources were listed as free-text responses: Micromedex®, REPROTOX®, UpToDate®, OMIM®, and PubMed. One respondent indicated that a patient’s lab report can contain guidance. Another respondent indicated that genetics-informed dosing guidance can be provided by genetic counselors.

Among ten respondents indicating an awareness of resources for genetics-informed dosing guidance, seven indicated a belief that guidance on genetics-informed drug dose use in pregnancy was moderately or slightly convenient to obtain. Three indicated that such guidance was not at all convenient. One respondent indicated resources for genetics-informed guidance in pregnancy are very useful, seven indicated that the resources are moderately or slightly useful, and two indicated that the resources are not at all useful.

**Value of Genetics-Informed Dosing Guidance for Obstetric Healthcare Providers**

In response to questions about access to genetics-informed dosing guidance, twenty-five (81%) indicated that they would like to have access to an app when seeking such guidance, four (13%) indicated that they may like to have access to an app, and two (6%) indicated that they would not like to have access to an app. Among twenty-five respondents indicating that they would like to have access to an app, they also indicated preferred modalities (they were able to select more than one): nine (36%) as an app that can be installed on a computer, seventeen (68%) as an app that is embedded in the EHR, and sixteen (64%) as a mobile app that can be installed on a tablet or cell phone.

Approximately one-half (48%-58%) of respondents perceived genetics-informed dose guidance to be important to achieve good outcomes when treating pregnant women with depression, hypertension or HIV (see Table 2). Regardless of the perceived importance, with one exception, 50% or more of the respondents indicated an interest in having access to genetics-informed drug dose guidance as an app or as a consult service. The one exception was that 44% healthcare providers perceiving genetics-informed drug dose guidance to be of low importance for anti-hypertensive medications indicated that it a consult service would be valuable (see Table 2).

The interest in having access to an app was higher among respondents indicating that genetics-informed dosing guidance was of high importance (important or very important) compared those indicating a low importance (moderate importance to not at all important, see Table 2 and Figure 4). When asked about interest in being able to access a consult service when seeking genetics-informed dosing guidance for pregnant women, sixteen (52%) indicated that they would like to have access and thirteen (42%) may like to have access. One respondent indicated that (s)he would not like to have access, and another indicated that (s)he already has access to a consult service. The interest in having access to a consult service is similar to or slightly higher than among respondents indicating that genetics-informed dosing guidance was of high importance compared to those indicating a low importance (see Table 2 and Figure 5).

Discussion and Conclusion

This study obtained feedback from a sample of thirty-one Johns Hopkins obstetric healthcare providers. We found that dose adjustments are relatively common in pregnant women, and they are made using a combination of factors. Most obstetric healthcare providers use body weight and organ system function. Height and body surface area are used less often, and genetic data is rarely used. Also, obstetric healthcare providers who report making dose adjustments, infrequently report using outside consultation. We believe that as more evidence to support the use of genetics becomes available and readily accessible as clinical decision support, physician education will improve and genetic information use will increase.

When asked about comfort in prescribing medications for which drug exposure is known to be influenced by genetics, obstetric healthcare providers indicated that they do not prescribe many of the medications we asked about. For those indicating that they do use the medications, around half were uncomfortable with prescribing antiretroviral medications. The majority of those indicating that they used the antidepressants and antihypertensive medications were comfortable with prescribing them. However, over a quarter of respondents were uncomfortable with prescribing many antidepressant medications. While the first and second line therapies are widely used, and may be working well at the time a patient becomes pregnant, dosing adjustments may still be needed. Furthermore, even those physicians that are comfortable with individual drugs, may need assistance with prescribing specific drug combinations. Genetics-informed dose adjustments may help guide dose adjustments for individual drugs and combination regimens.
When asked about clinical guidance on genetics-informed dosing, few respondents indicated that they were aware of or had ever used any. Most would, however, indicated an interest in having access to genetics-informed dosing information as an app embedded in an EHR and as an app that can be installed on a tablet or cell phone. In addition, around half of respondents indicated an interest in having access to a consultation service for guidance on genetics-informed dosing.

Findings from this study on genetics-informed drug dose guidance are concordant with other studies in identifying a need for more clinical guidance on using pharmacogenomics data\(^{4,16}\). One study indicated that healthcare providers had a preference for a pharmacogenomics educational resource to be electronic and to include information on how to interpret pharmacogenomic test results, recommendations for prescribing, population subgroups most likely to be affected, and contact information for laboratories offering pharmacogenomic testing\(^{16}\). Similarly, obstetric healthcare providers also had a preference for guidance to be made available electronically. Though it is not yet standard of practice, several institutions have established programs to perform prospective pharmacogenomics testing and also provide the results of those tests in the medication treatment context with clinical decision support\(^{17,22}\). The current study provides insights into the clinical decision support needs of obstetric healthcare providers that use pharmacogenomics testing.

Our finding that dose adjustments are relatively common and most often occur due to pregnancy progression, suggests that pharmacogenomics should be considered secondarily to other more common characteristics that also influence drug exposure in pregnant patients (e.g., physiological changes). However, there may be some uncertainty to what will be the added value of presenting pharmacogenomics in the context of other characteristics given that this rarely occurs today. While there remains a lack of research on pharmacogenetics changes during pregnancy\(^{23}\), pharmacogenomic testing developed in other populations can potentially help guide its use in pregnant women. There are already a few clinical decision support tools to consider patient genetics that are targeted to obstetrics healthcare providers\(^{24}\). None of these tools to these authors knowledge, however, provide drug dosing guidance based upon models that consider pharmacogenomics. Thus, there is a particular need for dosing models that integrate multiple patient characteristics in this special population.

A large number of pregnant women who take medications could potentially benefit from improved drug dosing guidance. One study conducted in 2004 indicated that 49.9% of their sample of 152,531 pregnant women used medications from Food and Drug Administration (FDA) categories C, D, or X at some point during their pregnancy\(^{25}\). Categories C, D, and X were previously used to denote potential or unknown risks to a human fetus. Another study examining the use of medications during pregnancy in a sample of 578 women found that 59.7% used prescription medications, 92.6% used at least one over-the-counter medication, and 45.2% used at least one herbal medication\(^{4}\). Further indicating a need for improved guidance, in 2014 the letter-based category system was retired in favor of the Pregnancy and Lactation Labeling (PLL) Rule\(^ {26,27}\). The PLL rule summarizes risks and provides information about testing, contraception, and infertility to be used by the health care providers. The new labels, however, do not provide the detailed information needed to make prescribing decisions, which “will require focused efforts on the part of multiple stakeholders.”

The safety of medications is an even greater concern for pregnant women given the potential risks that some medications pose to the fetus. Research by Adam et al\(^ {28}\) found that, of 172 drugs tested for teratogenicity (harmfulness for a fetus), 168 (97.7%) could not be definitively determined to pose a risk for the fetus, and 126 (73.3%) of those drugs did not even have enough data to begin assessment. While outside of the scope of our survey focusing on maternal pharmacogenomics, prenatal pharmacogenomics studies are on the rise. As the influence of pharmacogenomics on fetal exposure to medications is better understood, that data could also begin to be made available to obstetric healthcare providers for use to manage their patients\(^ {29}\).

We found that obstetric healthcare providers at Johns Hopkins would find access to genetics-informed dosing guidance to be valuable. This work thus motivates future work to develop electronically accessible software to offer drug dosing guidance targeted to obstetric healthcare providers (or designated parties that provide consultation) based upon a range of patient characteristics, including genetics. The work of others has also indicated that pharmacogenomics data alone is not always sufficient to change test ordering and prescriber decisions\(^ {30,31}\), further supporting this need to consider multiple patient characteristics.

Despite the perceived value of access to genetics-informed dosing guidance, there is also the potential for confidence in prescribing decisions to be impacted. Previous research of one co-author, for example, found that physicians indicated a lowered confidence in prescribing decisions with access to pharmacogenomics clinical decision support\(^ {22}\). This finding was also reflected in the proportion of physicians who changed doses toward doses supported by
published evidence. Thus, another area for future research will be to monitor prescribing patterns to see what is the impact of providing access to genetics-informed dosing guidance. Findings from self-reports of comfort prescribing in this work have potential to provide some insight into prescribing pattern observations. However, we believe that ultimately new approaches to enable assessing the clinical utility of having a more complete patient picture in drug dosing decisions are needed. Indeed, there are circumstances where pharmacogenomics differences become more critical for prescribing decisions (when pregnancy significantly changes pharmacokinetics), and other circumstances where factors having nothing to do with the pharmacogenomics of these drugs influence those decisions (e.g., weight gain as a drug side effect).

Furthermore, like many needs assessment studies, the generalizability of findings is limited to the group studied. Our goal, however, was to understand the value of genetics-informed dosing guidance to obstetric healthcare providers at Hopkins so that in follow-up work we can design clinical decision support with potential to support obstetric healthcare practices more broadly. There are some parallels from our previous work investigating opinions of junior physicians (cardiology and oncology fellows)\(^2\). Work here, however, includes physicians with a range of experience (obstetrics residents and attending physicians). Differences in responses and prescribing patterns between the residents and the attending physicians in the obstetrics clinical domain will be another interesting area to explore.

2 Farr Institute of Health Informatics Research, University College London, London, UK

Abstract

Electronic Health Records are electronic data generated during or as a byproduct of routine patient care. Structured, semi-structured and unstructured EHR offer researchers unprecedented phenotypic breadth and depth and have the potential to accelerate the development of precision medicine approaches at scale. A main EHR use-case is defining phenotyping algorithms that identify disease status, onset and severity. Phenotyping algorithms utilize diagnoses, prescriptions, laboratory tests, symptoms and other elements in order to identify patients with or without a specific trait. No common standardized, structured, computable format exists for storing phenotyping algorithms. The majority of algorithms are stored as human-readable descriptive text documents making their translation to code challenging due to their inherent complexity and hinders their sharing and re-use across the community. In this paper, we evaluate the two key Semantic Web Technologies, the Web Ontology Language and the Resource Description Framework, for enabling computable representations of EHR-driven phenotyping algorithms.

Introduction

Electronic Health Records (EHR) are structured, semi-structured and unstructured data that are generated during routine interactions of patients with primary care, hospital care and tertiary healthcare or as a byproduct of those interactions for billing or administrative purposes1. Structured EHR are recorded using controlled clinical terminologies while unstructured data include clinical text and narrative. Semi-structured EHR data often loosely follow a data specification (e.g. prescription events, medical imaging reports) but this varies greatly across information systems, clinical specialties and healthcare providers. High-throughput genotyping and increased availability of EHR data are giving scientists the unprecedented opportunity to exploit routinely generated clinical data to advance precision medicine at scale. EHR data can fundamentally alter the manner in which genetic association studies are performed and enable scientists to examine the association of genetic variants and traits in larger sample sizes and phenotypic breadth2.

A primary use-case of EHR data is the creation of phenotyping (or “case finding”) algorithms3, computational algorithms that identify patients that have (or have not) been diagnosed with a particular condition4 (e.g. acute myocardial infarction, prostate cancer, or anxiety etc.) and where applicable the disease onset and severity. Phenotyping algorithms tend to use clinical information such as diagnoses, laboratory tests, symptoms, clinical examination findings, prescriptions, referrals and other EHR data elements. While the term phenotype is traditionally defined as the physical manifestation of a particular trait, in the context of EHR research, phenotypes are broadly (but not exclusively) as the presence or absence of a particular clinical condition. In EHR resources linked with genetic data, such as the Electronic Medical Records and Genomics (eMERGE) consortium5, these phenotypes can enable large-scale genomic association studies which have been traditionally limited to a small set of traits. Phenotyping however is a challenging and time-consuming process since often data been collected for care, auditing or administrative purposes and not for research. The contents of EHR data sources are an indirect representation of the true patient state as skewed by the underlying healthcare process e.g. clinical guidelines, information systems, data standards6.

Defining and validating EHR phenotyping algorithms is challenging and time-consuming. Challenges are amplified by the lack of a common definition standard for algorithms, making their sharing across the scientific community problematic. Despite the fact that phenotype components are structured and often annotated by controlled clinical terminology terms, phenotype definitions, and their underlying logic are usually expressed as free-text which is not readily machine-readable. The translation from this narrative to programming code used to identify and extract patients (e.g. implementing a phenotyping algorithm using Structured Query Language for use in a relational database management system) can be problematic due to potential ambiguities in the manner in which the algorithm was expressed or potential ways of implementing it using local data. There is a clear and urgent need to develop and
evaluate a computable, standards-driven format to facilitate the systematic creation, sharing and re-use of EHR-derived phenotyping algorithms.

**Semantic Web Technologies (SWT)**

Semantic Web Technologies are a collection of World Wide Web Consortium (W3C) standards (https://www.w3.org) for annotating and sharing data using Web protocols and can potentially address some of these challenges and be utilized to define computable EHR-derived phenotypes. A key advantage of SWT is that they were specifically built to facilitate the automated integration and reuse of data in a machine-readable manner while in parallel enabling standard Web-driven user interaction in human-friendly formats. The Ontology Web Language (OWL) (https://www.w3.org/OWL/) is a specification of an ontology language based on a description logic. An ontology in OWL is mostly modeled as an RDF (Resource Description Framework) graph (https://www.w3.org/RDF/), a specification to describe data/resources in form of *triples* `<subject-predicate-object>`, where subject and predicate are resources and object is also a resource or a literal (value). Resources, uniquely identified by Internationalized Resource Identifiers (IRIs) which in turn are a generalization of Uniform Resource Identifiers (URIs), represent nodes (subjects and objects) and edges (relationships) of the graph structure and leaf nodes are created by literals (values) as for example in Figure 3.

The RDF Schema (RDFS) provides a set of basic predefined semantics (i.e. resources) for RDF graphs including data types and elements for the construction of classes and subclasses. OWL provides extended semantic expressions and constructs such as set operations, class disjoints, class equivalencies, and cardinality constraints. Semantic expressiveness (and thus a set of OWL constructs) is supplied by the OWL dialect and profile and influence the behavior of the *semantic reasoners*, engines able to automatically infer consequences and associations within the ontology which are not explicitly specified. The querying of RDF is enabled by the SPARQL Protocol and RDF Query Language (SPARQL) semantic language. SPARQL (https://www.w3.org/TR/rdf-sparql-query/) has a similar structure to Structured Query Language (SQL) which is widely used in relational database systems and enables queries for data stored as RDF through query processing engines called SPARQL end-points.

The use of SWT has been previously evaluated in the field of EHR phenotyping. The work by Pathak and colleagues was focused on the transformation of EHR data from multiple heterogeneous sources into RDF graphs. The created RDF graphs which were then queried via a single SPARQL end-point in order to assess research cohort. The research outlined in this paper is complementary to their work in that it is focused on the explicit description of the phenotype algorithm itself. EHRs are included into the process in the second step and outcome cohorts (or their parts) are inferred automatically by semantic reasoners. Compared to previous work, our approach describes how a phenotype algorithm and its logic can be defined by OWL constructs and queries can be implemented in SPARQL.

In this paper, we implement an OWL/RDF ontology-based approach for storing a deterministic EHR-derived diabetes phenotyping algorithm. We validate our approach against a pre-defined list of desiderata developed previously. We used diabetes as a case study since it exemplifies many of the associated challenges but our findings are generalizable to other diseases and syndromes.

**Methods**

**CALIBER**

We used a deterministic EHR phenotyping algorithm for diabetes developed and validated in the CALIBER resource. CALIBER is a translational research platform which links national, structured primary care, hospital care, disease registry, mortality data and socioeconomic information in the UK for ~10m patients. Primary care data are provided by the Clinical Practice Research Datalink, an anonymized national cohort of longitudinal data for all individuals registered with a general practitioner. Secondary care data are recorded in Hospital Episode Statistics (HES), a national database of administrative data used for hospital reimbursement. Finally, mortality and socioeconomic data are collected and curated by the Office of National Statistics (ONS).

Primary care data include diagnoses, referrals, symptoms, laboratory tests and clinical examination findings recorded using the Read controlled clinical terminology (a subset of SNOMED-CT, http://www.snomed.org/snomed-ct). Medication prescriptions are organized using the British National Formulary (https://www.bnf.org/), a structured resource for classifying all therapeutic agents prescribed in UK healthcare. Hospital care data include ranked diagnoses recorded using ICD-10 terms and interventional procedures recorded using the OPCS Classification of Interventions and Procedures version 4 (OPCS4) terms which are essentially semantically equivalent to the Current Procedural
Terminology (CPS) terms used in the United States. Mortality data are recorded using ICD-9 and ICD-10 and include the underlying cause of death and up to 15 contributory causes of mortality.

Diabetes phenotyping algorithm

Diabetes affects approximately 25 million people in the US and is one of the most common non-communicable diseases globally associated with a significant burden to patients and healthcare systems. Diabetes has a number of environmental (e.g. body mass index) and genetic risk factors and is one of the leading causes of heart disease and stroke. In addition, diabetes complications such as neuropathy, nephropathy, retinopathy and amputation have a substantial impact on the quality of life of patients. The ability of researchers to undertake studies in diabetes using electronic health records potentially linked to genetic data is of high value.

We used a previously validated EHR-derived phenotyping algorithm for identifying and classifying patients with diabetes into four distinct, non-overlapping groups: 1) patients with type 1 diabetes, 2) patients with type 2 diabetes, 3) patients with unspecified diabetes and 4) patients that are not diabetic. The algorithm (Figure 1) combines clinical information from specific diagnostic codes for type 1 and type 2 diabetes with less specific codes for 'insulin dependent diabetes' (IDDM) and 'non-insulin dependent diabetes' (NIDDM) recorded across both primary and secondary care. Patients with diacoses of both type 1 and type 2 diabetes are classified as patients with diabetes of unspecified type. The algorithm was designed to primarily identify patients with type 2 diabetes that can be on a variety of medications so it does not make use of medication data explicitly. Further refinements would be required to identify patients with type 1 diabetes with greater recall.

![Diagram of the CALIBER diabetes phenotyping algorithm](image)

**Figure 1.** CALIBER diabetes phenotyping algorithm: patients are classified in four distinct categories: type 1 diabetes, type 2 diabetes, diabetes of uncertain type and non-diabetic on the basis of diagnostic codes found in primary care EHR or hospital administrative data.

Individual phenotype components are stratified by data source - e.g. `dm_gprd` represents a diagnosis of diabetes from primary care, `dm_hes` a diagnosis from secondary care. Within each component, diagnostic terms from controlled clinical terminologies have been grouped by clinicians in terms of certainty e.g. `historical diagnoses, possible`
diagnosis, confirmed diagnosis. All individual components and definitions are made available through an open-access Data Portal (https://www.caliberresearch.org/portal/show/phenotype_diabetes).

Desiderata

We used the desiderata defined by Mo and colleagues in order to evaluate RDF/OWL for storing computable representations of phenotyping algorithms. In their work, the authors reviewed a series of EHR phenotyping algorithms (e.g. dementia, Crohn’s disease, cataract, HDL) developed as part of eMERGE and a series of authoring tools such as the Measure Authoring Tool (MAT) (https://www.emeasuretool.cms.gov/), i2b2 (https://www.i2b2.org/), and the SHARPn PhenotypePortal (http://phenotypeportal.org/). The authors propose a list of recommendations for desired features (desiderata) for computable phenotype representations models:

i. Support both human-readable and computable representations
ii. Implement set operations and relational algebra
iii. Represent phenotype criteria using structured rules (e.g. nested logical structure, Boolean logic, comparative operations, aggregative operations, and negation)
iv. Support defining temporal relations between clinical events
v. Utilize standardized controlled clinical terminologies and facilitate reuse of value sets
vi. Provide interfaces for external software algorithms or data components such as support for Natural Language Processing (NLP) operations for extracting clinically significant markers from unstructured EHR
vii. Maintain backwards compatibility to accommodate for temporal changes in the underlying healthcare process model and EHR data specifications.

Results

Phenotype ontology

As part of our work, a proof of concept application (Figure 2) for generating OWL phenotype ontologies was developed in Java using the OWL API, the Hermit reasoner (http://www.hermit-reasoner.com/) and the Protégé, software (http://protege.stanford.edu/). Phenotype ontologies were serialized into OWL/XML format by the semantic reasoners. We utilized SPARQL for defining and performing queries and additional operations, but the main algorithmic logic is defined by OWL constructs.

Figure 2. Diagram of the ontology-based phenotyping solution
We developed the following process to incrementally generate and extend the phenotype ontology using OWL DL:

1) **Generic structural core**: A generic ontology structure is predefined which essentially defines the generic structure for phenotyping algorithms.

2) **Phenotype components**: Individual components of phenotypes, such as lists of diagnostic terms associated with a diagnosis of diabetes in primary care or in administrative data in hospitals is processed. This results in the creation of phenotype element classes (i.e. component, category, diagnostic term) that will hold this information. Diagnostic term lists (*code lists*) associated with phenotype components (e.g. diagnoses of type 2 diabetes in primary care) are currently stored using a very simple bespoke format in CALIBER which enables their automatic processing and addition to the ontology as new classes and individuals. Terms from controlled clinical terminologies used in the algorithm specified as the literals can be defined using IRIs from external ontology/terminology repositories such as the Bioportal, the repository of biomedical ontologies (http://bioportal.bioontology.org/), which provides ontologies derived from e.g. SNOMED-CT, Read or ICD-10/9 vocabularies.

3) **Phenotype algorithm logic**: In this stage, the logic associated with a phenotyping algorithm is manually specified enabling the algorithm to be decomposed into sets and set operations. The phenotype algorithm is based on narrowing the initial set of patients to a final subset representing patients with type 1 diabetes, type 2 diabetes, and unknown type diabetes. Therefore, the algorithm can be described as a graph where nodes represent sets of patients (classes from the ontology perspective) and edges represent set operations and constraints. For example, a class defined as *subjects which have asserted at least 1 Read code of type 1 diabetes intersected with subjects which have asserted at least 1 Read code of type 2 diabetes* is a subclass of class of *subjects with unknown type diabetes*. Union of all subclasses of *unknown type diabetes* is equivalent to *subject with unknown type diabetes* class. With this step, the OWL phenotype description can be serialized. Class names are generated automatically as a composition of the original element names as they are presented in CALIBER and suffixes (and/or prefixes) of general class names.

4) **Subject classification**: In this final stage, structured EHRs are automatically transformed into RDF triples `<patient-obtained-code>` and added to the graph (Figure 3). Individual patients are asserted to the class `Subject` and individual diagnostic terms are asserted to the class `Code`. As the code and patient id are unique, Internationalized Resource Identifiers (IRIs) of those individuals are concatenated from ontology IRI and patient’s id/code. This step does not describe the phenotype itself, but it uses the phenotype for subject classification.
Figure 3. Part of the phenotype ontology including two imported subjects (patient pseudo-identifiers 10642 and 10643) and consequence inferences as generated from the reasoner, generated using Protégé 5. C100100 is the Read identifier for the term “Diabetes mellitus, adult onset, no mention of complication” and E10 is the ICD-10 term for “Type 1 diabetes mellitus”. DM GPRD is diagnosis of diabetes in primary care, DM HES is a diagnosis of diabetes in hospital care. Category 3 is “Insulin dependent diabetes” and Category 4 is “Non-insulin dependent diabetes”. Algorithm implementation details available on CALIBER Data Portal: https://www.caliberresearch.org/portal/show/dm_hes.

Once these steps are complete, the automatic semantic reasoner (e.g. Hermit, Fact++) can be applied over the ontology and new individual assertion axioms are inferred and stored in separate RDF graphs. From these inferences (Figure 4 shows inferred assertions of patients contained within a yellow rectangle), individual groups of classified patients (cohorts) can be extracted using SPARQL queries in which the additional constraints can be specified if required. OWL supports constructs specifying constraints as disjoint classes, complement classes, class closures or zero individual occurrence, but semantic reasoners operate under an open world assumptions e.g. they assume the truth value may be true irrespective of whether or not it is known to be true. As a result, to reach the exact patients subset which is constrained by non-existence of some elements, e.g. patients obtained no diagnostic term from secondary health care, additional restrictions into SPARQL queries has to be added. As an example, the semantic reasoner can infer all patients that have a diabetes type 1 diagnostic term and all patients that have both diabetes type 1 and type 2 diagnostic terms. Patients with only diabetes type 1 diagnostic terms can be query as an intersection of the previously mentioned classes and this intersection can be easily specified within the WHERE clause of SPARQL (Figure 6).
Figure 4. Part of the diabetes phenotype ontology. Blue boxes represent the core; green boxes represent the automatically imported elements; red boxes represent manually added elements; yellow box shows the inferred instances, which are otherwise asserted to the class subject

(i) Support both human-readable and computable representations

OWL/RDF directly supports various machine-readable serialization formats with XML-based serialization into OWL/XML (RDF/XML respectively) being the most common approach. A major advantage is the implicit compatibility with common XML parsers for integrating into external applications. Turtle is another widely used serialization format, which is designed specifically for RDF graphs (Figure 5). In contrary to OWL/XML, Turtle is more compact and easily readable for humans without requiring additional interpretation. Manchester syntax represents both human and machine readable serialization. While RDF/OWL represents named graphs, they can be easily expressed to humans in graphical representation (Figure 3).

```
:phenotype_diabetes_code rdf:type owl:Class ;
  owl:equivalentClass [ rdf:type owl:Class ;
    owl:unionOf ( :diabdiag_gprd_code
                :dm_gprd_code
                :dm_hes_code
    )]
  rdfs:subClassOf :code .
```

Figure 5. Example of Turtle serialization: part of the diabetes ontology and the definition of the diabetes code class used to denote terms from controlled clinical terminologies and their individual components. The class to hold diagnostic terms associated with diabetes diagnoses is a union between three classes of diagnostic terms specifically for primary and secondary care (e.g. diabdiag_gprd_code, dm_gprd_code, dm_hes_code).
(ii) Implement set operations and relational algebra

OWL natively supports set operations over defined classes and subjects. OWL allows us to define an operation of union, intersection and complement and to specify equivalent or disjoint classes and properties. SPARQL, a query language designed to query RDF graphs which grammar is similar to SQL supports relational algebra11. Figure 5 presents an example of OWL set operations of how the diabetes phenotype diagnostic terms are equivalent to a union of terms from three individual phenotype components.

(iii)-(iv) Structured and temporal phenotype rule representation

Nested logical structures can be created by merging individual structured RDF graphs. Comparative and aggregative operations are not implicitly supported by OWL itself, nevertheless SPARQL does support both as well as Boolean logic and negation and as a result, OWL constraints coupled with SPARQL and reasoners meet this criterion. As an example, the SPARQL query returning a set of patients with a type 1 diabetes diagnosis is illustrated in Figure 6. OWL/RDF does not directly support temporal relations, but since it natively provides a data-time datatype, the model for temporal relations could be designed and validity of the relation could be checked within individual SPARQL queries.

(v) Utilize standardized controlled clinical terminologies and facilitate reuse of value sets

One of the main driving principles of ontologies is reusability. The majority of controlled clinical terminologies enable the unambiguous reference of particular terms by a unique identifier and RDF graphs are designed to reference these resource elements by an IRI. Additionally, many controlled clinical terminologies (e.g. Read, ICD-10, ICD-9) which do not natively support IRI can be obtained in a form of ontology on e.g. Bioportal (https://bioportal.bioontology.org/). Presence of such ontologies allows us not only to use a standardized controlled clinical vocabulary, but use them in the context of RDF natively. In our use-case, the diabetes phenotype algorithm uses Read terms for primary healthcare diagnosis and ICD-10 terms for hospital diagnosis. Currently, terms are added to the ontology as the literals however they can be also added as IRIs to their external resources. For example, the ICD-10 term Insulin-dependent diabetes mellitus (E10) has an IRI in the Bioportal ICD-10 terminology resource http://purl.bioontology.org/ontology/ICD10/E10.

(vi) External software interfacing

Our solution does not natively support an interface for external software algorithms or data components as it only contains an explicit specification without the executive components. However commonly used APIs like OWL API provide powerful tools to build such interfaces. Moreover, any external software algorithms implemented in an API proposed for OWL/RDF could be applied on the phenotype in OWL/RDF. NLP is not natively supported by OWL/RDF however, NLP rules and lexicons can be described by and extended by the phenotype ontology graph12.

(vii) Maintain backwards compatibility
Backward compatibility on the level of versions is assured and OWL 2 is backward compatible to OWL 1. Additionally, as OWL/RDF are serialized into XML-based files, version control systems like Git (https://git-scm.com/) can potentially provide an effective manner to capture and control changes over time.

**Conclusion**

In this paper, we evaluated the use of SWT components such as OWL and RDF for storing computable representation of EHR-derived phenotyping algorithms and a proof of concept application using the OWL API and the Hermit reasoner was created. In our case study, we applied OWL in DL dialect on a deterministic diabetes EHR phenotype algorithm from the CALIBER resource. We propose a semi-automatic approach to constructing an ontology which serializes a phenotype description into a machine-readable XML-based file.

OWL/RDF has the potential to be a sufficient resource for storing phenotyping algorithms as it is versatile enough to meet most of the desiderata. The main significant limitation occurs in the case of supporting NLP methods for extracting clinical markers from unstructured text, which is not natively supported. On the other hand, NLP rules and lexicons for NLP engines could be specified in OWL and thus extend current phenotype ontology. Additionally, after ontology extension by structured EHRs in RDF, common reasoners like Hermit can automatically infer consequences and classify patients according to their diagnosis.

**Future work**

Future work includes evaluating the framework in additional phenotyping algorithms including complex phenotypes that make use of combinations of common EHR data such as diagnostic codes, lab measurements, prescription information or that rely on external data sources and integrate multimodal sources of clinical information (e.g. raw text found in patient charts or notes or medical images). Formal evaluation in terms of the algorithm implementation and it's accuracy in identifying patient cohorts should be undertaken and a comparison between other knowledge representation specifications and standards (e.g. the Guideline Interchange Format, GLIF13) would be very useful. As the automatic inferencing strongly depends on an algorithm logic specification which has to be added manually, a human-friendly interface should be implemented and formally evaluated to enable researchers to specify algorithmic logic easily and through a graphical user interface. Researchers should be allowed to specify algorithm logic (i.e., to create rules between classes) and ideally queries using SPARQL even without intimate knowledge of a programming language. Development of the user-friendly interface addresses one of many shortcomings of the semantic web14 and thus detailed investigation of these shortcomings (e.g. existence of competitive ontologies, performance loss for large datasets) and their influence on this work is highly beneficial for the future progress.

Tracking Health Related Discussions on Reddit for Public Health Applications

Albert Park, PhD¹, Mike Conway, PhD¹
¹Department of Biomedical Informatics, University of Utah, Salt Lake City, Utah

Abstract

We use Reddit to demonstrate social media’s potential for public health applications. First, we employ a lexicon-based approach to track the prevalence of keywords indicating public interest in Ebola, electronic cigarette, influenza, and marijuana. Second, to better understand the public reactions, we use the Latent Dirichlet Allocation algorithm, to identify either the general themes or motivations for extreme changes in the volume of discussion over time. We observe that discussions related to Ebola and influenza, infectious diseases of public health interests, surged when the first case of Ebola was diagnosed and a new strain of H1N1 influenza virus was confirmed in the United States. We also observed that discussions of a controversial health topic like marijuana increased with the announcement of a major change in United States federal policy. Discussions of electronic cigarette highlighted opportunities for better health education. Lastly, we discuss the implications of our findings for utilizing Reddit data for public health applications.

Introduction

Nearly two-thirds of American adults (65%) use social media: a nearly a tenfold increase in the past 10 years¹. Social media provides a platform for users to freely express their thoughts and provides an opportunity to interact with geographically dispersed likeminded individuals. These social media users discuss a wide variety of topics ranging from ordinary details of their daily life to information about infectious diseases of public health interest like Ebola². Due to the popularity and ubiquitous nature of social media, researchers advocate for utilizing social media for public health applications³–⁵. Public health agencies are in an early adoption stage of using social media for information distribution⁶. In addition to the substantial potential for using social media as a disease surveillance tool³–⁵ and means of information distribution⁶, social media also has the potential to provide other opportunities to improve public-health practice.

Studying the reactions or opinions of a population has traditionally involved nationally distributed data collection, such as surveys from government agencies. However, these methods are expensive, and perhaps more importantly, time consuming. Some researchers suggest that mining social media data can provide opportunities to reduce time and expense when understanding the reactions or opinions of a population on health issues⁷–¹⁰. For example, social media allows for accessing first person accounts of experiences⁷,⁸, public sentiments⁹, public knowledge¹⁰, and public attitudes¹⁰ that may help public health agencies and researchers to develop policies that improve public health outcomes. Moreover, social media can provide the contextual information and prevalence of public interests more efficiently than traditional public health methods. Tracking the prevalence of public interests and understanding the general public reactions and opinions on various health issues have the potential to expand the scope of public-health practice.

In this paper, we report on findings derived from social media data gathered from Reddit for the purpose of tracking the prevalence of public interests and understanding public reactions towards infectious diseases of public health interests like Ebola and influenza as well as controversial health issues, such as electronic cigarettes and marijuana. In fact, although Reddit is one of the most popular public social media platforms, it has been underutilized for public health applications. Reddit’s size and range of topics make it difficult to make use of the data without any knowledge of how the platform is used in practice. Thus, we aim to fill this gap in the literature with the current study and answer the following two research questions (RQ):

- (RQ1) Is Reddit an effective source for tracking the prevalence of public interests on infectious diseases (i.e., Ebola and influenza) and controversial health related issues (i.e., electronic cigarette and marijuana) over time?
- (RQ2) What do Reddit members discuss regarding these health issues (a) in times of elevated discussion volume or (b) in general, if the issues have a steady level of discussions?

The work described in this paper was exempted from review by the University of Utah's Institutional Review Board (IRB) [ethics committee] (IRB 00076188).
Background

A growing body of research has demonstrated the successful use of social media for public health applications\textsuperscript{11-13}. Often referred to as \textit{digital disease detection}\textsuperscript{1}, \textit{Infoveillance}\textsuperscript{4}, and \textit{digital epidemiology}\textsuperscript{5}, many studies have used Twitter data for applications in public health, primarily due to the real-time nature of the data. For example, Twitter data have been used to monitor or estimate influenza\textsuperscript{12,14}, seasonal allergies\textsuperscript{12}, alcohol sales and consumption\textsuperscript{15}, cholera outbreaks\textsuperscript{16}, earthquake\textsuperscript{17}, and smoking behavior\textsuperscript{18}, as well as to examine sentiment towards marijuana use\textsuperscript{19}. Although Twitter is highly popular and tweet analysis has performed well with the aforementioned topics, tweets provides relatively limited context due to a length limitation of 140 characters.

Other social media data, such as Facebook and online health community data, have also been mined to, for example, characterize and predict postpartum depression\textsuperscript{20}, classify opioid addiction phrases\textsuperscript{21} and predict adverse drug reactions\textsuperscript{22}. Google search queries allowed researchers to provide timely estimation of influenza rates\textsuperscript{23}. However, a previous study suggested that Facebook users are reluctant to discuss certain negative topics on Facebook, due to users’ desire to convey positive images of themselves\textsuperscript{24}. Online health communities can provide rich details of first person accounts of experiences\textsuperscript{25}, however, online health communities typically are single topic focused groups, often with a small number of members and attracting a substantial number of “lurkers”\textsuperscript{26} (i.e., individuals who participate without posting) and dropouts\textsuperscript{27}. Google search queries can be useful and timely, however, search queries are relatively limited in providing context and have been shown to overestimate disease rates, due (in part) to heightened media coverage\textsuperscript{28}.

Recently, Reddit, due to the availability of a public Application Programming Interface (API)\textsuperscript{29}, the capability of providing contextual information, and the support for throwaway accounts, has become a widely studied social media platform for controversial discussions. For example, using Reddit data, researchers have found empirical evidence that Reddit members openly discuss and exchange information support for potentially stigmatized issues like mental health illnesses\textsuperscript{30}, detected increases in suicidal content following reports of several celebrity suicides\textsuperscript{31}, identified distinct markers of shifts to suicidal ideation from mental illnesses\textsuperscript{32}, explored the relationship between social feedback and community participation\textsuperscript{33}, identified distinctive linguistic characteristics that are associated with mental illnesses\textsuperscript{34}, characterized smoking and drinking problems\textsuperscript{35}, and examined user experiences with different tobacco products\textsuperscript{36}. Thus, in this study, we explore Reddit’s utility as a data source for public health applications for tracking and understanding public opinions and reactions to health issues.

Data: Social Media Site

The data for this study is hosted in the popular social media platform, Reddit (http://www.reddit.com). We use Reddit to track and understand discussions of Ebola, influenza, electronic cigarettes, and marijuana for the following three reasons. First, Reddit is a highly active social media platform that had 83 billion page views from over 88,000 active sub-communities (subreddits) in 2015. Members of Reddit made over 73 million individual posts with over 725 million associated comments in the same year\textsuperscript{37}. Second, Reddit allows for throwaway and unidentifiable accounts that are suitable for controversial discussions, such as thoughts and feelings on electronic cigarettes and marijuana as well as epidemic concerns like Ebola and influenza that may be inappropriate or sensitive for identifiable accounts. Third, Reddit content is publicly available, in contrast to other health focused social media platforms like Facebook Groups or specifically health-focused online communities like PatientsLikeMe, where the content is typically not available on the open web.

Reddit members converse via a forum like platform. Reddit discussion consists of posts (i.e., a submission that starts a conversation) and associated comments (i.e., a submission that replies to posts or other comments) in various topical focused subreddits. Members who have achieved a certain status within the community are able to create new subreddits. For this study, we used a dataset\textsuperscript{38} released by a Reddit member. The dataset has been used in previous studies\textsuperscript{34,39,40}. The dataset for the current study is comprised of 239,772 (including both active and inactive) subreddits, 13,213,173 unique member IDs, 114,320,798 posts, and 1,659,361,605 associated comments that were made from October 2007 to May 2015.

Methods

RQ1. Is Reddit an effective source for tracking the prevalence of public interests on infectious diseases and controversial health related issues over time?

We used a lexicon-based approach to track discussions on Ebola, electronic cigarettes, influenza, and marijuana from all subreddits available in Reddit. First, we identified key terms associated with the topics of our interests. A
summary of key terms for each issue is shown in Table 1. Second, we preprocessed the entire dataset, which included converting text to lower case and removing punctuation. Third, to extract submissions (i.e., posts and comments) containing key terms from all available 239,772 subreddits, we employed a lexicon-based approach and extracted timestamps, comment or post IDs, member IDs, and subreddit IDs of the submissions. We extracted and included any partial matches in this process to cover a wide variation of terms. For example, a partial match of ‘cig’ can cover a variation of ‘cig’, ‘cigs’, ‘cigarette’, and ‘cigarettes’ for electronic cigarette. Fourth, we counted unique member IDs, subreddits, posts, and comments containing key terms. Fifth, we normalized the frequencies over time by dividing the frequency counts by the total number of the respective variables from all available subreddits for that period. Since the total number of submissions in Reddit generally increases over time, we report normalized frequencies over time counts.

RQ 2. What do Reddit members discuss on these health issues (a) in times of elevated activities or (b) in general, if the issues have a steady level of discussions?

Based on results of RQ 1, we created two scenarios deciding which time periods to further investigate for understanding the discussions on Ebola, electronic cigarette, influenza, and marijuana. (a) If the issue has a sudden elevated level of discussion, we investigated the time period in which the elevation occurs along with prior discussions of the same temporal length to understand the underlying causes for these sudden changes in public interest. Similar methods that contrast to prior time periods have been used to detect emerging topics\textsuperscript{41,42}. (b) If the issue has a steady level of discussions, we investigated the entire discussions on the issue to understand the main themes.

We used natural language processing (NLP) and language modeling for this research question. Due to the size of the dataset and range of topics discussed on Reddit, we used automated methods. Similar automated methods have been used in the health care domain to extract information and analyze data, and to enhance the personal health care experiences\textsuperscript{43–45}. First, we preprocessed the entire dataset as we did in RQ1. Second, to improve the language modeling results, we removed the URLs and comments and posts with less than 5 words, and then extracted nouns using Python Natural Language Toolkit (NLTK) package\textsuperscript{46}. The extracted nouns were used to create language models—a set of topics generated from document-level word co-occurrences for a given set of documents—using Latent Dirichlet Allocation\textsuperscript{47} (LDA) for the time period of our interests. We elected to use LDA, an unsupervised algorithm, due to the lack of a ground truth dataset. We considered each post and its associated comments as a single document.

One advantage of using LDA as opposed to other unsupervised clustering techniques is that the algorithm considers each document with multiple topics. A previous study of online health discussions suggested that discussions could have multiple topics due to topic drift\textsuperscript{48}. Thus, we employed LDA for this study. One disadvantage of using LDA is, however, it requires a pre-determined number of topics. After experimenting with varying numbers of topics, we generated 50 topics to understand Ebola, electronic cigarette, influenza, and marijuana related issues. We used the Python package genism\textsuperscript{49} to conduct LDA analysis. We then present the main topics and their top 50 associated words as the word cloud overview using the Python package wordcloud\textsuperscript{50}. Despite its simplicity, word cloud overview remains one of the more preferred and user-friendly visualizations that can also scale to different data sizes\textsuperscript{51}. We then manually investigated the identified topics and their associated words to thoroughly examine the LDA results.

Lastly, we performed two types of validity checks. First, for health issues with a sudden elevated level of discussion, we verified the LDA results via a systematic analysis of news at the time of the change. LDA results reflect motivations for the extreme changes, thus news can be an effective source for a validity check. Second, we extracted URLs using regular expressions and categorized the results. A previous study concerning electronic cigarettes—a product with few marketing restrictions in the US until recently—suggested that up to 90 percent of social media (in this case, Twitter) content could be related to product marketing\textsuperscript{52}. Thus, because marketing content can skew our result, we used URLs as a proxy to marketing content and reported the percentage of posts with URLs. We also manually examined several extracted URLs to ensure the quality of the validation process.

Results

RQ1. Is Reddit an effective source for tracking the prevalence of public interests on infectious diseases and controversial health related issues over time?

The lexicon-based approach identified Reddit posts, comments, and members discussing Ebola, electronic cigarette, influenza, and marijuana from October 2007 to May 2015 (Table 2). The most discussed matter was influenza, followed by marijuana, electronic cigarettes, and then Ebola. The raw counts of discussions and members who mentioned each topic generally increased with time.

We identified one notable increase in discussion each for Ebola, influenza, and marijuana using the normalized frequencies over time (Figure 1). First, the normalized count on marijuana almost doubled from the previous month in February 2009. The heightened level of discussions continued for two months then slowly dropped back to the previous level. Second, in April of 2009, the normalized count on influenza almost doubled from the previous month. Third, October 2014 accounts for the Ebola discussions. The discussions on Ebola showed the most increase, jumping more than five times from the previous month. The number of members discussing each issue increased in a similar manner (Figure 1). The Discussions on electronic cigarette was relatively steady from October 2007 to May 2015.

Figure 1. The Line Graphs of normalized frequencies over time for posts and comments with key terms and members who used the key terms
Discussions on Ebola, electronic cigarettes, influenza, and marijuana, however, only accumulated to a fraction of the overall discussions on Reddit (Table 2). Although the community as a whole did not frequently talk about these health-related issues, this still amounted to more than 3,000 members for Ebola, the least discussed issue, and more than 137,000 members for influenza, the most discussed issue in a month with a normal level of discussion, May 2015.

**New subreddits to discuss Ebola, Electronic Cigarette, Influenza, and Marijuana**

Members of Reddit created a number of subreddits specifically focusing on Ebola, electronic cigarettes, influenza, and marijuana, although they also discussed the issues in many different subreddits (Table 3). Using the key terms (Table 1), we detected a total of 450 topically dedicated subreddits that were created between October 2007 and May 2015. For example, marijuana was casually discussed in 18,236 subreddits (i.e., subreddits with key terms in posts or comments), while members created at least 244 subreddits (i.e., key terms in names of subreddits) to talk about marijuana.

**RQ 2. What do Reddit members discuss on these health issues (a) in times of elevated activities or (b) in general, if the issues have a steady level of discussions?**

![Figure 2. Word cloud overviews of emerging topics for Ebola (top left), influenza (top right), and marijuana (bottom left) as well as general word cloud overviews for electronic cigarette (bottom right)](image-url)
From RQ1, we learned that discussions focusing concerning Ebola, influenza, and marijuana, each had one sudden increase of activities. Thus, we created word cloud overviews of emerging topics for Ebola, influenza, and marijuana, while creating a general word cloud overviews for electronic cigarette (Figure 2).

According to the word cloud overview generated by the LDA topic modeling algorithm, we can infer that Reddit members are most concerned about ‘risk’ and ‘symptoms’ regarding Ebola. For influenza, members used terms like ‘Mexico’, ‘Obama’, ‘CDC’, and ‘conspiracy’, along with H1N1 influenza related terms (e.g., ‘H1N1’, ‘Swine’) as well as H5N1 related terms like ‘Egypt’ and ‘pig’. Topics regarding ‘legalization’, ‘prohibition’, ‘economy’, and ‘state’ appeared in discussions regarding marijuana. The general word cloud overview for electronic cigarettes has more commercially related terms such as ‘quality’, ‘prices’, ‘shop’, and ‘store’ than the other three discussions, however substantially more terms related to tobacco (e.g., ‘tobacco’, ‘cigarette’, ‘cigar’) are shown in Figure 2. Other notable topics for electronic cigarette that were identified via the LDA were ‘quitting smoking’, ‘fun experience’, and ‘health information’.

To check the validity of the results, we extracted and investigated the URLs to ensure that frequencies are not inflated by marketing content. The types of URLs shared by members were similar in nature for all four issues. Members shared websites that are concerning information (e.g., Wikipedia, CDC), news (e.g., NY Times), personal stories (e.g., blogs), other social media platforms, (e.g., Youtube), different Reddit posts, and commercial resources (e.g., amazon). Although the proportion of each type of URLs is different, members shared a relatively small number of posts and comments with URLs compared to the overall posts and comments focusing on all four issues.

Discussion

Principal Findings

We examined four different infectious disease related or potentially stigmatized health related issues discussed on Reddit. We discovered three periods with higher levels of activities on Reddit. We observed that there were almost twice as many marijuana related discussions in February 2009 compared to the previous month, due – we suspect – to the announcement of a major shift in federal policy. Attorney General Eric Holder confirmed that Drug Enforcement Administration would halt medical marijuana raids and give states the power to regulate medical marijuana usage for pain control in February of 2009. In April of 2009, discussions about influenza almost doubled from the previous month. This is likely due to the fact that a novel strain of H1N1 influenza virus was discovered in North America in the spring of 2009 and the Centers for Disease Control and Prevention (CDC) confirming the first two cases of human infection with H1N1 influenza virus in the United States in April of 2009. On September 30, 2014, the United States had its first diagnosed case of Ebola in Texas, and the first Ebola related death on October 8, 2014. We observed that discussions on Ebola, a potentially fatal infectious disease, surged more than five times from the previous month in October of 2014. The news related to Ebola, influenza, and Marijuana align well with the results from topic model analyses (RQ2). On the basis of these changes of activities, Reddit may be a valuable source of data for tracking the prevalence of public interests on infectious diseases (i.e., Ebola and influenza) and controversial health related issues (i.e., electronic cigarette and marijuana) over time (RQ1).

The result of our analysis on electronic cigarette discussions suggests that Reddit contains more than just commercial content despite the fact there are at least three subreddits focusing on classified content (Table 4). For instance, a subreddit called ‘Ecigclassifieds’ consists mainly of commercial content, thus the content of these subreddits deserves further investigation to better utilize the data. From electronic cigarette discussion, we identified three topics, ‘quitting smoking’, ‘fun experience’, and ‘health information’ that highlighted opportunities for better health education. From their associated terms (see Results), we can infer that Reddit members are seeking

information on these three topics. Information seeking behavior on Reddit suggests Reddit’s utility as another social media platform for information distribution and as a data source for understanding user groups (e.g., electronic cigarette smokers) and identifying better health education. Why members are seeking health information on Reddit is an unanswered research question, although a recent study suggests that electronic cigarette related health information from public health agencies may be too difficult for the general public to comprehend.

Reddit members also created at least 450 relevant new subreddits specifically focusing on these four issues. How the content from these subreddits contrast with the content from multiple subreddits on the same issue is an unanswered question. Previous studies\textsuperscript{30,31,33,34,39} analyzed content from a handful of especially dedicated subreddits for their studies. However, our finding suggests that at least for discussions of Ebola, influenza, electronic cigarettes, and marijuana, members mentioned these issues on thousands of subreddits (Table 3). For instance, a common issue like influenza was discussed in over 30,000 subreddits, and even a focused topic like Ebola were discussed in over 4,400 subreddits. Thus, we believe analyzing a wider number of subreddits can improve recall of the relevant content.

Limitation, Future Directions, and User Privacy

Reddit offers substantial potential for understanding the public reactions to health-related topics, however, not without a number of limitations. Although Reddit is a widely-used platform, it is more frequently used by young males\textsuperscript{38,59} and may be subjective to self-selection bias. Reddit members are not necessarily representative of the general public, however, the levels of activity on Reddit aligned with the United States news and deserve a further investigation, especially with respect to location of postings and the overall reactions in Reddit. To better understand the reaction of the general public, studying different platforms and avenues, Facebook and Twitter for example, is warranted. Our analysis suggests that given the increasing popularity and use of Reddit, as well as the increasing frequency of discussions concerning our topic of interests, Reddit provides a productive starting point for investigating infectious disease related or controversial health issues.

Another limitation lies in the methodology. In RQ1, we used a relatively rudimentary lexicon-based approach to extract posts and comments explicit mentioning variations of pre-specified key terms. One major shortcoming of such approach is the selection of key terms. For example, utilizing a large set of key terms will undoubtedly create more false-positives, whereas too limited a set of key terms will surely result in more false-negatives. Moreover, partial matches can produce false-positive matches. We believe the figures for influenza were inflated because ‘flu’ can be a part of a longer word such as ‘fluorine’ or ‘flute’. In future studies, we suggest that precision rather than recall should be emphasized in order to eliminate irrelevant discussions. Other difficulties in mining social media data include the fact that social media text is frequently characterized by extensive of acronyms, abbreviations, and slang terms.\textsuperscript{60} Although we included the most frequently found abbreviations and slang terms, lexicon-based approaches are to omit unknown forms of abbreviations and slang. More sophisticated methods utilizing knowledge-based\textsuperscript{61} or corpus-based\textsuperscript{62} approaches could produce different results. Furthermore, a smaller timeframe can better measure the timeliness of the observed reactions as oppose to the one month timeframe used in RQ1. In RQ2, we relied on a systematic analysis of the news to verify the result of our investigation. However, data driven qualitative analysis\textsuperscript{63} can further bolster our findings and provide the contextual information on the discussions of our interests. Sentiment analysis on the extracted discussion can also provide further clues about general public reactions on various health related topics\textsuperscript{9}.

Research and applications using social media data should be highly sensitive to user privacy, especially for potentially stigmatized topics. Although at least some social media data are publicly available, researchers should consider ethical implications when processing data even for population-level social media research using public data\textsuperscript{64–66}. For this reason, we have refrained from using direct quotations from Reddit users in this paper.

Conclusion

As evident by the frequencies over time of discussions, inflated discussions after major news, as well as newly created subreddits specifically focusing on these health-related issues, Reddit could be a useful platform for understanding the concerns and opinions of the general public, especially for issues focusing on controversial topics, such as abuse and addiction as well as infectious diseases of public health interest. By utilizing the content, we also identified opportunities for better health education that could improve public health outcomes. We created topic models using LDA and generated topically associated words and created word cloud visualizations to show (1) emerging topics by contrasting to the prior topic models or (2) main themes of the discussions. We believe our insights and analyses can be generalized to other similar health related issues in the Reddit platform. Understanding public reactions to these issues has the potential to expand the scope of public-health practice.

ABSTRACT
A value set is a collection of permissible values used to describe a specific conceptual domain for a given purpose. By helping to establish a shared semantic understanding across use cases, these artifacts are important enablers of interoperability and data standardization. As the size of repositories cataloging these value sets expand, knowledge management challenges become more pronounced. Specifically, discovering value sets applicable to a given use case may be challenging in a large repository. In this study, we describe methods to extract implicit relationships between value sets, and utilize these relationships to overlay organizational structure onto value set repositories. We successfully extract two different structurings, hierarchy and clustering, and show how tooling can leverage these structures to enable more effective value set discovery.

INTRODUCTION
Controlled terminologies are the semantic underpinnings of clinical data and facilitate interoperability\textsuperscript{1}, research\textsuperscript{2}, and quality reporting\textsuperscript{3}. These terminologies are shared knowledge assets, often designed to be used for a variety of purposes and use cases\textsuperscript{4,5}. A value set is a grouping of codes from one or more terminologies used to express some conceptual domain\textsuperscript{6,7}. Value sets narrow the broad semantics of controlled terminologies down to a more targeted domain, and have a variety of practical applications related to data standardization and analysis\textsuperscript{8,9,10}. Like controlled terminologies, value sets are shared assets, generally published in a repository or catalog to promote discoverability and reuse.

As a value set is intended to semantically express some domain of interest, it is important that it adequately convey to the consumer the semantics to which it is bound – or its intension. If this intension is not clearly stated, value set discoverability, or a user’s ability to locate and reuse value sets relevant to their use case, will suffer. As reuse becomes more difficult, users are increasingly likely to simply create a new value set according to their needs. This compounds the problem, resulting in the proliferation of many value sets that are conceptually similar but with slightly different sets of codes. Consequently, it then becomes difficult for a user to infer whether or not these subtle differences were intended and necessary, or simply a result of different authors interpreting the same conceptual space differently. At the extreme, there may also be cases where value sets are inadvertently duplicated\textsuperscript{11}. High redundancy may be a symptom of low reusability – a problem not dissimilar to challenges in software reuse\textsuperscript{12}.

So how, then, do we determine the intension of a value set in order to promote reuse? If left as an exercise for the repository user, the most accessible points of inspection are the value set name and its set of codes. Although generally intended to be descriptive, a text-based value set name places the burden of interpretation on each individual user. Moreover, the name may lack precision, as names have shown to be generally insufficient at expressing complex semantics\textsuperscript{13}. Manual review of the contained code set may provide a better representation of actual intension, but is not without its own challenges. By browsing the code set, a subject matter expert may be able to sufficiently reverse-engineer the value set intension, but this is a manual, potentially laborious process. Furthermore, value set repositories tend to organize content in flat (or nearly flat) structures. This makes it difficult to display and search for similar groups of value sets, or to scope searches to a specific context. More importantly, however, it keeps implicit relationships between value sets hidden, and awareness of these inferred connections is a valuable tool for discovery\textsuperscript{14}.

The purpose of this study is to utilize automated methods of capturing value set intension\textsuperscript{11} to extract additional structure and knowledge from a value set repository. We specifically aim to extract value set clusters based on similarity, and hierarchies based on specialization/generalization. By placing value sets in the context of similar ones, we aim to promote better repository search capability\textsuperscript{15}, and ultimately, better discoverability. Finally, we will show how these methods may be practically implemented and integrated into tooling.
MATERIALS AND METHODS

Extracting additional structure and knowledge from a value set repository is a multi-faceted activity. Specifically, our choice of algorithms and outputs must be user-centered, or oriented towards defined user needs and requests. Also, we cannot assume universal value set structure, as several standardized formats exist along with many non-standard, proprietary representations. Heterogeneously structured value sets must be consolidated via preprocessing and standardization to allow our methods to have the maximum breadth of applicability. Finally, analysis of the results, or the representation of the new knowledge, must be actionable and approachable by the user.

Knowledge Discovery in Databases (KDD) is an effort to place the activity of data mining within the context of a larger process encompassing domain analysis, data preprocessing, and ultimately knowledge presentation and utilization. We structure our methods generally following the guidance of the KDD process.

Data Preprocessing

Selection. The Value Set Authority Center (VSAC) is a National Library of Medicine (NLM) public repository for value sets referenced in Meaningful Use Clinical Quality Measures (CQMs). The VSAC also includes support for value set authoring, expanding its scope beyond Meaningful Use and into other applications and domains. We use this rich value set repository as our primary source of data.

Standardization. The VSAC exposes value sets programmatically via the VSAC v2 REST service, with value sets modeled using Sharing Value Sets (SVS), an Integrating the Healthcare Enterprise (IHE) initiative focused on value sets and their representation. To allow our methods to be portable to repositories beyond the VSAC, we implemented our algorithms to operate on value sets modeled using Common Terminology Services 2 (CTS2), an Object Management Group (OMG) and Health Level Seven (HL7) terminology standard. This necessitates an SVS to CTS2 conversion step in our process for value sets originating from the VSAC (see: https://gist.github.com/cts2/ for CTS2 ↔ SVS implementation details). Our methods are also specifically scoped to extensional value sets, or value sets represented as enumerated lists of codes.

ISO/IEC 11179 is a standard for representing metadata in registries with the goal of promoting standardization and interoperability of data. Part 3 of the specification describes the basic elements of the metadata registry metamodel, and is specifically applicable to our problem space, as it provides structure and formality around our notion of a value set and its contents. For our purposes, we focus on the following elements of the metamodel:

- **Enumerated Concept Domain.** A collection of valid meanings – in this case, a set of explicitly enumerated Value Meanings. This aligns with what we refer to in this study as a value set. Example: VSAC value set BMI Values (2.16.840.1.113883.3.600.1.889)

- **Value Meaning.** A representation of the semantic intension, or meaning of a value. For our purposes, this is a code drawn from a standard terminology. Example: ICD10CM Z68.1, Body mass index (BMI) 19 or less, adult

An Enumerated Concept Domain is a specialization of a Concept, defined as a “unit of knowledge created by a unique combination of characteristics.” This is notable for our study, as it allows us to model Enumerated Concept Domain → Enumerated Concept Domain (or, value set → value set) relationships. It is through ISO/IEC 11179 that we base our assumption that value sets are themselves a unit of knowledge, have intrinsic meaning, and can be meaningfully related to other value sets.

Algorithm Selection

Our aim is to extract meaningful structure from a value set repository, and we focus our efforts on two structural constructs: hierarchy and clustering. Algorithms for extracting these structures from a repository are described below.

**Containment Hierarchy.** Hierarchies, or the arrangement of entities into parent → child relationships, have long been used to structure knowledge artifacts and play important roles in knowledge discovery. Concept hierarchies
have strong mathematical formalizations\textsuperscript{27} rooted in concept maps and are an important part of knowledge management\textsuperscript{28}. These hierarchies, however, are not always explicitly stated (or even envisioned by the content authors). Text document repositories\textsuperscript{29}, Wikipedia entries\textsuperscript{30}, text books\textsuperscript{31}, and on-line dictionaries\textsuperscript{32} are all examples of domains where hierarchies have been extracted via mining the existing data sources.

Containment hierarchy is a general strategy for ordering sets based on strict subsets – for example: \{a, b, c\} \supset \{b, c\} \supset \{c\}. For our purposes, the sets under examination are the code sets for each value set. By recursively nesting subsets, we can begin to build hierarchies. Examples of this hierarchy can be seen in Figure 1.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{containment_hierarchy.png}
\caption{(a) Each graph node represents a set of elements organized with children nodes as strict subsets of the parent.
(b) A practical example highlighting three value sets. Here, \textbf{ProcedureActStatusCode} and \textbf{ProblemActStatusCode} are strict subsets of \textbf{ActStatusCode}.}
\end{figure}

\textbf{Clustering.} Jansen et al. demonstrated that users searching the web for information tend to use short (2.35 terms) queries\textsuperscript{33}. As searching is a fundamental pillar of knowledge management infrastructure\textsuperscript{34}, it is useful for us to take this behavioral model into consideration for our study. Specifically, we recognize that a small number of search terms does not provide enough context to sufficiently pinpoint the desired results\textsuperscript{35}.

Clustering search results around a conceptual topic has been extensively studied as a way to improve search quality\textsuperscript{36,37}. These approaches focus on grouping semantically similar documents together in order to tune the search to the perceived semantic intent of the user. Much like containment hierarchy, clustering aims to extract implicit relationships between value sets. Unlike hierarchy, however, we are not limited to containment relationships. Specifically, we can begin to envision a value set repository as an undirected graph, where the value sets are the nodes and the edges indicate some relationship between them.

Using these relationships, we can begin to analyze groups of closely connected value sets, or clusters, using community discovery approaches\textsuperscript{38,39}. We define a cluster \(C\) focused on a node \(i\) in some graph \(G\) to be \(i\) and all nodes directly connected to it, or its closed neighborhood, denoted as \(C_i = N_G[i]\). One interesting characteristic of these clusters is how tightly connected they are – or, how probable it is that the neighbor nodes of \(i\) are also connected. Densely connected graphs appear in several contexts, ranging from social media connections\textsuperscript{40} to cell biology\textsuperscript{41}. We measure the density of these connections by calculating the clustering coefficient, a measure of how connected the neighbors of a node are to one another\textsuperscript{42}. Given a node \(i\) in graph \(G\), let \(T_i\) represent the number of edges in \(G\) that connect any two neighbors of \(i\), and let \(K_i\) represent the degree, or number of outgoing edges of \(i\). The clustering coefficient \(CC_i\) can then be calculated for any node \(i\):

\begin{equation}
CC_i = \frac{2T_i}{K_i(K_i - 1)}
\end{equation}

Note that the clustering coefficient may only be calculated for a cluster of three or more nodes. As such, only groups of three or more related value sets were considered to be clusters.
Figure 2: Example Clustering Coefficient ($CC_i$) values for three sample graphs.

Figure 2 shows this calculation as applied to three example graphs. Note that as this measurement is focused around a single given node, it is referred to as the *local* clustering coefficient. We can compute the *global* clustering coefficient $CC$ of the entire graph by averaging the clustering coefficients of each node:

$$CC = \frac{1}{n} \sum_{i=1}^{n} CC_i$$

(2)

Thus far, we have considered the edges in our graph to be binary – either two value sets are connected or they are not. To properly reflect our domain, we must account not only for the relationship itself, but the intensity of the connection – in our case, the amount of similarity between two value sets. Assuming we have in place algorithms to compute this similarity, we now are able to treat value set similarity not as a binary condition, but as a degree. We reflect this in our graph by using *weighted* edges. With this change we must also utilize a *weighted* clustering coefficient\(^{43,44}\), which is an adjustment to our original formula to incorporate edge weights. This is similar to the original clustering coefficient equation, but incorporates edge weights ($w$) by calculating the geometric mean of the weights of all triangles originating from the focus node $i$. Note that weights were normalized ($\hat{w}$) to a value in the closed interval $[0, 1]$ by dividing the raw weight by the maximum weight found in the graph: $\hat{w}_{k,i} = \frac{w_{k,i}}{\max(w)}$.

$$\hat{CC}_i = \frac{2}{K_i(K_i - 1)} \sum_{k,j} (\hat{w}_{k,i}\hat{w}_{j,i}\hat{w}_{k,j})^{1/3}$$

(3)

For each cluster, an accompanying Erdős-Rényi random graph\(^{45}\) was created, with $\hat{CC}_i$ calculated similarly for this randomly assembled cluster. If $\hat{CC}_i$ for the actual cluster was higher than what was observed in the random cluster, we considered that cluster to be *dense*\(^{42}\).

**Defining Value Set Similarity**

Although our methods now account for varying degrees of similarity via weighted edges, the remaining challenge is to define what exactly makes two value sets *similar*. We recognize that value set similarity is context-specific and in many cases subjective. For our purposes, we define value set similarity as a measure of shared intension. We use two approaches to extract the intension of a value set: analysis of the name and code set. These methods, informed by the work of Winnenburg and Bodenreider\(^{11}\), are detailed below.

- **Value Set Name.** *Term Identification* is a Natural Language Processing (NLP) technique for extracting concepts from free text and mapping them to controlled vocabularies\(^{46}\). MetaMap\(^{47}\), an NLP tool developed by the National Library of Medicine (NLM), aims to assign Unified Medical Language System (UMLS)\(^{48}\) Concept Unique Identifiers (CUIs) to biomedical free text. Passing in the value set name to the MetaMap tool yields a set of CUIs representing the normalized semantics of the name.

- **Code Set.** A value set’s code set scopes the semantics of the value set by enumerating the permissible values for its domain. Using the code set as a representation of intension has some distinct advantages: (1) it requires
As a result, we represent value set intension as either a set of UMLS CUIs extracted from its name, or its member code set – in either case, a set of discrete values. The similarity of two value sets may then be computed as a measure of overlapping intension. Given two value sets, let $A$ and $B$ denote the derived UMLS CUI set or code set from each. Similarity is then defined as the Jaccard index of these two sets, or their intersection size divided by their union size:

$$J(A, B) = \frac{|A \cap B|}{|A \cup B|}$$

(4)

The higher the Jaccard index, the more similar we considered two value sets. Conversely, a low Jaccard index indicates dissimilarity, and similarity scores lower than a threshold of 0.25 were not considered in our cluster analysis.

The rationale for using two different similarity strategies is that we cannot necessarily rely on a single measure in isolation. For example, VSAC value sets BMI Values (2.16.840.1.113883.3.600.1.889) and BMI values (2.16.840.1.113883.3.600.1.888) have names that are semantically identical, but share no common codes, as they draw from two different code systems (ICD10CM and ICD9CM, respectively). Conversely, Procedures as Reasons for Admission to ICU Due to Pneumonia (2.16.840.1.113762.1.4.1111.26) and Need for Ventilator (2.16.840.1.113762.1.4.1045.82) share the exact same code set while having semantically dissimilar names. As such, we recognize that using different similarity measures will establish potentially different similarity relationships between value sets.

### Cluster Similarity

If the two different value set similarity measures relate value sets in different ways, we also expect them to produce different clusters of value sets. It is useful then to introduce a method to calculate just how dissimilar these clusters are – or cluster similarity. To determine this, we first compute two value set graphs, one with edges weighted by the code set similarity function and the other using value set name similarity. Next, we extract clusters from both graphs pairwise by a common focus node $i$, yielding clusters $C_i$ and $C_i'$. Finally, we compute similarity at a cluster level by inspecting how many nodes (or value sets) the clusters have in common by calculating the Jaccard index:

$$\text{cluster\_similarity}(i) = J(C_i, C_i')$$

(5)

### RESULTS

We analyzed 3820 total value sets from the VSAC repository, focusing on extracting implicit value set to value set relationships. Our methods sought to mine the overarching structures implied by these relationships – specifically hierarchies and clusterings of similar value sets. The metrics gathered were focused on quantifying the characteristics of these structures in an effort to better understand how they may be ultimately leveraged.

Analysis of the value set clustering characteristics gave insight into how interconnected the value sets were – or, how readily they formed into related groups. A cluster was defined as three or more connected value sets, and two sets of clusters were built using the two different similarity measures. Of the 3820 total value sets analyzed, 3185 clusters were found using the name similarity measurement, while 1190 were found via code set similarity. Table 1 reflects the results of the clustering coefficient calculation, a measure of how densely interconnected the clusters were. Valid clustering coefficients range from 0 – 1, with 0 indicating no neighbor connections and 1 being all neighbors interconnected (or a clique). This analysis was computed twice: once for each similarity algorithm, and the subtables reflect the result of both computations.

The clustering coefficient result for each cluster was also compared to a clustering coefficient for a similar, randomly assembled cluster. Through this calculation we were able to obtain the number of dense clusters, or clusters observed to have a weighted clustering coefficient greater than would be expected to occur randomly. For clusters grouped by value set name, 3170 out of 3185 clusters were considered dense. For code set groupings, it was 964 out of 1190.
Table 1: Clustering summary statistics. The clustering coefficient is a measure of how densely value sets tended to group together based on the two similarity measures.

(b) Name Similarity

$CC_i$: weighted local clustering coefficient

$|C_i|$: number of nodes in a cluster

Relationships between value sets indicated a degree of similarity. Our methods assumed that differences in how we computed value set similarity would result in different relationships, and consequently, different clusters. Table 2 shows in summary how similar the clusters from the two similarity measures were. Cluster similarity was computed as the Jaccard index of a cluster from each similarity measure, compared pairwise by a common focus node. For this measurement, the permissible cluster similarity range was $0 - 1$, with 0 indicating no shared value sets in the clusters (which is impossible, as via pairwise comparison by common focus the clusters will at least share one node), and 1 indicating that the clusters were identical.

Table 2: Similarity comparison of clusters computed from the two different similarity measures. Cluster similarity was calculated by pairwise comparison of clusters produced by both the value set name and code set similarity measures.

Analysis of these relationships was also leveraged to explore implicit hierarchical structures within the repository. Of the 3820 value sets analyzed, 1546 were found to be roots, or value sets with no computed hierarchical parents. To measure the extent of the extracted hierarchy, the longest path to a leaf for each root value set was calculated. Figure 3 summarizes our findings, reflecting the levels of hierarchies found in the repository, from 0 levels (meaning a value set with no children) to 5, the maximum level observed.

Figure 3: Analysis of extracted hierarchy levels. For each root value set (or value set with no computed parents), its height (or longest path to a leaf) was calculated, indicating the level of hierarchy. This figure relates these hierarchy levels to the number of value set roots in which they were observed.

DISCUSSION

We have described methods to extract two different organization structures from VSAC value sets, and we begin our discussion with an examination the structures found. Table 1 demonstrates high clustering coefficient values, indicating that value set clusters tend to be highly interconnected. We also find that the majority of clusters were dense, or exhibited a clustering coefficient value higher than would be expected for a similar random graph.
clustering is especially pronounced in clusters built using the value set name similarity measure, where almost all clusters (99.53%) were dense. This shows that not only are we able to extract clusters of similar value sets from a repository, but that value sets, at least in the VSAC repository, tend to be very closely clustered.

Our ability to infer connections between value sets is predicated on our ability to measure how connected, or similar they are. Utilizing two different similarity measures was assumed to produce different similarity connections, and thus, different clusters of related value sets. Table 2 shows that on average clusters computed using the two different similarity measures contained roughly 29% similar value sets. This indicates that while different similarity measures do indeed produce measurably different clusters, the clusters do show some degree of congruence. As value set similarity itself is inherently subjective and context dependent, we may be able to find underlying trends by looking at where different similarity measures agree.

A hierarchical structure was also successfully extracted from the repository. Figure 3 demonstrates that while the extracted hierarchy is relatively flat on average, some hierarchical structure does exist, and at times, can be as deep as 5 levels (see Figure 4). This is certainly an improvement organizationally over a flat list, especially since it required no manual curation or classification.

Our study purpose challenged us not only to extract structure, but to apply it in useful ways. As such, enhancing tooling with improved affordances for knowledge discovery is our end goal. In our previous work, we outlined the architecture for a value set management tool focused on usability\(^8\). We now leverage this toolset as our primary implementation platform. For hierarchy, Sunburst charts, or visual representations of hierarchy with radiating levels, have shown to be effective representations of hierarchical structures\(^5\). Figure 4 is an implementation of a Sunburst chart displaying an extracted VSAC value set hierarchy.

---

**Figure 4:** A Sunburst chart representing a value set hierarchy. Levels of hierarchy are represented as concentric circles radiating outward from a focus. In this example, the focus value set Mental Disorders is surrounded by radiating levels of hierarchy (shown left). On mouse-over, details of the value set Major Depressive Disorder New or Recurrent are displayed (shown right). The hierarchical path between the two is: Mental Disorders $\rightarrow$ Mental Disorders ICD10CM $\rightarrow$ Mental Health Diagnoses $\rightarrow$ BH Condition involving unipolar depression ICD-10-CM $\rightarrow$ Major Depression $\rightarrow$ Major Depressive Disorder New or Recurrent.

Clustering can be leveraged to suggest alternatives or possibly related value sets to users as they browse. Figure 5 depicts search results from a keyword search. Results found by traditional text-based searching are augmented by using See Also suggestions, where other members of the cluster are displayed as possibilities for further exploration.
In this study we have shown that data mining techniques can be employed to extract implicit relationships between value sets. These relationships in turn can be leveraged to add meaningful structure and organization to a repository. Ultimately, we show that these structures have practical applications in user-facing tooling, enhancing users’ ability to discover the correct value set for their use case, and thus, increasing value set reuse and general repository utility.

Limitations and Future Work

A limitation of our analysis is that hierarchy calculated by set containment algorithms may not always reflect the actual semantic hierarchies. There are certainly instances where a value set may contain a strict subset of codes from another but may not be a logical child, depending on context. Figure 6 illustrates one such example. In this case, the codes of Medication Fill Status are a strict subset of the codes of ProcedureActStatusCode and ProblemActStatusCode. It may be illogical (or at least context-dependent) to state that these value sets share a semantic relationship.

Future directions may include further integration of ISO/IEC 11179. Specifically, we look to consider data elements as a measure of value set similarity, such as grouping value sets by the data they describe (for example, grouping by object class or property). We also expect future work to focus on applying this process to value set repositories other than the VSAC to examine if hierarchies and clusters cross repository boundaries.

Acknowledgment. This study was supported in part by the LHSNet project (CDRN-1501-26638), the caCDE-QA project (U01 CA180940), and the BD2KonFHIR project (U01 HG009450). We also acknowledge Mayo Clinic’s Knowledge Management and Delivery effort, as well as the Rochester Epidemiology Project.

Abstract

Despite the shift towards collaborative healthcare and the increase in the use of eHealth technologies, there does not currently exist a model for the measurement of eHealth readiness in interdisciplinary healthcare teams. This research aims to address this gap in the literature through the development of a three phase methodology incorporating qualitative and quantitative methods. We propose a conceptual measurement model consisting of operationalized themes affecting readiness across four factors: (i) Organizational Capabilities, (ii) Team Capabilities, (iii) Patient Capabilities, and (iv) Technology Capabilities. The creation of this model will allow for the measurement of the readiness of interdisciplinary healthcare teams to use eHealth technologies to improve patient outcomes.

Introduction

The increase in the use of information and communication technology (ICT) in the delivery and administration of healthcare services has long been implicated to varying degrees as the cause of long term increases in health care expenditure [1–3]. Health technology more broadly however has and continues to have transformative effects on the delivery and administration of healthcare services. These transformations have significant implications for the efficacy and efficiency of the delivery of healthcare services to patients with the aim of improving health outcomes. Continued expenditure on health technology is inevitable. However, the total return on this investment could be improved through the existence of greater efficiency and effectiveness in use of health technologies by clinicians and patients. As such, need emerges for the determination of the level of fit that exists between a healthcare environment, its participants, and its technology.

The focus of this paper is to provide insight into factors that need to be considered for measuring eHealth readiness for healthcare teams, and in the construction of a conceptual model for the measurement of readiness in interdisciplinary healthcare teams. While this research aims to achieve an overarching understanding of the factors, there is a particular focus on eHealth and its application to healthcare within the domain of traumatic brain injury (TBI) rehabilitation. We developed a three phase methodology consisting of a qualitative study and literature review to identify relevant themes, construct and model formation, and model validation. From this methodology emerged a conceptual model for the measurement of the readiness of interdisciplinary healthcare teams to use eHealth technologies in the course of patient care.

Identification of readiness factors

eHealth technology has the capability and potential to transform the delivery of health services to patients everywhere. As it currently stands, there exists no model for the measurement of the ability for interdisciplinary healthcare teams to use eHealth in the context of the whole healthcare environment to improve patient outcomes.

There is a broad base of literature covering specific areas of eHealth such as the effect of public engagement [4], factors affecting clinician acceptance of technology [5], factors affecting team performance [6,7], organizational aspects of change and readiness [8,9] and factors affecting ongoing intervention participation[10].

Physician acceptance and decision to adopt eHealth technology has been identified as significant in explaining physician responses to technology [5,11,12]. As such, the level of technological acceptance by physicians and their decisions to adopt eHealth technology in their practice for their clients will form part of the assessment of the level of eHealth potential. In a study of 408 Hong Kong physicians, seven factors were identified as having significance in explaining physician technology acceptance: attitude, subjective norms, perceived behavioral control, perceived usefulness, perceived ease of use, and behavioral intention [5]. In a study of 519 responses by physicians practicing in the province of Quebec, significant factors influencing perceived responsibility were: perceived consequences,
personal normative belief, and self-identify [11]. Additionally, modelling of 114 Taiwan-based clinicians acceptance of eHealth found three factors with high explanatory fit; technology support and training, compatibility, and intention to use [12]. Factors concerned with physician acceptance of eHealth technology are necessities for diffusion into clinical practice [11].

Where eHealth technology is used by the patient in a setting such as their home, the level of acceptance in its use is likewise a necessity for improved clinical outcomes. Where the patient rejects or is unable to use the technology, the clinical outcome improvement is unable to be achieved. Investigation of such factors governing the engagement of patients with eHealth technology were determined as being: characteristics of users, technological functionality and issues, characteristics of eHealth services, social aspects of use, and eHealth services in use [4,10,13].

Factors have also been identified relating to the organization itself that affect employee engagement and acceptance of change. Culture and incentivization have been identified as contributing to employees having greater acceptance of change [14]. Management support and resource availability are also identified as being factors in organizational adoption of health technologies [12,15,16].

eHealth Literacy Toolkits

There are a number of frameworks which provide sets of measurement items and scales for constructs that have been established [17–20] to assess a participant's level of eHealth literacy. Norman and Skinner developed an eight item measure to ascertain the eHealth literacy of a participant (eHEALS) [17] with items concerned with patient competency with accessing health information found on the internet. The eight items are based on the six factor lily model [18] which establish the factors predicting eHealth literacy as: health literacy; traditional literacy and numeracy; computer literacy; information literacy; science literacy; and media literacy. Additionally there is the eHealth Literacy Assessment Toolkit (eHLA) [20] which similarly attempts to measure eHealth literacy and draws from the Norman and Skinner lily model and from the seven domains model [21].

The literature assessed is from a broad and fragmented body of work that has developed over the past five decades. The identification of relevant factors affecting the acceptance or the use of eHealth technologies is across three clusters: clinician, patient, and organization. Thus, these identified factors and clusters provide the basis for the formation of the conceptual model of eHealth readiness of interdisciplinary healthcare team.

Methodology

The goals of this research were to: (i) gain insight and an in-depth understanding of clinician perspectives of using eHealth technologies as an interdisciplinary team, (ii) develop a measurement model based on those experiences, and (iii) validate the model and propose a measure of readiness of an interdisciplinary healthcare team to use eHealth. The methodology combines qualitative and quantitative methods over three phases to devise a measurement. These phases are outlined below.

Phase 1 – Participant recruitment

Traumatic Brain Injury (TBI) was chosen as the domain due to the interdisciplinary nature of the work and the potential benefits that eHealth can bring to such work [22]. Thus, two focus groups and an interview were conducted to gain an understanding of the attitudes surrounding eHealth and interdisciplinary work within rehabilitation for people after TBI, with a third focus group used to confirm the content analyses of the two prior focus groups and interview [23]. Participants consisted of healthcare professionals working in TBI rehabilitation with two teams based in regional New South Wales (Australia), and the interview participant and the third team based in metropolitan New South Wales (Australia). Recruitment for all four studies was based upon the purposeful sampling technique [24].

Phase 1 – Focus group data collection

Four key questions were used to facilitate discussion between participants based on previously established principles [25]. The questions presented to participants were open-ended and aimed to elicit discussion [26] that uncovered the participants’ experiences with eHealth, the challenges they faced, and their attitudes towards the use of eHealth in
interdisciplinary healthcare. Additional sub-questions and visual prompts were provided as required to ensure that the discussion among the participants was relevant to the research questions.

Four researchers assisted with facilitating the focus groups and collecting data: the primary moderator, assistant moderator, and two assistants. All four researchers took notes on the discussion, and the discussion was digitally recorded and later transcribed verbatim. The transcripts were de-identified to ensure anonymity of participants and organizations. The transcripts were checked for accuracy against the digital recording by the researchers. The final transcripts and a summary of key points were then emailed to participants for verification (member checking). No request for alteration to the transcript or summary was made by any participant.

Table 1 Summary of participant demographics

Phase 1 – Focus group data analysis
A traditional approach was undertaken for qualitative analysis of the transcripts and is based upon the simple analysis framework by Krueger and Casey [28]. This involved the three main steps of: categorization of raw data, descriptive statements, and interpretation of data. As part of the first step, two researchers independently analyzed and categorized data into categories. The categories of raw data were then cross-analyzed and discussed by a group of researchers to ensure consensus and reliability in the development of descriptive statements for each theme.

Once consensus was achieved on the themes and categories of the data, these descriptive statements were interpreted. As the analysis of focus group data involves a level of subjectivity, care was taken during the analysis to ensure that bias was not introduced in the interpretation of the results. We took into consideration any researcher preconceptions, the specific words spoken by the participants and the context of their statements, and the internal consistency and specificity of statements. To reduce subjectivity, findings were strengthened by having two researchers analyze the data independently, with the results and main findings then given to an independent reviewer for validation.

Phase 1 – Themes from the literature
The primary purpose of the literature review was to identify additional factors which infer the readiness of interdisciplinary healthcare teams to use eHealth technologies in the treatment of patients to improve health outcomes to achieve the development of a model with greater content validity [29].

The themes that were identified within the literature were extracted through a process of interpreting the literary work and summarizing the themes identified within each piece of work. Where such themes were recurring across works in the literature or aligned with the pattern of themes within the focus groups, these themes were flagged for inclusion into the factors that would be used in the initial conceptual model.
Phase 2 – Model factor formation

The Resource-Based View (RBV) [30] was used to provide a framework through which aspects of the organization could be described in the form of a resource giving rise to capabilities where such resources contribute to the performance of the healthcare team specifically and the organization more broadly [31]. Each resource was considered to be a tangible or intangible asset in which the organization has invested in financially, materially, or temporally, and from which the healthcare team can reasonably expect to gain some benefit.

Using this definition of a resource, the factors that were identified within the literature review and the themes that emerged from the content and thematic analyses of the focus groups were transformed into discrete resources. Each conceptual resource was recorded as one or more written sentences describing the principle entity within the resource and the nature of the factor or theme. Hypothetical examples were included with the construction of the given resource if it was thought that such inclusion would clarify the meaning of the resource for the user of the model. In following this process, a link can be made between each focus group theme or literature factor and the set of resources that will make up the model.

Phase 2 – Model structure formation

A pre-existing model structure was used in the initial formation of the conceptual model with the HOT-fit model being used [32] owing to the model’s emphasis on the relationship and fit between the human, organizational, and technological factors in the environment [33].

The establishment of clusters of resources through the construction of three categories was performed with the categories being defined as: (i) User factors (analogous to the human factors) — which contained all resources where the healthcare team or the patient is the principle aspect of the resource, (ii) Organizational and external factors — which contained all resources relating principally to either the organization or factors external to the organization, and (iii) Technology factors — which contained resources principally related to the eHealth technology itself.

Due to the planned use of the Delphi methodology [add ref] with regards to the refinement and finalization of the conceptual model, the risk of information overload [34] was controlled through the use of sub-clusters to reduce the number of resources within each category of the model structure. Domains were established as categories of similar thematic content within the same cluster.

Phase 3 – Model content validation

The Delphi method [35] was used as the method to refine both the content and the structure of the model and to establish the content validity of the model [29] over a series of 3–5 iterations [36] allowing experts to systematically consider the complex problem of readiness measurements [37]. The stopping condition of the method is that of consensus being reached which is a satisfactory proxy for the content validity index’s stated purpose as a measurement of consensus [38].

The recruitment of the experts for the Delphi method occurred through a snowball technique utilizing recommendations of an expert within the information technology field. Experts were selected based upon their expertise domain with the final make-up of the Delphi panel consisting of five experts; four of whom were from The University of Sydney Faculty of Health Sciences, and one from The University of Sydney Faculty of Engineering and Information Technologies. All five experts were present for each of the three rounds required to reach consensus and each provided feedback into the process. At the end of each iteration the feedback was incorporated into the model and the revised model presented for discussion at the next iteration.

Phase 3 – Model construct validation

Q methodology [39] in the form of several q sorts previously developed as part of prior research [40] was used to assess the construct validity of the model through the assessment of the correlation of multiple individuals’ interpretation of the model resources [41]. If there is an appropriate similarity, then the interpretation of the resources and the placement of those resources within the model by individuals will be consistent with the theoretical a priori model, whereby construct validity can be established.

An open card sort and a closed card sort activity [42] were designed to have participants first sort all 59 of the resources of the model into four categories defined and named by each participant. Subsequently, the same participants then sort the same resources into four categories for which the names of the categories were given — the four names being those of the cluster names in the conceptual model. The participants were not aware of the names of the categories for the first sorting task. The card sort activities were performed using an online system and an offline system. Further construct validation is currently being undertaken using an online survey instrument to collect data for statistical validation.
Results and Analysis

The focus groups involved participants from organizations that provide services to the community with the aim of helping their clients transition back to their normal lives. While the team in focus group 1 (FG1) provide rehabilitation services for adults, the second and third focus groups (FG2 and FG3 respectively) provide rehabilitation services for both children and adults. The backgrounds of the three focus groups are similar, however FG2 and FG3 are managed under NSW Health while FG1 is managed externally to this network.

The participant from the individual interview (IP) is the principle of a Sydney metropolitan private practice that specializes in speech pathology services for adults with neurological impairments. Due to the nature of the industry, the participant operates as part of various interdisciplinary teams external to the practice on an ad-hoc basis.

Six main themes emerged from data analysis which are outlined in Table 2.

</table>

Table 2 Emergent Themes from Qualitative Study

Resource and structure formation

The operationalization of the themes from the qualitative study and the factors identified in the literature review resulted in the creation of an initial set of 44 distinct resources. These resources were categorized into three clusters: (i) the Organizational Capabilities cluster, (ii) the User Capabilities cluster, and (iii) the Technology Assets cluster. These categories were drawn from the HOT-fit model which was used as the initial foundational model for the structure formation. This structure and the contained resources were presented as the initial model for the consideration of the Delphi panel.

Delphi method implementation

The Delphi method was carried out over three rounds to determine the resources which would be used as a measure for each of the clusters of the model. At the completion of the third round consensus was given and it was deemed that the stopping condition, of reaching consensus, was achieved. The final model consisted of four clusters and 59 resources with 15 resources being included based on the feedback and agreement of the Delphi panel. Due to the consensus of the expert panel it was determined that the model possessed sufficient content validity.
Conceptual model construct validation

The q sort was undertaken to establish the construct validity of the model [29] where for a model with construct validity it would be expected that there would be convergence on the categorization of resources. The closed card sort was attempted by 12 participants and was successfully completed by 10 participants — that is they sorted all resources in the activity in a category. The participants of the sort were students from a health technology innovation class with individuals from clinical, health administration, and engineering backgrounds. The results of the sort were analyzed for convergence to identify which resources needing refinement. The evidence from the closed sorting task is that there does appear to be construct validity in at least three of the four clusters.

From the closed sort, there were six items of concern where less than 65% of the participants converged on the placement of the resource into a category — all six items were from the Technology Cluster. Additionally, there were two items — both from the Technology Capabilities cluster — which were categorized (with 70–80% convergence for both items) into a different cluster than that of the conceptual model. Where there is a miscategorization of a resource it must be determined whether the resource composition was the cause of the miscategorization or whether the participants interpreted the theme underlying the resource to be associated with a cluster different to that determined in the content validation phase.

The open card sort was attempted by 12 participants in total with 9 participants completing the activity. Overall 28 categories were created by 9 participants which indicated that some participants created greater or fewer than the four categories they were instructed to create.

The results of the open card sort were sorted into a hierarchical clustering using Ward's method [43] to determine the four clusters with the minimum within-cluster variance. The following themes emerged from the clustering: Organization, Users, electronic medical records (EMR), and Other Technology. However, the inter-cluster distance between EMR and Other Technology is minimal and it would be reasonable to merge them if the number of clusters was unrestricted. The emergent clusters while not significantly dissimilar to the proposed model do not reflect the expected clustering in some cases.

Discussion

The results from the qualitative study confirmed the issues raised in existing literature, including the need for rigorous evaluation of eHealth and the importance of considering the technology-environment fit. The findings also moved beyond the literature and present a conceptual model to measure the eHealth readiness — that is the technology-environment fit — of interdisciplinary healthcare teams. One of the most interesting findings from the study is that although the clinicians faced a number of challenges with regards to the use of eHealth and were unable to achieve the full benefits that it can offer, they presented positive attitudes towards eHealth. The majority of issues highlighted by the study are touched upon in the literature, however the focus is still largely on the technological aspects of evaluation such as functionality and the quality of the system, rather than having an equal focus on the external and environmental impacts on technology. Without understanding the inclusion of organizational factors such as procedures, policies, infrastructure, or even if the technology is effective, it is not likely to be successfully implemented. Thus, factors from both health technology and health informatics evaluation should be drawn to provide the foundation for a rigorous eHealth evaluation model that considers both the effectiveness of technology and the fit of technology within its environment.

Proposal of a health technology evaluation model

This study highlights the gaps within literature regarding the evaluation of eHealth within organizations. In particular, there is no evaluation model that considers the environment of health technology implementation within the context of a healthcare team and which includes factors such as the team or the organizations. The effect of this gap can be seen in the study, where eHealth was implemented with the belief that it can improve processes and client care, however these desired results were not observed. The results indicate that there is a lack of emphasis on particular elements in the evaluation of eHealth in literature such as infrastructure and policy. In the literature, many of these issues are often overlooked as being of lesser importance to factors such as technological and user impacts.

We propose a conceptual model that aims to integrate the two evaluation processes and bridge the gap between the evaluation of the health technology itself and the evaluation of the fit between the technology, its environment, and its users. These two processes need to be integrated to determine whether the technology is effective and safe to use, as well as consider the type of organization or individual that the technology is suited for. The proposed model consists of four clusters each containing domains which give rise to capabilities found to allow healthcare teams to implement and effectively use eHealth technologies for the improvement of patient outcomes. Current literature indicates the
challenges faced in the evaluation of non-traditional health technologies such as eHealth, however there is no coherent solution to bridging the gaps between the existing models. Thus, the proposed framework attempts to integrate health technology evaluation and health informatics evaluation to provide a means for the holistic evaluation of eHealth readiness in healthcare teams. The conceptual model (outlined in Error! Reference source not found.) consists of four clusters: (i) External Factors, (ii) Team Capabilities, (iii) Patient Capabilities, and (iv) Technology Capabilities.

<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Team Training Asset</td>
<td>Degree of training that a healthcare team has undergone regarding the use of eHealth, its integration into practice, and the effective operation as an interdisciplinary team.</td>
</tr>
<tr>
<td>Technology Use Asset</td>
<td>Measure of the use of eHealth by the healthcare team, the level of technology literacy of the healthcare team, and the extent of difficulties in using eHealth.</td>
</tr>
<tr>
<td>Leadership Asset</td>
<td>Activeness of the healthcare team’s diffusion of eHealth within the organization.</td>
</tr>
<tr>
<td>Communication Asset</td>
<td>Ability of the healthcare team to communicate ideas and concerns effectively and efficiently with external entities and within the team.</td>
</tr>
</tbody>
</table>

**Table 5** Team Capabilities: Domains and Descriptions

**Patient Capabilities**
The Patient Capabilities cluster (Table 6) measures the perceived and measured capabilities of the collective patients treated by the healthcare team to utilize eHealth practices and technologies in improving clinical outcomes. If the patients receiving treatment from the healthcare team are on average unable to use eHealth technologies then the team is as a function of this unable to use eHealth technologies in the patient care and as such the measured readiness of the team to use eHealth technologies will be low or non-existent.
### Technology Capabilities

The Technology Capabilities cluster (Table 7) seeks to provide a measure of the sufficiency of eHealth technologies, the support provided for those technologies, and the physical access afforded to those technologies in allowing for clinical teams to improve the health outcomes of patients. It is anticipated that a high measure in this cluster would correlate with increased efficiency of administrative tasks, increased availability of patient information, the timely provision of information technology support, or the provision of appropriate devices and internet infrastructure to allow for clinical teams to access patient information and other health information when required.

<td>The ability of the healthcare team and patients to access and obtain support for eHealth technologies used in the care of patients.</td>
</tr>
</tbody>
</table>

### Limitations

There are a number of inherent methodology limitations concerned with the qualitative study, the Delphi panel, and the q sort used. The content and thematic analysis conducted on the data from the qualitative study was based on limited non-saturated data which was subsequently supplemented by literature. Owing to this non-saturation it may be that the content validity of the model is limited. The experts used in the Delphi panel were drawn from a pool of individuals from the same research group. This limitation may cause the content validity of the model to be weaker than anticipated. The population used for the q sort had several limitations including that they may not have been representative of the wider healthcare population, that none of the participants were regionally based, and that the population used was small. Additionally, a varying number of categories were created per participant. This will affect the hierarchical cluster analysis as the distances between resources may result in the cluster formation not being representative of the participant’s intent. Further construct validation is as such being currently carried using an online survey instrument being disseminated to healthcare professionals.

### Conclusion

Health technologies and eHealth specifically have the potential to transform the delivery of healthcare services to patients for the purposes of improving health outcomes and quality of life for those patients. Such use of technologies however, is expensive and sustainable expenditure must be established within the framework of existing healthcare systems. Additionally, the value of eHealth technologies used in the delivery of healthcare services is limited by the skills, knowledge, and support available to both healthcare teams and patients — where an ineffective environment for the engagement with such technologies minimizes any beneficial outcomes that may be obtained from the use of the technologies.

The methodology framework has led to the proposal of the four-factor model with content validation and initial construct validation being found. Further work is currently being undertaken to provide construct validity of the measure using an online survey instrument. We believe that this conceptual model provides a foundation for the aggregation of multi-discipline constructs for the purposes of the creation of a measurement model. This model specifically targets interdisciplinary healthcare teams and their readiness to use eHealth and provides at the least a validated set of resources which should be considered for inclusion into future quantitative models.

Challenges with Collecting Smoking Status in Electronic Health Records

1Columbia University, New York, NY; 2NewYork-Presbyterian Hospital, New York, NY

Abstract

Smoking is the leading cause of preventable death in the United States. Obtaining patients’ smoking status is the first step in delivering smoking cessation counseling. In this study, we assessed the quality of smoking status captured in an electronic health record from a large academic medical center. We analyzed data from structured notes, finding that smoking status was documented in 98% of 64,451 hospital encounters in 2016. 32% hospital encounters had discrepant documentation, and 54.5% of patients had implausible changes (e.g., changes from “current smoker” to “never smoker”). Overall, only 2.9% of patients were documented as active smokers, but 36.4% were documented as “unknown” or had discrepancies in their smoking status. These results suggest that patients that smoke are not appropriately identified. Centralized documentation with clinically actionable smoking status categories and implementation of patient-facing tools that allow patients to directly record their information could improve data quality of smoking status.

Introduction

Smoking is an important risk factor for multiple diseases, including cardiovascular diseases and numerous types of cancer. It remains the number one cause of preventable death in the United States.1 The collection of patients’ smoking status during clinical encounters is critical to providing patients with resources to quit smoking. Smoking cessation can be difficult, and clinical visits are opportunities to intervene and recommend smoking cessation programs and therapies. Obtaining a patient’s smoking status is a crucial step in beginning smoking cessation interventions and monitoring progress.2 It may seem that recording updates to smoking status in a timely and accurate manner would be straightforward using modern electronic health records. This may not be the case for several reasons, including lack of standard terminology and granularity for data collection, shifting cultural attitudes regarding tobacco use, and potentially frequent changes in individuals’ smoking behavior.3,4 As the American author, Mark Twain, famously quipped, “Giving up smoking is the easiest thing in the world. I know because I’ve done it thousands of times.”

Given the clinical importance of smoking status, the “Meaningful Use” financial incentive program for electronic health record (EHR) adoption in the U.S. included a requirement for healthcare providers to capture patients’ smoking status electronically in structured fashion.5 Meaningful Use has helped to standardize data collection of smoking status and other information. However, even with improved standards for representing information, data quality issues have persisted in many patient-provided data types, such as race and ethnicity6,7 and family history.8,9 Previous studies on data quality have shown that clinicians describe a need for free-text documentation for expressiveness of documentation; however, these affordances challenge data reuse.10

Appreciating the challenges associated with data quality and the balance between the expressiveness of free-text and the benefits of structured data, we set out to answer a very simple question: how many of our hospital’s patients are known to be active smokers? We undertook a study to analyze how smoking status is currently being collected in a large academic medical center and to evaluate the quality of this data in EHRs.

Methods

We conducted a retrospective analysis of smoking status related data from the Allscripts Sunrise EHR (Allscripts Corp., Chicago IL) used at NewYork-Presbyterian Hospital/Columbia University Medical Center. We included patients that had at least one hospitalization during 2016, specifically patients that were discharged between January 1, 2016 to December 31, 2016.
The EHR system contained thousands of active templates for documentation. Each of these templates contained one to several hundred discrete observations. An observation could be a text box, a Boolean (e.g., a checkbox or radio button), or numeric value. We identified observations in which the description contained the stemmed words “smok”, “cigar” or “tobacco” and queried the EHR database to identify the number of times each one of these observations have been recorded during the study period. The value can be either textual (e.g. when the parameter is “Cigarettes (packs per day)”) with the response typed into a free-text box, or it can be structured (e.g. selected from a picklist). The picklist is often shown as a set of radio buttons that users can pick one. For example, there is a parameter labeled “Tobacco Use / Smoking Status”, and one possible choice in the picklist is “Never smoker.”

Exploratory analysis showed that 94% of patients had at least one structured smoking status observation recorded in a structured field. Based on this finding, we chose to use only the structured data for the remainder of the analyses. For comparison purposes, we classified smoking status into one out of four possible categories: “Current smoker”, “Former smoker”, “Never smoker”, and “Unknown smoking status” as described in Table 1. Observations such as “n/a for age” or “as per pt” were excluded from the analysis. Differences in smoking status recording were classified into two distinct categories: plausible, when the change is feasible to happen, and implausible, when the conflict is not possible to happen or in cases where there is loss of information. The description of this classification is illustrated in Figure 1. We also calculated the time interval (in days) between smoking status documentations to better understand the distribution of the data during the one-year study period. For example, time interval of zero means that both observations were recorded in the same day, time difference of one means that the second observation was recorded one day after the first one was recorded.

Furthermore, we analyzed the discrepancies in smoking status reported for the same patient during the same visit, using data from different clinical notes in the EHR. We also investigated the discrepancies of smoking status recorded by different provider types (e.g., nurses, medical doctors, care coordinators, social workers). To analyze if provider types would have an impact in the number of discrepancies observed, we calculated the number of distinct provider roles recording smoking status for each admission. We then compared the number of distinct provider roles for patients with and without discrepancies in the smoking status recorded.

Overall, data quality of smoking status was assessed based on the percentage of patients with consistent and informative smoking status available (i.e., not classified as “Unknown” in the database, and not conflicting).

Results

Overall, we reviewed 48,909 patients having 64,451 hospital encounters in the one-year study period. We identified 203,048 observations of smoking status for 47,849 unique patients across 62,988 distinct hospital encounters. No smoking status documentation was identified for 1,463 visits from 1,060 distinct patients, representing 2% of the number of hospital encounters and 2% of the overall number of patients. In other words, 98% of patients and 98% of hospital visits had documentation regarding the patient’s smoking status. Of those records with smoking status, 59,663 visits (93%) from 45,822 patients (94%) had this information recorded in structured format. After pre-processing, 45,771 patients (94%), including 59,593 visits (92%) and 129,134 observations were classified into four distinct smoking status categories. The number of observations and the mapping to the simplified smoking categories are described in Table 1. The description of smoking status data during the one-year study period is described in Table 2. Patients had an average of 1.3 visits/patient during the study period, with the maximum number of visits a single patient being 23 visits.

Longitudinal One-year Review

Overall, 15,048 patients (32.9%) had smoking status recorded in a single note, and 30,723 patients (67.1%) had more than one note with documentation regarding smoking status. Among the patients with more than one note with smoking status documented, we identified 83,363 changes in documented smoking status collected longitudinally during the one-year study period.

Among the changes in smoking status documentation, 32,582 (39.1%) had a conflicting smoking status. These discrepancies were observed in records from 15,207 distinct patients, representing 33.2% of our study population. However, because we are working on longitudinal data and smoking status is not a static concept since it can change over time, some of these discrepancies are feasible to happen. For example, someone that never smoked can become a smoker. Others, however, are implausible. For example, a non-smoker cannot become a former smoker, or a current smoker cannot become a never smoker, unless some of the data was recorded incorrectly. Other changes are
plausible, however not good from a data quality standpoint. Having a patient with documentation regarding smoking status and later not having smoking status (smoking status as “unknown”) demonstrates loss of information. Implausible changes as well as changes from a well-defined smoking status to uninformative category were considered discrepancies due to data quality issues. We identified 17,757 discrepancies (implausible changes and loss of information changes), which constituted 54.5% of changes, in 10,836 distinct patients. These discrepancies are represented in Figure 1 as dashed lines, while the other changes are represented in continuous lines.

Table 1. Description of the mapping from smoking status categories as recorded in the EHR to the four clinically actionable categories. Smoking status categories documented in the EHR that utilize the standard criteria defined by the Meaningful Use program are highlighted in bold.

Figure 1. Changes of smoking status overtime. Dashed changes demonstrate implausible discrepancies and continuous lines represent plausible changes in longitudinal data. The number of changes recorded in our sample is reported in parentheses and the percentage it represents for each category is included in the figure.

On average the time interval between different smoking status documentation was 11 days, with a minimum of 0 days (same day documentation), and a maximum of 362 days. Most patients (80.6%) had a time interval between documentation events of less than or equal to 10 days, with 61.1% of patients having a subsequent documentation event within one day of the previous event.

Figure 2. Number of smoking status changes by time interval documentation. Time interval is measured in days. Number of status changes is represented in logarithmic scale. CDF = cumulative distribution function.
Duplicate Assessments During the Same Hospital Encounter

While it is plausible to observe changes in smoking status over the course of one year, smoking status should not change during the same hospital encounter. Given this rationale, we considered all changes during a hospital encounter to reflect a data quality issue, since smoking status should be consistent throughout a single admission. During the study period, we identified 59,663 distinct encounters from 45,822 patients. Of those, 32.2% of the hospital encounters (19,176 visits) had at least one conflicting smoking status recorded, which includes 14,798 patients (32.3% of our cohort of patients).

Discrepancies Among Various Provider Roles

For patients with a smoking status recorded in a structured field, 70.8% were documented as part of nursing notes, 12.9% came from social work notes, 11.6% from physician notes, and the remaining (4.7%) from notes entered by other health care professionals.

Among hospital encounters with more than one assessment of smoking status, encounters with documentation from a single role of provider (e.g., nurse) had fewer discrepancies compared with encounters containing smoking status assessments from providers with disparate roles (Table 3). For example, if multiple nurses documented smoking status during an admission, the number of distinct provider roles would be equal to one. However, if multiple nurses and multiple physicians documented this information, then the number of distinct provider roles would be two.

How many patients are smokers?

Overall, 54.2% of the patients in our sample were classified as non-smokers, 6.5% as former smokers, 2.9% as current smokers and 3.2% as having unknown smoking status. The remaining 33.2% of patients had at least one discrepant assessment of smoking status documented. We determined that only 63.6% of our study population had a consistent, unchanging smoking status during the one-year study period (Figure 3).

Figure 3. Smoking status of patients seen in 2016.
Discussion

The Centers for Medicare and Medicaid Services (CMS) Meaningful Use program requires participating healthcare providers to record patients’ smoking status in a structured fashion. The program specifies eight distinct categories for collecting smoking status: “Current every day smoker”, “Current some day smoker”, “Former smoker”, “Never smoker”, “Smoker, current status unknown”, “Unknown if ever smoked”, “Heavy tobacco smoker” and “Light tobacco smoker”.

We identified smoking status assessments (either represented in free-text or structured fields) for 98% of patients and 98% of visits. When focusing on structured documentation, we observed that 94% of patients and 92% of visits had at least one structured smoking status observation recorded.

Despite the well-known and well-described importance of collecting smoking status, our institution’s EHR did not have a centralized location to store smoking status information. Smoking status was collected as part of clinical notes, in either structured or free-text format. The fact that disparate healthcare providers recorded this information in several different notes resulted in many inconsistencies across notes. Further complicating the matter, different note templates allowed for different granularities of smoking status data collection. Some templates included a free-text box that allowed clinicians to enter details such as intensity of smoking, number of cigarettes per day, or when the patient stopped smoking. Other templates had only the Meaningful Use-required structured fields embedded.

When analyzing smoking status data in the EHR, we transformed the Meaningful Use categories and other smoking status assessments into four clinically actionable categories: “Current smoker”, “Former smoker”, “Never smoker” and “Unknown smoking status”. We observed that a 33.2% of the patients had inconsistencies in the documented smoking status during the one-year study period and 32.3% of the patients had at least one discrepancy during a single visit. These discrepancies suggest that reliable information on smoking status may not be available for a large number of patients.

Since we used longitudinal data, and smoking status is not a static concept (i.e., it can change over time), we classified smoking status changes into two distinct categories: plausible and implausible. In our study, implausible changes constituted 21.3% of all changes. Previous research has also identified consistency issues regarding tobacco use recorded in different notes in EHR systems. For example, in 2016 a research study used natural language processing to parse clinical notes and extract smoking status from various clinical notes. The authors identified several inconsistencies when comparing smoking status recorded in clinical notes.

Inconsistencies can be attributed to challenges in the data collection process, including clinician-related and patient-related factors. Clinicians may not inquire at all about a patient’s smoking status, or they might ask the question in a manner that leads to bias in the patient’s answer. Depending on how clinicians phrase the question, patients may not feel comfortable answering. On the other hand, patients may have their own motivations to be less than truthful when providing smoking status information to clinicians, or they may inexplicably provide different smoking status responses depending on the person asking.

We conducted an analysis to identify whether hospital encounters with more than one clinical note without discrepancies were more likely to have documentation from a single provider role than encounters with discrepancies. Interestingly, we identified that encounters with multiple notes documented by the same type of provider had less discrepancies than patients with documentation from multiple types of providers. The difference we observed in discrepancies may be explained by the fact that clinicians usually do not read notes from other clinicians’ roles. Previous studies have shown that most clinical notes are not read by the entire clinical team. Instead, clinicians may be more inclined to read clinical notes from their peers (i.e., within the same provider role).

While it is important for multiple providers to assess patients’ smoking status, barriers to accessing previously documented information regarding tobacco use by healthcare providers may increase vulnerabilities that allow discrepancies to propagate.

Going back to our initial question of “how many patients are current smokers?” -- the answer is, we do not know. Based on the analysis conducted in this study, more than half of the patients during the one-year study period were recorded consistently as non-smokers and just 2.9% were recorded consistently as current smokers. In contrast, other population-based studies estimate that 15.1% of adult Americans smoke. One-third of the studied population had inconsistencies in their smoking status, making the determination of tobacco use for these patients difficult. While smoking status was documented in 98% of hospital encounters (and therefore the criteria of Meaningful Use were
satisfied), our one-year sample of hospital encounters did not contain consistent smoking status information for 36.4% of patients.

One limitation of our analysis was the use of data from only a single year and from only a single healthcare system. During a one-year period within our EHR system, we found that 33.2% of patients had discrepancies in documentation of smoking status. Furthermore, 54.5% of those inconsistencies were deemed implausible (Figure 1). Most patients had changes recorded within 10 days of the previous smoking status assessment. Given the short time difference between documentation events, even plausible changes (e.g., converting from “current smoker” to “former smoker”) seem unlikely. These data quality issues demonstrate just some of the considerable challenges healthcare providers and secondary users of EHR data. If we have difficulty in identifying a single meaningful and consistent smoking status using only one-year worth of data, the use and sharing of multiple years of data present even bigger challenges. For example, for encounters with conflicting smoking statuses, which one should be used in a clinical decision support system related to smoking cessation? Or which one should be reported to external organizations? Efforts using smoking status information from EHRs, including future smoking cessation initiatives, should further investigate patients identified as “Unknown smoking status” as well as patients with discrepancies in smoking status.

**Recommendations**

In this study, we observed that smoking status is currently being collected as part of clinical notes by multiple healthcare providers, and for almost all patients. The categories used are not consistent across clinical notes, recording smoking status in different granularities. We propose the use of four distinct clinically actionable categories: “Never smoker”, “Current smoker”, “Former smoker” and “Unknown smoking status”. More detailed information for each one of these could also be collected in a standardized fashion, such as “packs/day” and start and quit date. Currently, this additional information is being captured in free-text format and inconsistent across notes (e.g. some use packs/day while other record this information as cigarettes/day).

In our institution, smoking status is not stored in a centralized location, but is rather being collected as part of disparate clinical notes. The current system of data collection of smoking status presents challenges consistently collecting this information. While it is important for multiple providers to collect patients’ tobacco use information, the fact that this information is collected and stored in various notes without standardization makes it challenging for clinicians to know if the patient already provided their smoking status to other clinicians, and whether this information is longitudinally consistent. In an attempt to solve these challenges, we propose to store patients’ smoking status in a centralized fashion and having clinicians verifying this information in every encounter by asking patients about tobacco use.

One way to improve the consistency and correctness of patient-reported information, such as smoking status, is to allow patients to review and update their own information. This task can be facilitated by health information technology in many ways, including the use of patient portals and tablet computers for this task. Patient-facing tools have been used for collection of multiple patient-provided data types such as race and ethnicity, family history, symptoms, medication reconciliation and adherence. These studies have shown that patients are willing to provide and review their information\(^ {14-16}\), that EHR data is often incomplete or inaccurate\(^ {6-8,17-23}\) and that patients can identify discrepancies, provide useful information and help keeping records up-to-date.\(^ {18,24-26}\) Studies have also shown that there are many benefits of involving patients in their care, including improving patient engagement, patient satisfaction, health behaviors and health status as well as helping to attract and retain patients.\(^ {27,31}\) With patient-facing tools, patients could provide their smoking status based on the four clinically actionable categories, as described above. Patients providing this information to a computer could also mitigate the potential biases introduced by clinicians asking the question.

**Conclusion**

In summary, while 98% of hospital encounters at our institution during 2016 contained information regarding the patients’ smoking status, 32% of the encounters had discrepancies in smoking status information. For encounters with more than one clinical note documenting smoking status information, 54% of the subsequent documentation events had implausible changes. While other sources suggest that approximately 15% of adult Americans smoke, only 2.9% of our patients were consistently documented as current smokers. This finding demonstrates that while
Meaningful Use has improved data collection of smoking status in terms of completeness, we may not be appropriately identifying patients that smoke. Centralized documentation with clinically actionable smoking status categories available for data collection, and implementation of patient-facing tools that allow patients to directly record their information, may help improve data quality of smoking status in EHRs.

Abstract

During the 2014 West African Ebola Virus outbreak it became apparent that the initial response to the outbreak was hampered by limitations in the collection, aggregation, analysis and use of data for intervention planning. As part of the post-Ebola recovery phase, IBM Research Africa partnered with the Port Loko District Health Management Team (DHMT) in Sierra Leone and GOAL Global, to design, implement and deploy a web-based decision support tool for district-level disease surveillance. This paper discusses the design process and the functionality of the first version of the system. The paper presents evaluation results prior to a pilot deployment and identifies features for future iterations. A qualitative assessment of the tool prior to pilot deployment indicates that it improves the timeliness and ease of using data for making decisions at the DHMT level.

Introduction

The 2014 West African Ebola Virus Disease (EVD) outbreak led to the deaths of over 11,000 people across the three worst affected countries: Guinea, Liberia and Sierra Leone1. A key factor in curbing the outbreak was data management and use in i) case management for patients, ii) operational and logistics planning for the response, and iii) community engagement for outbreak mitigation2. Knowledge of the viral transmission rate, the number and location of suspected cases and their contacts, estimated time of infection and the resources available at health facilities was vital for containing the 2014 EVD outbreak.

The Ministries of Health in the three most affected countries and the partners involved in the EVD response developed a plethora of digital and paper-based data collection solutions to provide real-time data to plan interventions. These tools produced a large number of datasets that were owned and stored by the various partners. A number of digital data collection solutions, such as KoboToolbox3 and CommCare4, as well as custom-built tools, were used to collect data in-field. Several organizations utilized existing data portals during the outbreak, such as Humanitarian Data Exchange, or developed new portals such as Ebola GeoNode and The World Health Organization Data Coordination Platform (WHO DCP), making these digitized datasets available for use across multiple partners.

The process of data collection and sharing was highly fragmented, leading to delays in data availability. For example, delays of several weeks were reported for data entry into the Centers for Disease Control's (CDC) Viral Hemorrhagic Fever (VHF) database2, with up to 50% of confirmed cases in the database lacking outcomes data2. The delays were exacerbated by the lack of a central coordination authority for data and the high turnover of staff, leading to a loss of institutional knowledge of the data available. In addition, digital solutions could not be implemented in all areas due to limited access to power and mobile networks, resulting in duplicate paper-based and digital systems. The Fighting Ebola With Information report produced by USAID extensively discusses the challenges with using data during the EVD outbreak2. While some of these issues were due to the organization of the international response, local infrastructure and skills capacity, there were additional challenges that could potentially have been addressed by technology solutions, as discussed below.

Competing reporting requirements: District-level staff had competing reporting requirements from different agencies and donors for the same data. Manually creating multiple reports was time-consuming, and limited the time available for operational and planning tasks.
Lack of standards for data entry: This could be broken down into three areas: entity resolution, lack of standardized definitions, and lack of standardized collection formats. Entity resolution was difficult due to the large number of entities, particularly facilities and places, with the same or similar names. Lack of standardized definitions led to incompatibilities between datasets e.g. different case definitions were used for reporting EVD cases in different districts. Finally, the lack of standardization of forms and terms between partners made it difficult to verify, collate and use data collected by different organizations.

Lack of structure and security for data sharing: The United Nations Mission for Emergency Ebola Response (UNMEER) was created to support the EVD response across affected countries. However, since it was a new organization, there were no data sharing policies established beforehand, resulting in a lack of clarity over how data could be shared. This led to data sharing delays or in some cases, data not being shared at all. Conversely, data with personally identifiable information were shared through platforms such as Dropbox, Google Drive and emails due to the lack of a secure sharing platform. Even where datasets were shared, information on metadata and version control was difficult to find or resolve.

Siloed data: Digital data collection tools deployed during the outbreak were largely set up as one-off pilots, with different applications built by different organizations to collect the same data in different regions. This resulted in over 300 new, digital solutions being deployed across Sierra Leone, Liberia and Guinea. These data terminated in a multitude of web endpoints, making it difficult to collate similar datasets.

Timeliness and quality of data for making decisions: Digital collection of data in low-resource health settings can improve the timeliness of data collection and reporting, and the quality and completeness of data. However, key information was often shared in non-machine readable formats, such as the CDC and The World Health Organization (WHO) case data that were reported as weekly Situation Reports in PDF format. These had to be manually entered into machine readable formats, delaying decision-making processes.

Skills in the health management workforce: The high volume of digital data collected required analysis by data teams skilled in using software packages, such as QGIS and R. However, the number of personnel trained to conduct the required analyses remained consistently insufficient throughout the outbreak.

In partnership with Port Loko DHMT and GOAL Global, we have developed a system that aims to address the challenges listed above by enabling easier and faster sharing and analyses of health data, for the prevention and detection of large-scale infectious disease outbreaks. The system was designed and developed to improve epidemic preparedness in the district by enabling fast detection and response in the event of an outbreak. Port Loko district, located in the northwest of Sierra Leone, was one of the areas hit hardest by the EVD outbreak. Below, we outline the requirements gathered for the system, an overview of the initial system developed, and the formative evaluation of the system gained through feedback from users during development and a pre-deployment qualitative evaluation.

Methods

User requirements: Initial user requirements were determined in collaboration with DHMT members. Process maps were created in consultation with the DHMT for each of the three datasets used for the system: Integrated Disease Surveillance and Response (IDSR), Infection, Prevention and Control (IPC) and Alerts (district-level reports of deaths or serious disease incidents in the community). During the in-development formative evaluation, the DHMT also helped to identify the key pain points in the current processes, which informed the user requirements. Other requirements for the system were gathered from DHMT team members iteratively using Scrum, a methodology comprising of a loop of ideation, software development, user demos, feedback from end users, and redesign over sprints for a period of six months. User requirements were classified into the following categories: 1) core functionality, 2) backend analytics, 3) usability, 4) security, and 5) network.

Systems requirements: System requirements were determined through an evaluation of the hardware available at Port Loko DHMT, and the needs for such a system beyond pilot scale deployments. These were classified into the following categories:

1. Hardware: What hardware is currently available at DHMTs?
2. Connectivity: What is the current network speed achievable at the DHMT?
3. Scalability: How can the system be scaled nationally and internationally?
4. Extensibility: Can additional functionality be added to the system without needing to redesign the architecture?
5. Data security regulations: Does the system comply with existing data security regulations in Sierra Leone?
**Formative evaluation:** In addition to the iterative feedback captured in the Scrum process, the first version of the system was evaluated through focus group discussions, one-on-one interviews, and a task completion exercise with key stakeholders in the DHMT. The focus group was conducted with DHMT members from the IDS, IPC, and Alerts teams. It was used to identify changes in process maps and data models from those captured at the start of the design process. This ultimately provided the baseline of processes used in disease surveillance and control prior to a pilot deployment of the system. The formative evaluation was also used to ascertain how users had interacted with the system to date, as they had access to the system during the iterative development. The focus group and interviews focused on four questions:

1) What are the key decisions that need to be made and by whom?
2) Which datasets are currently used to make these decisions?
3) What analyses are required to inform and support these decisions?
4) What technologies are currently used or are available to conduct the required analyses?

Individual interviews were conducted with key personnel and managers in the DHMT to understand how they had used, or planned to use, the system as part of their workflow, and to capture detailed feedback on the design of the system. Finally, as part of the one-on-one interviews, a task completion exercise was conducted, in which the interviewees were asked to retrieve and interpret a specific piece of information using the system. The goal was to assess the ease of manipulating data using the system.

The system was piloted from October 2016 to January 2017. The results discussed in this paper are from the iterative design process and the pre-deployment baseline study (conducted in September 2016) described above. The authors plan to publish a separate report on the findings from the pilot.

**Results**

**User and system requirements:** The user requirements gathered through the focus groups and one-on-one interviews could be clustered into five categories: core system, analytics, network, usability and security. Details of specific requirements are given in Table 1. The systems requirements were determined by the existing infrastructure at the District Health office in Port Loko, and are given in Table 2.

**System Architecture:** A schematic diagram of the architecture is given in Figure 1. The system comprises of four modules: i) data and data models, ii) data cleaning and curation services, iii) analytics services, and iv) visualizations. The current version of the system is built on a Python Django framework backend and AngularJS frontend deployed on a Red Hat Enterprise Linux 6.5 server. The backend was developed in Python 2.7 as established Python libraries for data manipulation, machine learning and natural language processing were available. The system is modular, and uses services exposed through Application Program Interface (API) calls. Optimization mechanisms such as minification, caching and background data processing were used to improve the performance of the system for use in areas with very low bandwidth.

The system was deployed on a remote, secure server with HTTP protocols. To access and use the system, users connected to the machine via a VPN connection. Once their log-in was authenticated, they could view pages for which they had authorization.

**Data and data models:** In the current implementation, datasets are uploaded via APIs to a Postgres database. A Postgres database was used due to its ability to ingest relational data.

**Data cleaning, curation, and analytics services:** Disparity in data standards across datasets necessitates that the system can dynamically create data models. Through Data Access Linking and Integration (DALI)\textsuperscript{11}, an IBM Research proprietary software, each file is processed and stored in its own schema. Relationships between schemas are created using semantic closeness between fields. Data cleaning and curation services ensure that relational formats (.xls, .csv, .dbf) can be uploaded into the system. Entities, such as health unit names, are resolved to a single identifier across datasets. These datasets are cleaned and curated using a series of API calls, utilizing new APIs for entity resolution and geocoding using OpenStreetMap place names. The backend analytics services for both health facility and community risk profiling were done using custom-built APIs.

**Visualization:** HTML, CSS and JavaScript were used to build the visualization dashboards.

Core functionality

The web application consists of four pages: Home, Health Units, Reports and Data Store. The charts on all pages can be exported as PDF files.

**Home Page:** The home page provides the DHMT management with an overview of reporting rates for the number of facilities reporting on time, late or not reporting, along with the aggregate risk levels (a description of how the risk level was calculated is given later). A screenshot of the page (Figure 2) shows the IDSR reporting rates for the district and the risk levels for a given week. The users can choose which administrative level (district, chiefdom and section) they wish to aggregate data over, and the week they wish to see.

**Health Units Page:** The Health Units page provides a list of the peripheral health units (PHU) in the chosen administrative level, prioritized by risk level, as shown in Figure 3. The page provides the DHMT with a view of the most at-risk facilities in a given week. A description of how the risk score is calculated is provided in the Analytics section. The color coding on the page is used to indicate which dataset triggered the alarm, along with a description of the alarm. If the user requires further information about the health facility, the user can click on the menu icon to the right to see a full report, including IDSR, IPC and Alerts data over time for that facility.

**Reports Page:** The Reports page consists of three subpages for each of the datasets: IDSR, IPC and Alerts. Each page provides a map with markers colored by risk level for each of the health facilities. In addition, it includes the reporting rates over time. For IDSR, the page also has an interactive graph of disease notifications, allowing the user to investigate trends over time. Components of the IDSR Reports page are shown in Figure 4. For IPC, the user can investigate specific measures (the assessment measures included were defined by members of the DHMT). For Alerts, the user can select specific case definitions, locations and age ranges. For all pages, the user can choose to view data for a given administrative level and over a range of dates.

**Data Store Page:** The data store accepts non-routine tabular data, such as ad hoc assessments and surveys to allow these data to be easily shared between the DHMT and partners. This page allows users to upload tabulated data and, if the data contains GIS information, to automatically map the data. Users can search across all data sets geographically, using a bounding box to select a geographic area of interest, or semantically. The semantic search utilizes the DALI semantic search API, which is based on ontologies from DBPedia$^{11,12,13}$. A screenshot of the data store page is shown in Figure 5.

**Analytics**

**IDSR, IPC and Alerts:** The risk level for IDSR was determined by whether a disease reported was classified as immediately notifiable$^{14}$, as described in Figure 6. The latest version of the IPC assessment available in November...
2016 was used, which consisted of nine sections on the availability, process and knowledge around protective equipment, decontamination, water, sanitation, screening and isolation. The IPC survey consisted of 68 binary questions, which are in turn converted into a percentage score. The thresholds for the risk scoring shown in Figure 6 are based on the MoHS thresholds used in the national IPC Excel template.

![Figure 2: The Home page provides an overview of the aggregate reporting rate (1) and risk level (2) of facilities.](image)

![Figure 3: The Health Unit page provides a list of health units in a given geographic area selected by the user (1), prioritized by highest risk score. The user can click on the report icon to see a full report for each facility (2).](image)

Alerts are reported by chiefdom through the national health emergency hotline, local district alerts lines or, during the outbreak, through conversations with Ebola responders. All alerts were entered into the eHealth Africa call center system, and the risk score was calculated based on deaths per 1000 population relative to the a baseline mortality value of 17.4 deaths of per month for Sierra Leone, based on data from 2012. The risk level for Alerts was determined by using a moving window to average the deaths reported in the previous four weeks, as given by Equation 1, in which \( N_c \) is the number of deaths per week in a given chiefdom, \( t \) is the current week number, \( P_c \) is the population in a given chiefdom in thousands and \( M.R. \) is mortality rate per 1000 population. The chiefdom was said to be high risk if the monthly mortality rate was below 17.4 deaths per 1000 population, not reporting if no deaths were reported, and low risk if \( 0 < M.R. < 17.4 \) deaths per 1000 population.

\[
M.R. = \frac{N_{ct} + N_{ct-1} + N_{ct-2} + N_{ct-3}}{P_c}
\]

*Equation 1*
Figure 4: IDSR Report page showing (1) health facilities color coded by their current risk level, (2) cumulative reporting rates for the chosen geographic area and (3) disease incidence trends for the chosen geographic area.

Figure 5: A screenshot of the Data Store Page. The user can (1) easily upload local tabulated data files, (2) map files with GIS information and search for files related to the selected file or word using semantic search, (3) view the data in a tabular view and (4) search for files by geographic area using a bounding box.

Performance
Network speeds were measured between clients in Nairobi, Freetown and Port Loko, and the remote server. Due to lower speeds and a less reliable connection, loading times for the first version of the system, which was not optimized, were considerably slower with a stable connection in Sierra Leone (80 seconds) when compared to Kenya (10 seconds). The system was optimized to meet the loading requirement for the entire website of less than 5 seconds under normal conditions in Port Loko.
**Formative evaluation**

The following five key themes emerged from the formative and pre-deployment evaluations.

1) **Visually integrate multiple datasets for decision making:** Prior to the deployment of the system, each DHMT team (IDSR, IPC and Alerts) analyzed only their own datasets for presentation to the rest of the DHMT on a weekly basis. Having access to all three datasets, particularly side-by-side on the Health Units page, allowed users to contextualize information and interact with other data. For example, if a given PHU had an alarm for IDSR, the team could easily check the IPC risk score to see if there were sufficient measures in place to manage the case or cases recorded in IDSR.

![Facility risk score = IDSR score + IPC score (max = 8, min = 2)](image)

**Figure 6:** A schematic diagram of the facility risk scoring algorithm used in the deployed version of the system.

2) **Prioritization of information:** During the pre-deployment evaluation, several suggestions were made for refining the facility risk scoring. Specifically:

- Use of both the absolute number of cases, as well as the population normalized notification rate of an immediately notifiable disease in the scoring algorithm;
- Addition of a weighting factor based on reporting rates for expected death rate per chiefdom, since reporting rates have dropped significantly since the end of the EVD outbreak. The adjusted threshold could then be used to determine under-reporting more accurately. For example, $T_{\text{underreport}} = A r_{\text{reporting}} - M R_{\text{baseline}}$, where $T_{\text{underreport}}$ is the threshold for underreporting for a given chiefdom, $A$ is a constant chosen as the threshold below which an alarm is raised for underreporting, $r_{\text{reporting}}$ is the reporting rate based either from extrapolation of reporting rates over time or a value calculated during an audit, and $M R_{\text{baseline}}$ is the baseline mortality for the country.

3) **Converting decision making into action:** After interacting with the system, several users suggested incorporating a means to track the completion of follow-on actions, such as case investigations by the District Rapid Response Teams (RRTs) for immediately notifiable diseases, into the platform.

4) **Interface Omissions:** From the in-development and pre-deployment evaluations, several user interface omissions were detected. A Comparison page was added as a result of user testing. The page allows IDSR data to be compared between PHUs, and Alerts data to be compared between chiefdoms to enable the DHMT to quickly assess the relationships between PHUs of interest and to visualize trends across chiefdoms.

5) **Improvements to the timeliness of analysis and decision making:** The eight key users interviewed from the DHMT team found that the first version of the system reduced the time taken for the completion of routine tasks. Depending on the specific task, they reported the time taken was reduced to 5 to 15 minutes using the system, compared with 30 minutes to 8 hours using manual analysis. Overall, the system was found to be helpful by members of the DHMT for easy and quick visualization of data for making decisions. The team reported that they could use the system to generate reports and explore data in real-time for routine district health coordination meetings and partners’ meetings held at the DHMT.

**Discussion**

**Sustainability of the platform in the face of data changes:** Data structures changed significantly throughout the development process. During the 6-month scrum process, the IPC structure as provided by the MOHS/WHO changed five times, and the IDSR format was changed twice. While this affected system features, particularly in the
Building smarter epidemic preparedness systems: The initial analytics built into our system were based on the workflows described by users. However, through the formative evaluation, it became apparent that, once data were easily available and presented in such a way that it was easy to consume, users requested further analytics based on their current decision making processes. Some of these would be relatively simple to implement, such as including diseases that are not immediately notifiable in the IDSR risk calculation, and weighting the risk by the number of cases or the population normalized incidence. However, certain aspects are less clear: how should cases at referral facilities be weighted relative to primary facilities given what they are likely to see and be more prepared for more severe cases? In addition, the deployed system could allow more complex analytics, such as epidemiological models, to be run in real time, eventually allowing proactive planning for seasonal outbreaks, such as waterborne diseases during rainy season. Finally, this architecture opens up opportunities for providing further decision support, specifically around planning for potential scenarios.

Conclusions
This paper presents the design and evaluation of an epidemic preparedness system for DHMTs in low-resource settings. The system discussed in this paper was developed in partnership with, and for use by the Port Loko DHMT in Sierra Leone after the 2014 EVD outbreak. It integrates and analyzes multiple data sources and data types in near real-time. It was shown that such a system reduced the time taken for current workflows to five to fifteen minutes, compared eight hours to thirty minutes prior to the system, depending on the specific task. One of the key strengths of the deployed system was the ability for the DHMT to quickly retrieve relevant data for decision-making. For example, from the Home page, they can quickly drill down to see which facilities had not reported for that week, or which were reported as high risk. In addition, the Health Unit page allows users to quickly prioritize which data to look at. The formative evaluation indicated that a system that provides support for day-to-day operations at the DHMT across all programs, not just disease surveillance, would be valuable. Such a system would allow workflows to be tracked, and data to be automatically pushed to and pulled from systems such as DHIS2 and OpenMRS. The development and testing of the system demonstrated the feasibility of running a cloud-based health analytics service.
in a low-resource setting. The formative evaluation highlighted the potential of future versions of the system to enable higher level analytics and decision support to be introduced into the workflow of the DHMT, and for the integration of the system with public health information systems.

Acknowledgments
The authors would like to acknowledge USAID’s Fighting Ebola Grand Challenges (BAA-EBOLA-2014 AID-OAA-A-15-00041) fund for financially supporting this work. They would like to thank Port Loko DHMT and GOAL Global, Sierra Leone for their cooperation and technical expertise that made the project possible, particularly the GOAL Port Loko surveillance data team including Hilton Matthews, Alhassan Dumbaya and Ibrahim Yansaneh.

Stage-Specific Survivability Prediction Models across Different Cancer Types

Elham Sagheb Hossein Pour¹, MS, Rohit J. Kate², PhD

Abstract

For all cancer types, survivability rates vary widely across different stages of cancer. But survivability prediction models built in past were trained using examples of all stages together and were also evaluated on all stages together. In this work, for ten cancer types and using three machine learning methods, we built survivability prediction models trained on each stage separately and compared their performance with the traditional models trained on all stages together. For both kinds of models, the evaluation was done on each stage separately as well as on all stages together. Our results show that for most cancer types the stages are sufficiently different from each other that it is best to build survivability prediction models separately for each stage. We also found that evaluating survivability prediction models on all stages together, as was done previously, overestimates performance for all the stages on all cancer types.

Introduction

Cancer is one of the leading causes of morbidity and mortality worldwide with approximately 14 million new cases and 8.2 million cancer related deaths recorded in 2012, the latest year for which these numbers are available [1]. In the US, 25.52% of total deaths in 2014 were due to cancer making it the second leading cause of death after heart diseases [2]. Such high rates of morbidity and mortality have prompted researchers to build survivability prediction models for cancer [3, 4, 5, 6]. Accurate prediction of survivability can help physicians make more informed decisions about their patients’ treatment. For example, they may choose new medications or more aggressive therapies for patients with less hope of survival.

Cancer survivability is commonly defined as surviving for five years after diagnosis and its rate greatly depends on the stage of the cancer which is assigned based on tumor size and the extent of spread. Machine learning methods have been extensively used for building predictive models for cancer survivability [7, 8]. Although researchers in past have used a wide variety of machine learning methods and training mechanisms for building cancer survivability prediction models, they did not distinguish between various stages of cancer either during training or during evaluation. Stage was used only as one of the several features for building the models. However, it was recently found that for breast cancer the most suitable model to predict survivability for a stage is the model which was trained specifically for that stage [9]. It was also found that evaluating the models on all stages together, as was done in past, leads to an overestimation of performance. While that work was specific to breast cancer, in this paper we investigated whether those findings also generalize to other cancer types.

We built survivability prediction models using three different machine learning methods for ten different cancer types. To the best of our knowledge, it is the first work to report performance of survivability prediction models across multiple cancer types in a uniform experimental setting. This helps in generalizing the findings across cancer types. For each cancer type, we trained models for each stage separately and compared them with models trained on all stages together. We evaluated both types of models on each stage separately as well as on all stages together. Our results show that the findings regarding breast cancer [9] generalize to most other cancer types. The only few exceptions were for the cancer types with similar survivability rates across various stages along with insufficient number of training examples available for a few of its stages.

Experimental Methodology

Dataset

We used the publicly available SEER cancer dataset [10] for the experiments presented in this paper. This dataset is a collection of cancer incidences that happened in the US since 1973 in certain geographical regions that represent...
around 28% of the US population. The data is collected in an ongoing basis and the latest version used in this study covers years up to 2013 for a total of 9.18 million cancer incidences.

</table>

Although the dataset does not include any genomic information or detailed clinical information about patients, it includes several demographic and cancer related attributes for each incidence which can be used as features to predict survivability. Table 1 shows the features that we used in this work. These are largely the same features as have been used in the past work [5, 11, 12, 9] and their detailed descriptions can be found in the documentation of the SEER dataset [10]. Gold standard five-year survivability was determined using survival months, vital status recode and cause of death attributes of SEER dataset using the logic shown in Figure 1. SEER uses the summary stage system for cancer incidences. In this staging system, a cancer incidence can be in-situ (cancer confined to the layer of cells), localized (limited to the organ), regional (has spread to nearby lymph nodes, tissues and organs) or distant (has spread to distant lymph nodes, tissues and organs) summary stage. In past work summary stage was used only as a feature, but in this paper we built prediction models as well as evaluated them separately for each summary stage.

**Figure 1:** Logic used to determine gold standard five year survivability of patients from each cancer type. Survival months, vital status recode and cause of death are attributes in the SEER dataset.

Cancer survivability rates have improved over the years. For example, breast cancer 5-year survivability rate was 75.2% in 1980 in the US and was 90.6% in 2013 [13]. Similarly, it was 48.6% for colorectal cancer in 1975 and was 67.2% in 2013. Hence it is not advisable to use very old data for training and evaluating survivability prediction models. Codes of some of the attributes in the SEER data were redefined in the year 2004 and a few new attributes were also introduced. For the above two reasons, we decided to use only the part of the SEER dataset from the year 2004 onwards. Given that survivability is defined as surviving for five years after diagnosis, we had to also exclude incidences which were diagnosed less than five years before the latest year in the current dataset. The survival rate for in-situ stage is nearly 100% for all the cancer types hence we decided to exclude that stage for survivability prediction.
**Prediction Models**

In this study, we considered ten cancer types – bladder, breast, cervix uteri, colorectal, corpus uteri, esophagus, liver, lung, prostate and stomach. These are among the most common cancer types found in men and women [1]. About 1% of breast cancer incidences occur in men, but for this study we included incidences of only women. We built two kinds of survivability prediction models for each cancer type. For a cancer type, a model of the first kind was built to work for all stages and was hence trained using incidences of all stages together. We call this kind of model a joint model. Most previous work had used only this kind of model in which stage was used only as a feature. Our joint models also use stage as a feature (Table 1). For a cancer type, models of the second kind were built to work for each stage separately. Each model of the second kind was trained using incidences of only its particular stage. We call these stage-specific models. We compared joint models and stage-specific models for predicting survivability on the ten cancer types.

Both joint and stage-specific models can be evaluated on all stages together as well as on each stage separately. When evaluated on all stages together (test data consists of incidences of all stages), a single classification evaluation measure is reported for all the stages. When evaluated on each stage separately (test data consists of incidences of only one stage), a single classification evaluation measure is reported for each stage. Note that stage-specific models can be tested on all stages together by classifying each test incidence using the stage-specific model of that incidence’s stage.

**Machine Learning Methods**

We used naive Bayes [14], logistic regression [15] and decision trees [16] machine learning methods to predict cancer survivability. We did not use support vector machines [17] or neural networks [18] because they would take impractical amount of computational time on cancer types with very large number of incidences and in pilot studies we did not find them to perform better than the methods we used. All these methods have been previously used for cancer survivability prediction [7, 8]. We used the Weka software [19] for all the methods. Among various decision tree methods available in Weka, we used “ADTree” (alternating decision trees [20]) which we found to work best for our dataset through a pilot study. The three machine learning methods we used do not have any major parameter to set in Weka and we used Weka’s default values for all the minor parameters. We also used Weka’s default mechanism for handling missing feature values for each of these methods. However, cancer incidences that had the stage missing or the information to determine patient’s survival missing were excluded from our experiments.

Given the unbalanced nature of our dataset, from very high to very low survival rates among various stages of various cancer types, we used Weka’s cost-sensitive meta-classifier which relatively penalizes misclassifying minority class compared to misclassifying majority class in order to maximize classification accuracy across both the classes. The right weight was determined out of 0.25, 0.5, 1, 2, 4, ..., 18, 20 through internal five-fold cross-validation within the training data.

**Evaluation**

Separate evaluation was done for each cancer type. We used the standard ten-fold cross-validation to evaluate all our models. All folds were stratified to have the same distribution of stages and classes. For each fold, the training data used for the joint model was divided into disjoint subsets according to the stages of the incidences and each subset was used to train the corresponding stage-specific model for that fold. This makes the comparison between joint and stage-specific models fair. The test data was the same for each fold for both kinds of models. The exact same folds were used for each of the machine learning methods.

We used the standard area under ROC curve (AUC) [21] as our evaluation measure. ROC is a curve between a model’s true positive rate (fraction of positive examples correctly classified as positive, also called sensitivity) and false negative rate (fraction of negative examples incorrectly classified as positive, equivalent to 1-specificity). In our experiments, positive class is “survived” and negative class is “not survived”. ROC curve is independent of class distribution [22] which makes it a robust evaluation measure for our task in comparison to other evaluation measures such as precision and recall. Given the large number of evaluations in our experiments, we report only the area under ROC curve (AUC) which summarizes an ROC curve. A perfect classifier has an AUC of 1. When stage-specific models are evaluated on all stages together, their respective ROC curves for each stage needed to be

Table 2: Area under ROC curve (AUC) results comparing joint and stage-specific survivability prediction models built using the three machine learning methods. Separate models were built for each cancer type. A number shown in bold was found to be statistically significant (p < 0.05; two-tailed paired t-test) compared to the number in the same row for the same machine learning method. The numbers in the “All Stages” row of each cancer type can be seen to be misleadingly high when compared to the numbers for the individual stages.
combined into one ROC curve. We achieved this by considering all combinations of individual confidence thresholds to determine combined true positive rate and false positive rate to plot one ROC curve [9].

**Results and Discussion**

Table 2 shows the results obtained by both the joint and stage-specific survivability prediction models (shown column-wise) evaluated on all stages together as well as on each stage separately (shown row-wise). For each cancer type, the models were separately built and evaluated. The first two columns of the table show the number of incidences and survival rates of various stages of the ten cancer types. The rest of the columns show the AUC values obtained by the two kinds of models built using the three machine learning methods. Any AUC value shown in bold was found to be statistically significant (p < 0.05; two-tailed paired t-test) when compared to the corresponding AUC value of the other type of model in the same row for the same machine learning method.

Several observations can be made from Table 2. First, a broad observation is that survival prediction models generally obtain reasonable AUC values on all the cancer types. This indicates that the information present in the SEER dataset is good enough to build reasonably accurate cancer survivability prediction models.

Looking closely at the results obtained by evaluating the models on all stages together (first row of each cancer type) and evaluating them separately on each stage (rest of the rows of that cancer type), one can make a striking observation that the performance obtained on all stages is almost always higher than obtained on each individual stage. Although this appears counter-intuitive, there is an explanation for it. Given the differing survival rates of the three stages, from high for localized to low for distant, it is possible to obtain a seemingly high survivability prediction performance when evaluated on all stages together by simply making predictions strictly based on the stages. For example, calling everyone in the localized stage to survive and others to not survive will give a high accuracy because the predictions will be often correct. But such a predictive model is practically of little use because for a particular cancer incidence it does not tell anything more than what is already known. When such a classifier is evaluated separately on each stage, its performance will be as bad as a majority classifier that predicts every incidence to belong to the majority class. Hence this classifier will do well when evaluated on all stages together but will do very poorly when evaluated on each stage separately.

Learned models also suffer from this tendency because given the cancer survivability data they can easily learn to rank localized stage incidences above regional stage incidences and these in turn above distant stage incidences and thus similarly get a phony boost in performance when evaluated on all stages together. This is exactly what happened in the results shown in Table 2. The results obtained by evaluating on all stages together are thus overestimations of the actual performance. This was earlier observed for breast cancer [9]. Our results show that it is true for other cancer types as well. It is important to note that all past work had only reported performance on all stages together and were thus reporting overestimations. For the rest of the paper, we do not consider the results in the “All Stages” rows of Table 2.

Comparing joint models and stage-specific models for different cancer types and different machine learning methods taking into account statistical significance, one can observe that stage-specific models often do better than joint models. It should be noted that joint models always get examples of all the stages for training hence they get significantly more number of training examples than stage-specific models which get examples that are always subset of the examples joint models get for training in each fold. In spite of that, stage-specific models outperform joint models. For example, for prostate cancer, while the joint model gets 197192 examples for training (9/10th of the total examples in each fold of 10-fold cross-validation), the stage-specific model for the distant stage gets only 7729 examples for training (9/10th of total distant stage examples), but yet the stage-specific model for the distant stage outperforms the joint model on that stage in case of each machine learning method. This shows that various cancer stages are distinct enough from each other that it is best to build separate survivability prediction models for each stage. Adding examples of other stages during training does not benefit in predicting survivability for a particular stage, in fact, it often hurts the performance.

A fundamental requirement for machine learning methods to work well is that training and testing examples come from the same distribution, otherwise the model learned from the training data will not generalize to the test data. The above results indicate that examples of different cancer stages constitute different data distributions and hence mixing them during training, as joint model does, is not beneficial but hurtful. The recent study, [9], had reported

1408
this observation only for breast cancer (our numbers do not exactly match their numbers for breast cancer because they had excluded examples with missing feature values). Our results show that this observation generalizes to other cancer types as well.

**Figure 2:** A graph showing differences between the distant summary stage of the ten cancer types in terms of the number of incidences in that stage and differences in survivability rates from other stages. Stage-specific models were found to perform better than joint models with more number of incidences in the stage and with a higher difference in survivability rate from other stages.

We note, however, that there are a few cases in our results when the joint model statistically significantly outperforms the stage-specific model, namely for the distant stage of bladder (logistic regression), esophagus (logistic regression and decision tree) and liver (all methods), and the regional stage of liver (logistic regression and decision tree). We note that although joint model also does better on the localized stage of prostate cancer for naive Bayes, the actual difference of 0.002 is negligible. Looking further into these cases we find that all of them had relatively few incidences of those stages and in addition they had survivability rates similar to other stages (all on the low side). Hence in these cases when there were insufficient number of training examples to learn from, adding examples of other stages that do not have very different survivability rates was found to benefit. We depict this in Figure 2 in which we show all the cancer types in a plot between their number of incidences in the distant stage and the difference in survivability rate of the distant stage from other stages. The latter was obtained by subtracting survivability rate of incidences in the distant stage from the survivability rate of all incidences not in distant stage. We find that liver and esophagus cancers for which we found the exception on the distant stage appear on the bottom left side in the graph. This is the area representing fewer available training examples for the distant stage and similar survivability rates with other stages. Note that bladder cancer, for which the exception was found for only one method, also appears at the bottom but more in the middle. It is interesting to note that even though distant stage of lung cancer had survivability rate not far from other stages (it is on the left side in the graph), its joint model does not do better. This is clearly because it already had sufficient number of training examples of the distant stage for training the stage-specific model (it is on the top in the graph).
Figure 3: Learning curves for the logistic regression stage-specific models for the distant stage on a few cancer types.

We further look into this in Figure 3 by plotting learning curves for the stage-specific models for logistic regression. It is clear that the learning curve of lung cancer has almost plateaued with around 40% training examples and hence it has little scope of improvement. However, the learning curves of liver and esophagus cancers are yet to plateau indicating that their performance can still be improved with more examples. But on the other hand, for cervix uteri and corpus uteri cancers, although there are not many training examples of the distant stage (they are near the bottom in Figure 2) and their learning curves have not yet plateaued but they still do not benefit by adding examples of other stages (i.e. joint model does worse than stage-specific model). This is because for these cancers the survivability rate, and hence the data distribution, of the distant stage is very different from the other stages (they are on the right side in Figure 2). Please note that besides survivability rates, it is possible that feature values are also differently distributed in different cancer stages.

We also note that compared to other stages, performance was generally better on localized stage for which there were typically more number of examples. The results thus also indicate that performance on other stages could be improved with more training data. Given that our results have shown that including examples of other stages during training is only rarely helpful, a possibility for future work is to leverage examples of other stages through transfer learning [23]. This could be particularly useful for cancer types with fewer number of incidences.

Conclusions

In this paper we built two kinds of survivability prediction models for ten different cancer types. The joint models were trained on all cancer stages together, as in the past work, while the stage-specific models were trained on each cancer stage separately. They were both evaluated on all stages together, and on each stage separately. We showed that evaluating survivability performance on all stages together, as used to be done in the past, is not appropriate because it gives an artificial gain in performance owing to the inherent low to high survivability rates among the cancer stages. Evaluating models separately on each stage gives the realistic measure of survivability prediction performance. We also showed that stage-specific models perform better than joint models indicating that cancer stages are sufficiently different from each other that it is best to train survivability prediction models separately for each stage. With a few exceptions on cancer types with insufficient number of training examples and low survivability across stages, our results generalize to all cancer types and all cancer stages. Future work can
investigate the use of transfer learning between cancer stages to improve performance when faced with insufficient number of training examples.

Abstract

Biomedical data continues to grow in quantity and quality, creating new opportunities for research and data-driven applications. To realize these activities at scale, data must be shared beyond its initial point of collection. To maintain privacy, healthcare organizations often de-identify data, but they assume worst-case adversaries, inducing high levels of data corruption. Recently, game theory has been proposed to account for the incentives of data publishers and recipients (who attempt to re-identify patients), but this perspective has been more hypothetical than practical. In this paper, we report on a new game theoretic data publication strategy and its integration into the open source software ARX. We evaluate our implementation with an analysis on the relationship between data transformation, utility, and efficiency for over 30,000 demographic records drawn from the U.S. Census Bureau. The results indicate that our implementation is scalable and can be combined with various data privacy risk and quality measures.

Introduction

The healthcare community is increasingly driven by programs that collect and process large quantities of patient-specific data¹,². At the same time, these programs make use of highly detailed aspects about a patient and their daily activities within, as well as outside of, traditional clinical environments. To ensure that research studies are conducted, and healthcare applications are managed, at scale, it is critical to share data beyond the confines of where it was initially collected³. The push to make data accessible is exacerbated by initiatives that aim to enhance transparency in activities, reproducibility of research findings, and reuse of data for novel investigations. Such initiatives are being driven by federal agencies in the United States (U.S.), such as through the various data sharing policies of the National Institutes of Health⁴ and the National Science Foundation⁵, as well as in Europe, such as through Policy 0070 of the European Medicines Agency (EMA) for the public dissemination of clinical trials data⁶. However, as the quantity and quality of biomedical data grows, so too does its attractiveness to would-be attackers. There is, for instance, ample evidence to show that data breaches for healthcare organizations have grown substantially over the past several years⁷.

Privacy is a complex concept with ethical, legal and societal aspects⁸ and, consequently, it requires a mix of social (e.g., consent and trust) and technical constructs to realize⁹. In this work, we confine ourselves solely in the technical space, where a patient’s privacy is typically supported through a process referred to as de-identification in the U.S. (the convention we use in this paper) and anonymization elsewhere. De-identification is often achieved through the amendment of data that pertains to an individual’s identity. Such amendments may be realized through randomization, generalization to less specific terms, or suppression (i.e., redaction) of factors that can be leveraged to ascertain an individual’s identity (e.g., demographic factors). Specific rules for doing so have been codified in laws and regulations¹⁰,¹¹.

In parallel with these developments, a variety of studies have shown that de-identified health data can be re-identified (i.e., linked to identified individuals)¹². This has sparked a debate in which it has been argued that de-identification fails to provide adequate privacy protection¹³. However, it is important to realize that re-identification studies tend to focus on how attacks can be carried out, not on the likelihood they will be realized. As such, they demonstrate what is possible and not necessarily what is probable¹⁴. It has long been understood that de-identification involves trading privacy risks off against data quality and that privacy risks can never be entirely eliminated⁶.

Most recently, it was suggested that de-identification frameworks should formalize the capabilities of adversaries¹⁵. This shifts the view to an economic perspective, where the publishers gain benefit from sharing data at a certain level of fidelity, while attackers (i.e., the recipients) gain benefit from re-identifying the data. By modeling re-identification as a Stackelberg (or what is also called a leader-follower) game¹⁶ between two players, it was shown that attacks initially
thought to be quite detrimental to the management of biomedical research infrastructure may actually not be likely to occur in practice. Moreover, it was shown that the publisher’s gain can be maximized by de-identifying data under the assumption that the adversary will only attempt re-identification if there is a tangible economic benefit\textsuperscript{16}. While this approach is a notable advance in the field\textsuperscript{17}, it has not been made accessible through an easy-to-use software system.

**Objective and Contributions**

Traditionally, de-identification has been understood to be an optimization problem, in which data is transformed while an increase in privacy protection is traded off against a decrease in data quality. To balance both aspects, models for quantifying them are needed. Typically, a threshold is defined for privacy risks, which reduces the task to a simpler optimization problem, where the objective is to ensure that risk thresholds are met while data quality is maximized. At first glance, the game theoretic model appears to differ from this perspective. This paper reports on an in-depth analysis to identify integration options, as well as how we adapted and transitioned the game theoretic approach into scalable software. We extended ARX, an open source de-identification tool\textsuperscript{18}, with methods for de-identifying demographic and clinical data under the Stackelberg setting.

The specific contributions of this paper are as follows. First, we present an analysis of the game theoretic approach. Our findings show that (1) a specific variant of the game can be implemented with traditional privacy models and (2) the model can be interpreted in a manner that is consistent with the traditional perspective (i.e., as a combination of a privacy model and a data quality model). This interpretation forms the basis of our integration. Second, we further developed a search space pruning strategy that is specific to the game theoretic model and improves the scalability of the implementation significantly. Third, we describe how we integrated the game theoretic model into ARX (version 3.5.0), such that the implementation is fully compatible with all other de-identification methods implemented by the software. This is notable because it implies that the game theoretic approach can be combined, as well as compared, with other models for quantifying health data privacy risks and quality.

Beyond a software implementation, we report on an extensive experimental evaluation with over 30,000 demographic records from the U.S. Census. The results indicate that our highly scalable implementation often provides an overall payout (a measure that combines risk and utility) to the publisher that is comparable to what can be achieved using more sophisticated, though computationally costly, routines. Finally, we conclude this paper by reporting on ways to further extend our implementation towards the handling of high-dimensional (e.g., genomic) data.

**Background and Related Work**

**Data De-identification**

The Privacy Rule of the Health Insurance Portability and Accountability Act (HIPAA)\textsuperscript{10} provides specific guidance for the de-identification of health data via the *Safe Harbor* method. This method specifies 18 rules for modifying explicit (e.g., patient names and Social Security Numbers) and quasi-identifying (e.g., dates, ZIP codes with fidelity above 3 digits) factors that constitute sufficiently high re-identification risk. As an alternative, the HIPAA Privacy Rule permits the use of formal risk assessments under its *Expert Determination* methodology\textsuperscript{10}. This approach designates health data as de-identified when it is shown that the risk an anticipated recipient of the data could uniquely identify an individual is small. The method is notable as it allows for the application of an explicit adversarial model (i.e., anticipated recipient) and can explicitly manage risk through a quantified mechanism. Moreover, the approach is similar to how privacy is maintained in other countries. For example, the upcoming European General Data Protection Regulation (GDPR) states that "account should be taken of all the means reasonably likely to be used [for re-identification]"\textsuperscript{11}.

**Data De-identification Software**

There are various mature software solutions for facilitating data privacy risk assessments and de-identification, which have proven themselves in practice. μ-ARGUS and sdcMicro are open-source tools developed in the context of official statistics\textsuperscript{19}. By contrast, Privacy Analytics Eclipse is a commercial big data platform for risk-based de-identification of structured health records\textsuperscript{20}. In this paper, we focus on ARX, an open source tool that was also specifically designed for de-identifying biomedical data\textsuperscript{18}. ARX has been under constant development since 2011 and has found notable
adoption due to its comprehensive feature set and its easy-to-use graphical user interface. For example, it has been recommended by the EMA for implementing Policy 0070. ARX supports a wide variety of models for quantifying privacy risks and data quality as well as multiple models for transforming data.

### Data Transformation

Formal de-identification is typically applied to data derived from the healthcare setting by reducing the distinguishability of patient-level records. There are varying approaches for doing so, such as the injection of noise to adhere to emerging privacy models like differential privacy. However, the most popular approach in this domain remains reducing the fidelity of attributes that are likely to be exploited in re-identification attacks through linkage to named individuals in some external resource. This process renders records of a dataset to be less distinguishable for an attacker, thus reducing the certainty in executing a re-identification attack.

A generalization hierarchy is often relied upon for managing the valid transformations that can be applied to patient-level values. Two examples are shown in Figure 1. Here, values of an age attribute are transformed to different levels. To prevent overgeneralization, the former approach is often combined with subsequent record-level suppression. In this process, outliers (e.g., records with a high re-identification risk) are dropped from the dataset. The set of all possible combinations of levels with decreasing precision over increasing levels of generalization. Note that assigning a value to level 0 of its hierarchy leaves the value unchanged. In ARX, generalization hierarchies can be composed for categorical and continuous variables. In the latter case, this is accomplished by specifying functions for performing on-the-fly categorization of the space (e.g., creating an arbitrary grouping of heights or weights).

![Figure 1: Example generalization hierarchies for patient demographics that are vulnerable to re-identification attacks.](image)

While generalization can be realized in a variety of ways, in this article, we focus on two in particular. In full-domain generalization, all values of an attribute are transformed to the same generalization level in all records. By contrast, in record-level generalization, the values in each record can be generalized to different levels. To prevent overgeneralization, the former approach is often combined with subsequent record-level suppression. In this process, outliers (e.g., records with a high re-identification risk) are dropped from the dataset. The set of all possible combinations of generalization levels for all attributes forms a generalization lattice, where each element is called a de-identification policy. The generalization lattice for the example hierarchies from Figure 1 is shown in Figure 2. The latter figure also depicts the results of applying two de-identification policies for full-domain generalization, followed by subsequent record suppression. The payout indicated in the figure will be used as an example throughout this paper.

![Figure 2: A generalization lattice, de-identification policies, and output datasets for full-domain generalization.](image)

### Models for Quantifying Data Quality and Data Protection

Data transformation can influence the specificity of the data, so it is critical to balance an increase in protection with a decrease in data quality. To do so, we need to define formal measures for both criteria.

As alluded to, there are many models for measuring data protection, but in this work we focus on re-identification risk, because this is the primary concern addressed by current law and regulation. The re-identification risk of a record is typically estimated by calculating the inverse of the size of the group of indistinguishable records to which it
belongs. The universe of records that needs to be considered when forming groups depends on assumptions about the adversary’s prior knowledge.

First, in the Prosecutor model, it is assumed that the adversary already knows a record for a targeted individual is contained in the dataset. As such, groups must be formed using all records from the output dataset. This is the risk model underlying the $k$-anonymity privacy model. Second, in the Journalist model, it is assumed the adversary has no prior knowledge about membership. Thus, groups can be formed using a population table (i.e., a dataset containing records about all individuals from the population) generalized in the same way as the given record. This is the approach underlying the $k$-map privacy model. If no population table is available, a conservative estimate of the size of a record’s population group can be derived from the given dataset generalized in the same way as the record.

There are also various models for quantifying data quality. In this article we focus on the entropy-based model proposed by Wan et al. For a given record $r$, the information loss function $IL(r)$ returns a number in range $[0, 1]$ where a value of 0 indicates that the record has been preserved in its original state and a value of 1 indicates that all data has been suppressed.

The Game Theoretic Model

The game theoretic approach uses models for privacy protection and data quality to trade both aspects off against each other. For this purpose, it incorporates four intuitive parameters to construct a Stackelberg game in which the players, the data publisher (or defender) and the recipient (or attacker), are motivated by monetary incentives:

- **Adversary Gain**: The benefit that the adversary gains for a successfully re-identified record.
- **Adversary Cost**: The adversary’s cost to launch a re-identification attack against one record.
- **Publisher Benefit**: The benefit that the publisher receives by sharing a record in its original form.
- **Publisher Loss**: The publisher’s loss for one record due to successful re-identification.

By applying a model for quantifying re-identification risks to estimate the attacker’s success probability $SP(r)$ when attacking a record $r$, a monetary cost-benefit analysis can be performed. Our implementation supports all models described in the previous section.

The adversary attacks a record $r$ when the expected payoff is positive. More formally:

$$\text{Attack}(r) = \begin{cases} 1, & \text{if } SP(r) \cdot Gain > Cost \\ 0, & \text{otherwise} \end{cases}$$

As noted earlier, the value of a published record decreases when the amount of information content decreases. Thus, the publisher’s payoff for publishing a record $r$ can therefore be defined as:

$$\text{Benefit}(r) = (1 - IL(r)) \cdot \text{Benefit}$$

Additionally, when a record is successfully attacked, the publisher loses money. The expected loss per record is relative to the success probability of the adversary. Consequently, the publisher’s expected overall payout for a record $r$ is:

$$\text{Payout}(r) = \text{Benefit}(r) - \text{Attack}(r) \cdot SP(r) \cdot \text{Loss}$$

Methods

System Design

The de-identification methods supported by ARX are centered on generic data transformation algorithms that invoke full-domain generalization followed by record suppression. The algorithms rely on a user-specified 1) privacy model to determine which records need to be suppressed and 2) data quality model for optimizing the output.

In essence, ARX iterates over all available de-identification policies. For each policy, it follows a three step process (ignoring the various implemented optimizations): 1) **Transform** all records according to the policy, 2) **Suppress** records as indicated by the privacy model, and 3) **Assess** data quality using the quality model. Once all of the policies have been processed, ARX selects the policy with the best data quality to de-identify the dataset.
Implementation of the Basic Game

Prior work in game theoretic de-identification pursued a record-level perspective by transforming each record in such a way that the resulting payout is maximized. However, the implementation of the model in ARX relies upon full-domain generalization, as this approach has been shown to be more desirable to the biostatistics community. Later on, we will show that this basic implementation can be used to implement the record-level method.

To integrate the game theoretic model with ARX, we defined a privacy model and a quality model. The privacy model, called Profitability, is defined as follows:

\[
\text{Profitable}(r) = \begin{cases} 
1 & \text{if } \text{Payout}(r) >= 0 \\
0 & \text{otherwise}
\end{cases}
\]  

(4)

ARX uses this model to decide which records should be suppressed. We note that for any given dataset \( D \), suppressing all records \( r \in D \) with \( \text{Profitable}(r) = 0 \) is the optimal strategy for record-level suppression. This is because the decision of whether or not a record should be suppressed can be made independently for each record. Specifically, suppressing a record will not affect the information loss measured by the function \( IL \) for any other record. Moreover, when using a population table or the input dataset to calculate the adversary’s success probability \( SP \), removing a record from the output will also not affect the value returned by the function \( SP \) for other records. When using the output dataset to evaluate \( SP \), suppressing a nonprofitable record will only increase the value of \( SP \) for records that are in the same group. However, the group only contains nonprofitable records and increasing the value returned by \( SP \) makes publishing them even less profitable. As a consequence, suppressing a record does not affect whether publishing other records is profitable to the publisher. Obviously, the optimal strategy is to keep all profitable records and to remove all nonprofitable records.

The quality model is an objective function that measures the overall payout of the publisher for the complete dataset \( D \). Suppressed records will not be published, so we neither gain nor lose any money from them:

\[
\text{Payout}(D) = \sum_{r \in D} \text{Payout}(r) \cdot \text{Profitable}(r)
\]  

(5)

By parameterizing ARX with these models, we can solve the game using full-domain attribute generalization followed by record-level suppression. The process is sketched in Figure 3. As can be seen, ARX will suppress all records for which publishing will result in a negative payoff for the publisher. The overall payout for a (potentially generalized) dataset is defined as the sum of the payoffs for each record. The payoff for a suppressed record is defined as zero.

For each policy \( p \)
  - For each record
    - Apply \( p \)
  - For each record
    - Calculate payout
      - Suppress if payout < 0
    - Calculate payout
      (Suppressed: payout = 0)
  - Store optimum

Transformation phase
Payout optimization phase
Payout assessment phase

Figure 3: Basic algorithm executed by ARX for solving the game.

The output of this algorithm is globally optimal (in terms of overall publisher payout) regarding all possible transformations that rely on a combination of full-domain generalization and record suppression. This is because the algorithm implements an exhaustive search; i.e., it assesses every de-identification policy. For each policy, it first generalizes the dataset, then performs record suppression and stores the resulting payout. Since there is only a single optimal record
suppression strategy for any dataset, the algorithm has checked all potentially optimal outputs and the solution must therefore be globally optimal.

We also implemented a pruning strategy that eliminates solution candidates by reducing the search space of potentially optimal policies. To do so, we take advantage of the fact that the entropy-based information loss model used by the game theoretic approach is monotonic over paths in the generalization lattice. This means that, when data is only transformed with full-domain generalization, information loss will increase monotonically on each path from the bottom node of the generalization lattice to the top node. We note that this is not the case when data is transformed with full-domain generalization followed by record suppression\textsuperscript{26}. However, the monotonicity of the quality model can still be invoked to construct a pruning strategy.

For this purpose, we first calculate an upper bound on the maximal payout that can be obtained for a dataset $D$ by assuming that the adversary never attacks (i.e., that $\forall r, SP(r) = 0$):

$$\text{MaximalPayout}(D) = \sum_{r \in D} \text{Benefit}(r) = \sum_{r \in D} (1 - \text{IL}(r)) \cdot \text{Benefit}$$  \hspace{1cm} (6)

Due to the fact that $\text{MaximalPayout}(D)$ only depends on $\text{IL}(r)$, it follows that it also decreases monotonically within the lattice when data is only transformed with full-domain generalization. We can exploit this to prune portions of the search space by implementing the following strategy.

While traversing the solution space, we always keep track of the $\text{OptimalPayout}$, i.e. the payout of the best solution found so far. We note that $\text{OptimalPayout}$ represents the highest payout obtained using full-domain generalization and record suppression. When processing a new policy $p$, we retrieve a dataset $D$ as a result of the transformation phase. Next, we check whether $\text{MaximalPayout}(D) \leq \text{OptimalPayout}$. If this is the case, $p$ and all of its successors can be pruned, because the maximal payout that can be obtained by using them is already lower than the current optimum. Our implementation uses the generic framework provided by ARX for implementing such pruning strategies\textsuperscript{26}.

For context, Figure 2 provides an example. Let us assume that the algorithm first processes the policy $(1, 0)$ by generalizing the data and then suppressing one record. The resulting payout is the current optimum, so $\text{OptimalPayout} = \$1000$. Next, the algorithm processes policy $(0, 1)$. In doing so, it first generalizes to retrieve a dataset $D'$ and finds that $\text{MaximalPayout}(D') = \$800$. Policy $(0, 1)$ and all of its successors (i.e. $(1, 1), (2, 1), (3, 1)$) can now be pruned because none can result in output with a higher payout than the current optimum ($\$800 \leq \$1000$).

**Implementation of Variants of the Game**

There are several variants of the game theoretic model that have been proposed\textsuperscript{16} that we chose to integrate into ARX. The first is the $\text{SH-Friendly}$ variant, which guarantees that the degree of protection from re-identification is no lower than when using the HIPAA Safe Harbor policy. This can be achieved with ARX by using generalization hierarchies that reflect the Safe Harbor policy and by defining appropriate minimal levels of generalization.

The second is the $\text{No-Attack}$ variant of the game, which guarantees that the adversary has no incentives to ever attack. This variant can be implemented in an optimized manner, as can be seen as follows. Let $k$ be the size of the group of indistinguishable records used for calculating $SP(r)$. As described above, the adversary will only attack a record if:

$$SP(r) \cdot \text{Gain} > \text{Cost}. \hspace{1cm} (7)$$

So, it follows that:

$$SP(r) > \frac{\text{Cost}}{\text{Gain}} \Rightarrow \frac{1}{k} > \frac{\text{Cost}}{\text{Gain}} \Rightarrow k > \frac{\text{Gain}}{\text{Cost}}. \hspace{1cm} (8)$$

This indicates that the $\text{No-Attack}$ variant of the game implies a threshold on $k$. Depending on how the game has been configured to quantify re-identification risks (see Section Models for Quantifying Data Quality and Data Protection) this can be implemented with $k$-anonymity\textsuperscript{23} or $k$-map\textsuperscript{24}. As an example, given the realistic parameters derived by Wan et al. (i.e. $\text{Cost} = \$4$ and $\text{Gain} = \$300$\textsuperscript{16}), we obtain $k > \frac{300}{4} = 75$.  

1418
In addition to enforcing a threshold on $k$, we also need to maximize the publisher’s payout. Since we know that the adversary will never attack, Equation 3 can be simplified as follows:

$$Payout(r) = Benefit(r) - \underset{=0}{\text{Attack}}(r) \cdot SP(r) \cdot \text{Loss} = Benefit(r) = (1 - IL(r)) \cdot Benefit$$

(9)

These specifics of the No-Attack variant are important from an implementation perspective. They show that it is sufficient to minimize information loss in order to maximize publisher payout and that payout is monotonic in the lattice when only full-domain generalization is being used\textsuperscript{23,24}. This can be used to speed up record-level generalization.

**Implementation of Record-Level Generalization**

Our implementation of the game theoretic model is fully integrated into ARX. Figure 4 depicts two examples of how the API can be invoked. These illustrate how to de-identify an example dataset $D$ using the game theoretic approach with different models for transforming data and quantifying re-identification risks.

![Algorithm 1](image1)

**Algorithm 1** Full-domain generalization + record suppression

```java
arx ← new ARX();
arx.setPrivacyModel(new Profitability());
arx.setQualityModel(new PublisherPayout());
output ← arx.process(D);
```

![Algorithm 2](image2)

**Algorithm 2** Record-level generalization

```java
for (0 ≤ i < |D|) {
arx ← new ARX();
arx.setPrivacyModel(new Profitability());
arx.setQualityModel(new PublisherPayout());
arx.setSample(i);
output ← output ∪ arx.process(D);
}
```

**Figure 4**: Implementing different transformation models using the ARX API.

The first example shows pseudocode for invoking the API using full-domain generalization followed by record suppression and the prosecutor risk model. It should be noted that ARX can also be configured to use a population table. To do so, the dataset to be de-identified needs to be defined as a sample of the population table. With this configuration, our implementation uses the journalist risk model.

In the second example, we invoke the method without an explicit population table to estimate journalist risks as described previously. For this purpose, we de-identify the dataset $|D|$ times, using a sample of exactly one record of $D$ in each execution. The result for $D$ is simply the union of the individual outputs for each record.

**Experimental Design**

**Materials.** We evaluate our methods on the extract of 32,561 records from the 1994 U.S. Census and the generalization hierarchies used by Wan et al.\textsuperscript{16}. The dataset was enriched with demographics extracted from additional U.S. Census data for the state of Tennessee to enable comparisons with HIPAA Safe Harbor. We used traditional demographics in the form of 1) age, 2) sex, 3) ZIP code, and 4) race as quasi-identifying variables given their known contribution to re-identification attacks.

**Parameterization.** As a base case, we used the setup from Wan et al.\textsuperscript{16}: Adversary cost = $4, based on the costs for obtaining detailed information about individuals online. Publisher benefit = $1,200, based on an analysis of grant funding received divided by the number of records published by the five member institutions of the Electronic Medical Records and Genomics (EMERGE) network, an NIH consortium. Publisher loss = $300, based on an analysis of HIPAA breach violation cases reported by the U.S. Department of Health and Human Services.

In our experiments, we rely on the default parameterization for adversary cost and publisher benefit, but we further defined adversary gain to be equal to publisher loss. By varying this single parameter between $0$ and $2,000$ we were able to investigate a wide variety of scenarios, in which either the data publisher or the adversary is at an advantage.

**Performance Measures.** When reporting results, we express the overall publisher payout relative to the theoretical maximum, which can be obtained when the data will never be attacked. In this case, the publisher payout equals (number of records) * (publisher benefit). This results in a maximal payout of $32,561 \times 1,200 = 39.0732$ million for our setup. We compared our approach to prior work and performed a runtime analysis of our implementation.
Results

Comparison with Prior Work

Wan et al. solved the game with record-level generalization using journalist risks calculated with a population table. As mentioned, we developed methods to solve the game in the context record-level generalization and full-domain generalization with and without supplying a population table. Here, we present results of a comparison.

As a baseline, we used HIPAA Safe Harbor, which we applied by replacing all values of the attribute ZIP code with their initial 3 digits, masking zip codes with populations of less than 20,000 individuals and top-coding ages to 90 and above. The results of the experiment are shown in Figure 5. The first vertical line in each plot denotes the parameterization $GL = Gain = Loss = $300, which has been shown to be a realistic scenario. The second vertical line indicates the point at which the data sharing scenario becomes disadvantageous for the publisher.

![Figure 5: Publisher payout for the output of different implementations calculated using a population table.](image)

The results obtained for the basic game are shown in Figure 5 (a) and (b). There are a several notable findings to highlight. First, all of the methods provided a higher payout than Safe Harbor when the publisher was at an advantage. Second, it can be seen that, up to $GL = $400, full-domain generalization with risks calculated from the dataset resulted in a publisher payout that is close to that achieved using record-level generalization and a population table. This notable because for $GL = $300 the method by Wan et al. achieved only 0.17% more relative payout. Third, it can be seen that, when using a population table, full-domain generalization generally resulted in a payout similar to that obtained using record-level generalization. Even for $GL = $2000, the method by Wan et al. provided only 1.9% more relative payout. Finally, it can be observed that when calculating risks from the dataset, full-domain generalization resulted in a greater payout than record-level generalization up to about $GL = $600. This is because record-level generalization is much more flexible and, therefore, leads to a pronounced overgeneralization when risks are overestimated significantly.

Figures 5 (c) and (d) present the results obtained for the No-Attack variant of the game. It can be seen that this model can not be implemented effectively without supplying a population table. This is an intuitive finding as we have shown that the model implies a significant risk threshold (i.e., up to $\frac{1}{500} = 0.2\%$ for $GL = $2000). Still, it is notable that using full-domain generalization and a population table resulted in higher payout than Safe Harbor for $GL \leq $800.

Analysis of Scalability

We further investigated the scalability of our implementation in ARX. To do so, we (1) measured the impact of the pruning strategy, (2) compared execution times for full-domain generalization with record-level generalization and (3) measured the speed up achieved by implementing the No-Attack variant with $k$-anonymity or $k$-map. The experiments were performed on an Intel Core i5 3.1 GHz machine running a 64-bit Linux 3.2.0 kernel and a 64-bit JVM (1.7.0). Our method for record-level generalization using a population table is not included in the current release of ARX. Using full-domain generalization and a population table took around 2 seconds in the experiments described above. The results shown in Figure 6 focus on methods that calculate risks from the dataset.

Figure 6 (a) depicts the impact of the pruning strategy. It can be seen that the optimization was more effective in scenarios that were advantageous to the publisher. For example, we achieved a 4x speedup for $GL = $300 and only a
Figure 6: Execution times for solving the game without using a population table.

2x speedup for \( GL = $2,000 \). The main reason is that, when the scenario is less advantageous to the publisher, more generalization is required to obtain a good solution to the de-identification problem. This makes the optimization less effective and, consequently, increases execution times.

A comparison of execution times measured for full-domain generalization and for record-level generalization is shown in Figure 6 (b). It can be observed that full-domain generalization is four orders of magnitude more efficient than record-level generalization. This is reasonable, as the latter was implemented by executing full-domain generalization for every record in the dataset (i.e., 32,561 times).

Finally, Figure 6 (c) summarizes a comparison of the execution times measured for a naïve implementation of the No-Attack variant of the game and the optimized implementation proposed previously. It can be seen that implementing the model using traditional privacy models and de-identification algorithms reduced execution times by up to 67%. We measured more pronounced improvements for record-level generalization, which is significantly more computationally complex than full-domain generalization.

Discussion and Conclusions

In this paper, we introduced new variations of the game theoretic approach to health data de-identification and described their integration into the open source software ARX. In contrast to many other methods of data de-identification, the game theoretic approach explicitly accounts for the incentives of data publishers and recipients. The experiments showed that our implementation provides a novel means for balancing publisher payout with execution times by using different models for transforming data. Our approach does not rely upon the existence of a population table, but users are free to specify one when it is available.

There are a wide variety of directions for further improving our implementation. In particular we believe our approach can be extended to support higher-dimensional data, such as genomic summary statistics, akin to the approach recently proposed for the minor allele frequencies of single nucleotide polymorphisms (SNPs). This is a natural extension because ARX is based on a modular design with a focus on scalability. The tool is already able to load very large and high-dimensional data, but two additional modules will need be developed to fully support the processing of such data. First, the existing implementation of ARX’s generalization lattice needs to be complemented with an implementation that represents attribute suppression policies as bit vectors. Second, the search algorithms currently implemented by the tool need to be complemented with a genetic algorithm developed by Wan et al. This algorithm is generic in design (that is, it is not specific unto genomic data) and focuses solely on attribute suppression (i.e., either an attribute is retained or redacted). Since ARX supports attribute-level suppression, integration into the tool should be a feasible endeavour.

Abstract

Traumatic brain injury (TBI), spinal cord injury (SCI) and stroke are conditions of interest to public health as they can result in long-term outcomes and disabilities. Specialized registries can facilitate public health surveillance, however only 4% of hospitals in the United States actively engage in electronic reporting to these registries. We leveraged electronic claims and clinical data from a health information exchange to create a statewide TBI/SCI/Stroke registry to facilitate the study of long-term outcomes and health services utilization. The registry contains 109,943 TBI patients, 9,027 SCI patients and 117,084 stroke patients with a mean of 3 years of follow-up data after injury. Additionally, the registry contains data on individual patient encounters, prescriptions and clinical variables. The high-dimensional data with large sample sizes may present a valuable informatics resource for injury research as well as public health surveillance.

Introduction

Following the passage of the Health Information Technology for Economic and Clinical Health (HITECH) act in 2009, the landscape for health IT in the United States changed dramatically. The meaningful use (MU) initiative provisioned under HITECH can be attributed with the widespread adoption of electronic health records (EHRs) among both office-based physicians and hospitals in the US. While 78% of office-based physicians have adopted certified EHRs, 87% physicians in the US use some form of EHR¹. Adoption of EHRs among hospitals is even higher with 97% of all US hospitals using certified EHRs². Requirements in MU prioritize sharing of patient health information collected during the process of routine care between providers and hospitals to provide comprehensive patient health information at all points of care. Additionally, MU incentivizes the creation of specialized disease registries: registries for conditions other than cancer, to improve population and public health.

Traumatic brain injury (TBI) is one of the most prevalent and severely disabling neurological disorders in the US. Nationwide, 1.7 million people experience TBI annually and 3.2–5.3 million live with a TBI-related disability³–⁵. An estimated 53,000 people die every year due to TBI, representing 30.5% of all injury related deaths⁴,⁶. The economic burden of TBI in terms of total lifetime costs due to loss of productivity is estimated at $63.9 billion and an additional $13.1 billion in direct medical costs⁷,⁸. On the other hand, spinal cord injuries (SCIs) while rare, account for about 17,000 cases per year and an estimated range of 243,000 and 347,000 people lived with an SCI in 2016⁹. Incomplete paralysis of all four limbs is the most frequent outcome of SCI with less than 1% of patients experiencing complete neurological recovery by the time they are discharged from the hospital. Additionally, about 13% of all patients experience complete paralysis of all four limbs. Lifetime costs due to SCIs are between $1.5 million and $4.7 million for those with an SCI at 25 years of age. As such, SCIs in combination with TBIs greatly contribute to permanent disability, high medical costs and costs due to loss of productivity.

Although TBIs and SCIs can result in permanent disability, the leading cause of long-term disability as well as the leading preventable cause of disability in the US is stroke¹⁰. Approximately 795,000 people in the US have a stroke each year with more than 75% of these being first or new strokes. Stroke is also the fifth leading cause of death in the US. Racial disparities exist with risk of first stroke in blacks being twice that of whites; compared to whites, blacks are
also more likely to die from stroke. While not a form of TBI, stroke results in injury to the brain that may be permanent and result in impairments in cognition, strength, and swallowing that require specialized rehabilitation training, and/or long-term assistance due to disability. As such, the total cost of stroke due to health care utilization, medication and loss of productivity is estimated at $33 billion each year. Therefore, due to the profound impact these events have on individuals and generally the society; TBI, SCI and stroke are significant from a public health perspective.

TBI, SCI and stroke are chronic diseases based on the World Health Organization (WHO) definition as they have one or more of the following characteristics: permanent, caused by non-reversible pathological alterations; requires special training of the patient for rehabilitation; and/or may require a long period of observation, supervision, or care. Despite understanding the association of TBI and SCI with a host of long-term diseases and disorders, as well as the growing understanding of the causative and accelerative nature of these associations, TBI and SCI are too often seen as isolated events by the health care delivery system rather than as the onset of chronic disease. As a result, TBI and SCI are chronic diseases for which the health care system has only an acute plan of care. Finally, considering that the three conditions: TBI, SCI and stroke, can result in similar outcomes and disabilities following an acute injury; studying them together may be of interest.

To study the long-term outcomes and health services utilization among patients with TBI, SCI and stroke, the Indiana State Department of Health (ISDH) supported the creation of a specialized registry at the Regenstrief Institute. The goal was to create a virtual environment in which public health epidemiologists and researchers could collaboratively examine the TBI, SCI and stroke populations in Indiana. External support was necessary since typical data sources available to state health departments (e.g. Medicaid claims, trauma registries) contain limited details about patients immediately following their injury. In this paper, we describe the creation of the Indiana Registry for TBI, SCI and Stroke, detailing the data housed within the registry while discussing the lessons learned in creating a disease registry to support public health surveillance and research.

Methods

Indiana Network of Patient Care (INPC)

The Indiana Network for Patient Care (INPC) is the longest-tenured and most comprehensive health information exchange (HIE) network in the United States. The goal of creating the INPC was the timely availability of clinical information when and where it is needed. The network includes data from more than 100 hospitals; 12,000 practices; local and state health departments; local and national laboratories; a national pharmacy benefit manager consortium; long term post-acute care facilities; free standing radiology centers; several large-group practices closely tied to hospital systems; as well as payers including the state Medicaid program. The INPC data repository contains over 9 billion pieces of clinical data, including over 195 million text reports, for approximately 12 million unique patients. The INPC employs a robust master person index (MPI) that supports integration of patient data across 1,000 information systems (e.g., lab, radiology) and processes more than 350,000 messages each day.

Data extraction and preparation

In order to create the registry, we first identified patients who had an event of TBI, SCI or stroke between 2005 and 2014. The patients were identified using a set of codes (Table 1) from version 9, Clinical Modification of the International Classification of Diseases (ICD). The inclusion criteria were limited to the requirement that the patients have their first event or the “index” event of TBI/SCI/stroke during the specified time frame (2005–2014). This definition of TBI is broad and based on that which is used by public health agencies to ensure complete capture of all possible cases. Specific analyses by registry users could utilize more precise case definitions based on individual study needs.

For included patients, comprehensive and longitudinal de-identified health record data was extracted at the encounter level. Specifically, we extracted data on demographic (e.g., patient id, age, gender, race, rurality of residence), encounter (e.g., visit type, visit location, diagnosis at visit, length of stay), prescriptions (e.g., medication prescribed, dose, strength) and clinical (e.g., diagnostic test and test results, age at test, procedures conducted) characteristics from the INPC. The complete list of extracted data elements is presented in Table 2.

Encounter data was derived from admission, discharge, and transfer data as well as medical claims and discharge summary data captured by the INPC. Encounters in the INPC represent visits to a variety of care settings, including acute care hospitals, skilled nursing facilities, and ambulatory providers. Visits are coded by the sending facility and often include admission diagnosis as well as length of stay (for acute care visits).

Medication data was derived from dispensing events with medications identified using National Drug Code (NDC) numbers. The NDC numbers are 11-digit drug identifiers consisting of three segments which identify the labeler (e.g. manufacturer); the product, form and strength (e.g. Prozac, capsule 20 mg); and the packaging (e.g. 100 caps). Consequently, the same active ingredient could have multiple NDC numbers based on differences in the labeler, strength and packaging. Therefore, data from the Anatomical Therapeutic Chemical Classification System (ATC) controlled by the WHO was used to create a crosswalk mapping individual NDC codes to therapeutic drug classes (e.g. Antithrombotic agents, Diuretics). Considerable variation was also seen in the presentation of visit types, which were aggregated into broader categories using the Centers for Medicaid and Medicare Services (CMS) place of service codes and descriptions.

Additional clinical variables, or observations recorded in the EHR, were derived from various types of messages exchanged within the INPC between various clinical information systems. Test results from laboratory information systems, procedure codes from claims messages, problem lists in a variety of messages, and other observations recorded...
for patients who might be of interest for surveillance or research were extracted. These variables only contain discrete values as the registry cannot contain free-text documents that may contain identifiable data.

The Indiana Registry for TBI, SCI and Stroke

Whereas the INPC is an operational system that supports transactional HIE for patient care, the Indiana Registry for TBI, SCI and Stroke is a disease registry designed to support population health surveillance and research. Therefore, the transactional data from INPC were extracted, transformed, and loaded into a virtual server where they could be accessed independently from the transactional system. The transformation of the data included a step whereby medical record numbers were translated into study identifiers and other patient identifiers (e.g., phone number, address) were removed. The registry therefore contains a de-identified dataset with patient age, number of days following the index event, and other data that enable analysis without the possibility of re-identification. As depicted in Figure 1, the data from the INPC is loaded onto a virtual server running within the research environment at Indiana University. Researchers at IU and Regenstrief can access the data via applications (e.g., SQL Server, R, SAS) that run on other virtual machines within the IU environment. Similarly, external collaborators, including the staff at the ISDH Injury Prevention Division, can connect into the virtual environment to analyze the data for surveillance or research aims.

![Figure 1: Diagram depicting data integration from different sources to create the TBI/SCI/Stroke registry](image)

Data Analysis

The analysis focuses on a description of the demographic, encounter, medication and clinical data extracted for the registry along with descriptive statistics for the demographic and encounter data in the registry. First, we present an overview of the registry’s data, detailing the total observations for all type of data including the average follow-up time in years. Next, we determined the incidence rates for TBI, SCI and stroke between 2005 and 2014. Incidence rates were calculated using census estimates on the population of Indiana for each year as the denominator. Unique visits were calculated as each visit that a patient made on a new day. Thus, multiple outpatient visits by a patient on different days would count as separate and unique visits.

* Before or After the event

Results

The TBI/SCI/Stroke registry had 109,493, 9,927 and 117,084 patients who had their first event of TBI, SCI and stroke respectively, between 2005 and 2014 (Table 3). Total follow-up duration for patients was 6.1 years for TBI, 6.39 years for SCI and 5.86 years for stroke patients. Additionally, patients were followed for at least 2.86 years before or after any of the 3 events. The clinical variables table containing information such as procedure codes, test and test results etc. accounted for the majority of the health information in the registry with at least 7 million observations for SCI patients and over 126 million observations for stroke patients. Furthermore, observations ranged between 5 and 53 million in the encounter tables and between 1.3 and 17 million in the medication tables across the TBI/SCI/Stroke registry.

![Incidence of TBI, SCI and stroke in Indiana from 2005 – 2014](image)

The incidence of TBI, SCI and stroke for each year in the registry is shown in Figure 2. While the incidence for TBI and stroke shows a steady increase from 2005 to 2014, that of SCI remains relatively unchanged. Table 4 presents the demographic characteristics of the patients in the registry. Just under half the patients in the TBI (45.11%) and SCI (48.14%) registry were females, with the stroke registry having a higher proportion of female (58.72%) patients. Patients for TBI (75.33%), SCI (52.88%) and stroke (75.04%) were majority white, however there was variation in the availability of race data across the three conditions; whereas about 7% of the TBI and stroke patients lacked information on race, almost 34% SCI patients had no race related information. Majority of the patients in all three registries resided in an urban location.

*Native Hawaiian or Pacific Islander
American Indian or Alaskan Native

The number of patients with TBI, SCI or stroke varied by age groups as well (Figure 3). TBI was more commonly seen in the younger age-groups with the greatest proportion of patients experiencing the first TBI event between the ages of 15 years and 25 years. On the other hand, stroke patients were generally older with more than half of all patients being 65 years or older at the time of first stroke event. SCI patients were generally younger than stroke patients at the time of first event with most patients having their first event between the ages 45 years and 65 years. Overall, SCI and stroke patients were older or middle-aged whereas patients with TBI were generally younger.

Figure 3: Proportion of total cases by age-group at first event

At the encounter level, the registry had 17,923,338; 2,569,718 and 26,381,982 unique visits in the TBI, SCI and stroke registry for all care settings (Table 5). After aggregating care setting types based on the CMS place of service order, 13 distinct care settings were identified. Of these outpatient care had the greatest number of visits in all three registries. While TBI (13.73%) and stroke (15.04%) had pharmacy as the next most common type of visit, SCI (16.90%) patients had home visits as the second most common type of visit. “Other facility” included facilities which could not be clearly identified or care settings that collectively made up less than 0.5% of the total unique visits.

Discussion

Using data routinely collected by EHRs during clinical care processes, we created a specialized registry for TBI, SCI and stroke patients. The registry contains large volumes of encounter level data providing details on patients following their index injury with an average of about 3 years worth of data before and after the event. Given the richness and longitudinality of the data, this registry may be a valuable informatics resource for long-term injury surveillance as well as research.

While not the first registry to focus on TBI, SCI or stroke, this registry is unique in that it was created using readily available data part of a HIE network from multiple health systems. In other words, there was no additional effort required on the part of patients or care providers to report cases to this registry. Although there are MU incentives for public health reporting to specialized registries, these criteria are optional in Stage 3 MU and will continue to remain so under the Medicare Access and CHIP Reauthorization Act (MACRA). Consequently, only about 4% of hospitals in the US were actively engaged in public health reporting to specialized registries as of 201516. Since our registry was created by leveraging existing HIE data and does not require providers actively reporting, our methods are likely to capture more cases than passive surveillance systems, therefore allowing for a larger patient population.

The large patient population in our registry presents a novel dataset for studying long-term outcomes and health services utilization among patients with TBI, SCI or stroke. The high-dimensional nature of the data allows for robust study designs to assess research questions focused on outcomes in these patients. A key strength of the registry lies in the availability of visits data, including the type of setting and the length of stay. Additionally, since the data is longitudinal at the encounter level it is possible to track individual patients through the care process. For instance, a 55 year old male patient living in an urban area has a TBI event on day 0 and is air-lifted to the emergency room where the ICD codes provide a diagnosis of “brain hemorrhage with loss of consciousness”. In the same visit, additional ICD codes mention further injuries in the form of multiple fractures and mechanism of injury codes that indicate the cause was a motor vehicle crash in which the patient was the driver. On day 1, the patient is admitted to the inpatient facility where the patient’s progress can be tracked using ICD codes until he is transferred to an inpatient rehab facility by ambulance on day 8. During the patient’s stay, ICD codes provide a snapshot of the aftercare provided to the patient at the inpatient rehab facility. On day 24, the patient is discharged to home. Data of this nature may be of immense value in examining the relationship between care processes and patient outcomes. In addition, it may also be possible to examine outcomes based on specific conditions within any one registry, e.g. comparing post-stroke outcomes among diabetics vs. non-diabetics. Given the availability of data both before and after the event, along with sufficiently large sample sizes; studies using this data could potentially generate high-quality, real-world evidence for policymakers as well as clinical care organizations.

The registry is further a unique informatics resource in that it allows for access by both public health epidemiologists
as well as researchers. Current information resources used by epidemiologists in governmental public health agencies are limited to data feeds around acute events. Trauma registries, which receive data from emergency departments, in-patient stays, and emergency medical services; capture details of an injury when it occurs along with prognosis at time of discharge and from short term rehab. Further, trauma registries depend on primary data collection and require dedicated staff for abstraction of patient record and other activities. Syndromic surveillance systems, which also receive data from emergency departments, capture data on patient-reported chief complaints and, in some states, admitting diagnoses\textsuperscript{17}. These resources, however, report de-identified data in a way that does not allow the health department to examine repeat visits for the same individual longitudinally. Nor do these resources provide information on follow up care after discharge. By linking individuals’ medical records and hosting the linked data in a de-identified yet protected environment, the registry facilitates collaboration between health services researchers and epidemiologists. This method may become a model for other diseases as well as replication in other states.

**Role of Health Information Exchange in Creation of the TBI, SCI, and Stroke Registry**

A commitment from Indiana’s community HIE, the INPC, to support public health and research played an instrumental role in the creation of the TBI, SCI, and stroke registry. The robust and highly connected nature of the INPC made it possible to gather data from discrete sources from across Indiana. As such widespread HIE adoption may be viewed as a precursor to creating a registry of this nature. In its current state, HIE adoption within individual states as well as nations is heterogeneous. While the business case for HIE adoption largely focuses on the benefits to clinical care, the literature evaluating the effect of HIE on health outcomes finds only mixed evidence for these benefits\textsuperscript{18}. Our work demonstrates the feasibility in creating a public health resource using HIE data and as such the potential public health benefits of HIEs should be explored further.

To our knowledge, this is the first specialized registry created for surveillance as well as research that uses data from a mature HIE. While other registries for TBI and stroke exist, these were created as a result of initiatives specifically aimed at creating epidemiological datasets and not as a positive externality of an existing resource. Similarly, while research datasets that focus on these conditions exist, enormous resources were expended for their conception. Whereas our registry was built using secondary data from existing clinical processes versus collection of primary data which involves significant resource expenditure and time. Although, it is true that the establishment of an HIE also presents a significant investment of resources, the ability to create registries and research datasets presents a desirable unintended consequence. As such considering these benefits in cost-benefit analysis may present a better understanding of “true” cost of HIE adoption.

**Limitations of EHR-derived Registries for Population Health**

We observed three important limitations of available EHR data from the perspective of public (or population) health in the process of creating the Indiana Registry for TBI, SCI and stroke. First, data from EHRs, while voluminous, are also “noisy” and heterogeneous, which presents analytical challenges for rapid, just-in-time scenarios. Many of the planned analyses for the data in this registry require significant effort from researchers and epidemiologists to “clean” and prepare analytical datasets. Thus, the hope of a turnkey solution for extracting EHR data for rapid ascertainment of population health — a tenet of the Learning Health System\textsuperscript{19}— that is also of interest to agencies that respond to emerging disease threats, is unlikely given the reality of current EHR systems.

Second, while the breadth of data from EHR systems holds many opportunities for public health their depth remains a challenge. Public health departments are interested in examining not only utilization, mortality and clinical outcomes but also the social determinants of health. In particular, public health agencies desire robust data on race and ethnicity as they are chief among organizations who analyze health disparities. Data on race and ethnicity was missing for one-third of SCI patients, a rate not unlike other studies involving EHR data. Furthermore, data on the social determinants of health are not routinely captured by EHR systems\textsuperscript{20}. Many epidemiological cohort studies capture these data directly from patients. While direct capture may not be possible, deriving such data from other sources (e.g. clinical notes) could help improve the value of specialized registries.

Finally, the registry was unable to tap into free-text data available within the INPC due to concerns around identifiable
data that may be embedded within discharge summaries, history and physical notes, admission notes, etc. While methods exist for automating the de-identification of a clinical note\textsuperscript{21,22}, these methods are not yet routinely used by health systems or HIE networks. If such methods could be implemented, concepts could be automatically extracted from free-text for use by registries.

**Future Directions**
The TBI, SCI and stroke registry presents a wealth of data which may be used to evaluate the outcomes for these conditions. The following analyses are currently being conducted by our team for dissemination in the coming years:

- **Opioid usage and secondary stroke events:** Prolonged opioid usage is associated with adverse cardiovascular events. In our analysis of the medication data from the stroke registry we found that opioid and opioid combination medications were the second most commonly prescribed drug class among stroke patients both before and after the stroke event. We will compare secondary stroke outcomes in patients that had prolonged opioid usage with those that did not.

- **Antidepressant usage and stroke outcomes:** Mixed evidence suggests that second generation antidepressants may be associated with adverse cardiovascular events. Depression is a frequently observed co-morbidity among stroke patients and understanding whether the use of second generation antidepressants is related to increased risk of adverse events may inform best practices in the care of these patients. We will examine adverse cardiovascular events and all-cause mortality in stroke patients who were diagnosed with depression and were also medicated with second generation antidepressants.

**Conclusion**
We used EHR data from multiple health systems and providers to build a specialized registry of TBI, SCI and stroke patients. In addition to providing injury surveillance, data from this registry may also be used for research purposes. Further, this data may provide a deeper understanding of the care process as well as long-term outcomes in TBI, SCI and stroke patients. Our registry demonstrates that it is feasible to create a specialized registry by leveraging EHR data from an HIE.

Stakeholder Use and Feedback on Vaccination History and Clinical Decision Support for Immunizations Offered by Public Health

Sripriya Rajamani, MBBS, PhD, MPH1, 2, Aaron Bieringer, BS3, Similoluwa Sowunmi, MPH3, Miriam Muscoplat, MPH3
1Public Health Informatics Program, 2Institute for Health Informatics, University of Minnesota, Minneapolis, MN; 3Minnesota Department of Health, St. Paul, MN

Abstract
National initiatives on Electronic Health Records (EHRs) recognize the vital role of public health and recommend reporting to Immunization Information Systems (IIS) and access of its clinical decision support for immunizations (CDSi). The objective of this study was to collect stakeholder feedback on access and utilization of CDSi from the Minnesota Immunization Information Connection (MIIC), Minnesota’s IIS. Input was solicited using a semi-structured questionnaire developed by experts, and from a sample of 17 key informants from February 2015 through May 2016. Analysis highlighted the appreciation of MIIC services, comprehensive vaccination history across providers and CDSi functionality, with public health users relying on MIIC. It also identified issues such as data entry due to read-only view, data quality and communications for improvement. These findings underscore the critical role of IIS, need to engage stakeholders, ensure CDSi updates, maintain good data quality, and promote bi-directional data exchanges across EHRs-IIS.

Introduction
Immunization Information Systems (IIS) are population-based, secure computerized systems present in most US states and territories1. IIS serve as a hub for immunization data given across providers over time. As delivery of certain preventive services, including immunizations, spreads beyond the confines of traditional healthcare organizations, IIS play a critical role in collating immunizations obtained through a spectrum of stakeholders. It aims to present a comprehensive vaccination history and addresses the potential record scatter across providers. IIS contains clinical decision support for immunizations (CDSi), incorporating recommendations from the Advisory Committee on Immunization Practices (ACIP)2. These guidelines are complex and include a range of factors like age, number of doses, dose intervals, medical conditions and vaccine contraindications. IIS are recognized as one of the strategies to utilize to meet Healthy People 2020 goals of decreasing vaccine-preventable infectious diseases by improving vaccination rates.

National initiatives that promoted adoption of electronic health records (EHRs)3,4 have also advocated for data exchange across settings using nationally recommended standards5. These regulations have recognized the vital role of public health and recommended reporting to Immunization Information Systems (IIS) as one of the priority areas. Recent regulations have built upon this to include bi-directional communications across EHRs-IIS6. The Advancing Care Information (ACI) measures for Merit-Based Incentive Payment System (MIPS) includes submission of immunization data and receipt of immunization forecasts and histories from the public health immunization registry/immunization information system7. Given these regulatory drivers, the Preventive Taskforce recommendations8, studies on IIS effectiveness9,10 and the increasing use of CDS with embedded immunization guidelines in EHRs, there is a need to understand the stakeholder access and utilization of IIS CDSi.

EHR-IIS research to-date comprises of single clinical setting reports11,12 and assessing automated reporting from EHR to IIS13,14. The overlap of functionalities between EHRs and IIS have been outlined with recommendations for guiding their integration15. Bi-directionality across IIS and EHRs has been advocated wherein benefits of integration supersede the challenges posed by variability in EHR technologies and various IIS16. Given the increasing importance of CDSi, there have been efforts to examine EHRs for functionality17 and creation of computable CDSi logic18. Study on access to IIS decision support within EHR19 concluded that visual integration of external registries into an EHR was feasible with improvement in provider satisfaction and registry reporting. Recent studies have examined EHR-IIS data exchange and access of IIS CDSi, but are focused in single system/setting19,20. A collaborative strategy emphasizing shareable solutions has been proposed with goals of making CDS sustainable for private and public sectors21. Given this landscape, there is a growing need for research to understand the access and use of CDSi at point of care, specifically through EHRs.

The Minnesota Immunization Information Connection (MIIC)22, the IIS in Minnesota, has been operational since 2002 and currently has 84 million immunizations and 7.8 million individuals across the life span. Overall, there are approximately 5,300 active organizations in MIIC ranging from primary care clinics, specialty providers, hospitals, pharmacy, schools and public health. MIIC currently offers an option to access MIIC from the provider EHR and is branded as ‘Alternate Access’23. This solution generates a query to MIIC for vaccination history and
forecasting and is based on demographics of the record in the EHR. It does not require separate MIIC log-in and addresses the issue of data entry for the query. With this functionality, the history and forecast are presented to the user within their EHR. This data can either be displayed as a ‘read-only’ view or can be ‘integrated’. Many have implemented a ‘read-only’ option, but moving towards ‘integrated’ with recent EHR system upgrades.

Prior research by authors has examined the technological and organizational context around immunization reporting to MIIC to portray increasing electronic reporting from EHRs using standards and real-time methods. Recent MIIC CDSi studies have focused on understanding the queries and its variability across providers and EHR implementations and analyzing the CDSi presentation through direct access by IIS interface and by access through electronic health records (EHRs) to outline similarities and differences. Building upon prior work and on national recommendations which promote IIS CDSi use, the goal of this research is to understand various aspects of MIIC CDSi from end-user/stakeholder perspectives. The main study objective was to collect stakeholder feedback on access and use of MIIC CDSi with the intent of utilizing results for prioritizing system enhancements and for program improvement. The overarching goal is to enhance the utility of IIS and its CDSi functionality. The study will have potential implications for using IIS CDSi as a strategy to increase immunization rates and improve population health.

Methods

Subject and Site Selection

Data was collected from a purposive sample of subject matter experts selected from healthcare systems and public health clinics. A total of 17 professionals were interviewed from 12 organizations representing 324 individual care sites. Their expertise spanned across public health and clinical care settings, and across clinical and administrative roles. These experts were selected based on their prior collaborations with MIIC and for their familiarity with the tool. The interviewee selection was also based on their ability to share information at a health system level vs. a site level, as approximately nine healthcare delivery systems hold 90% of the health services market in Minnesota due to the high presence of integrated delivery networks. Likewise, the interviewees of local public health were chosen from relatively high volume clinics to get granular information on MIIC CDSi access and some had an EHR in place for the last few years. Table 1 presents their various roles which range from vaccine coordinator, clinical analyst, nurse administrator, quality improvement manager and EHR project manager.

Table 1: Participant Roles and Settings

| Roles          | Clinical Care Setting                              | Public Health Setting                        |
|               | Health System / clinic                             | Local health department / public health clinic |
| Clinical       | Clinical Analyst (1)                               | Clinical Director (1)                        |
|               | Vaccine Coordinator (2)                            | Vaccine/Immunization Coordinator (2)         |
|               | Licensed Practical Nurse (1)                       | Immunization Manager (1)                     |
|               | Vaccine and Infection Prevention Specialist (1)    | Nurse Epidemiologist (1)                     |
|               | Health Outreach Coordinator (1)                    | Public Health Nurse (2)                      |
| Administrative | Nurse Administrator (1)                            | EHR Project Manager (1)                      |
|               | Quality Improvement Manager (1)                    | Support Staff (1)                            |

Development of the Interview Questionnaire

The study utilized qualitative methodology to collect information from main stakeholders and users of MIIC CDSi. These are subject matter experts from healthcare systems and local health departments / public health clinics. A semi-structured interview questionnaire was developed by study authors (SR, AB) and refined through input from MIIC leadership and experts in CDSi and IIS. The tool aimed to collect data across four domains and consisted of both structured and open-ended questions to facilitate the gathering of information (Refer to Table 2 for the Interview Questionnaire). The tool was pilot tested with a clinic first, minor edits incorporated and was then utilized as the main data collection instrument.

The background section aimed to understand the number of sites in the organization that had access to MIIC CDSi functionality (both embedded EHR access and also access by MIIC interface); time and reason for installation of EHR access feature and if it was included in EHR training or other user education efforts. This was followed by
a section on the awareness and use of MIIC CDSi collecting data on number of users, type of users (e.g. provider, nurse, clinic manager) and if it was accessed for all visits/select visits. This section also focused on immunization data across EHRs and MIIC and if data missing across either systems was shared/reported, including highlighting of errors. It also aimed to solicit awareness of MIIC CDSi. The third section addressed the value of MIIC CDSi by gathering data on perceived value of the tool, information that is sought (e.g. vaccination history, immunization forecast) and integration with workflow. Tracking of missed opportunities by the system/clinic (if any) and ideas for MIIC CDSi improvement were some essential elements of this interview process. The closing section aimed to collect information on organizational initiatives under which MIIC CDSi is promoted (if any) and other organizational subject matter experts.

</tr>
</tbody>
</table>

Data Collection

Subject matter experts were contacted over email and interview questions were shared a couple of weeks in advance to help them prepare and gather additional information as needed. An opportunity was given to extend the interview to their colleagues as needed. These interviews were conducted over the time period of February 2015 through May 2016. WebEx was used for set-up and recording of the meetings. Three study authors (SR, AB and SS) were present during all the interviews and two authors (SR and SS) took detailed notes during the interview process which was utilized for the study analysis. Verbal consent was obtained prior to the interview and each lasted for approximately 45 minutes. Notes were exchanged immediately after the interview and cross referenced so that any discrepancy can be resolved.
**Data Analysis**

Preliminary analysis and exchange of notes (SR, SS) occurred between the interviews. Analysis of qualitative open-ended answers was supported by NVivo 11 software (QSR International). One of the study authors (SR) participated in all the interviews, was one the main note takers, has worked in public health and in immunization program for many years and was the main coder. These codes were synthesized through discussion (SR, AB and MM) which lead to consolidating categories that overlapped and identifying higher level themes. The responses to structured questions were analyzed using descriptive statistics and tabulation was utilized to present results. The responses considered important to highlight were selected through group consensus (SR, AB, MM).

**Results**

Table 3 presents the responses by the 17 subject matter experts from 12 organizations, and highlight the key areas with MIIC access. Themes and categories identified in the analysis along with sample quotes are in Table 4.

Most of the organizations interviewed (10 of 12, 80%) had MIIC access within their EHRs. Of the 10 organizations with embedded EHR access to MIIC, almost all had included this functionality as part of their EHR training (8 answered yes and 2 were uncertain). All the public health clinics interviewed (with the exception of 1) had bi-directional data exchange across MIIC and EHRs which indicated that data was being transferred from MIIC to EHRs and integrated into the EHR record. Of the organizations which had pre-visit planning in place (10 of 12), almost all had access to MIIC as part of patient preparation/arrival. Scenarios which prompted access to MIIC varied across the organizations, and predominantly part of pre-visit and MIIC look-up during a clinical encounter was done only for urgent care visits. Two organizations (A and B) which are the dominant integrated health systems in the state utilized the CDSi present in their EHR and looked up MIIC only for vaccination history. MIIC was accessed by nurses, clinic assistants and care support professionals (e.g. front desk, scheduling, billing) in all the organizations (12 of 12, 100%) and had limited access by providers (e.g. physicians).

</tbody>
</table>
Four main themes were identified which included feedback on MIIC CDSi tool and its utility and items which
needed action: Recognition of the Value of MIIC; Benefits of System and Workflow Integration; Functionality
and System Requirements to Address and Need for Better Communications. MIIC value proposition was due to
the comprehensive vaccination history provided, the immunization forecaster (CDSi) and other
services/functionality offered (e.g. Reminder/Recall, Improbable shots report, Vaccine Management). The access
which was integrated within the EHR eliminating the need for a separate user interface and data entry was highly
appreciated by the users. Overall, MIIC access seemed well integrated within the workflow of various
organizations. Five functional/system requirements were identified for improvement ranging from need for
additional details on the vaccine given; improvement of the forecaster by inclusion of guidelines for those who
don’t fit into regular schedule; improving the quality of data in MIIC; need for bi-directional data
exchange/dynamic data flow to eliminate dual data entry and finally enhancing the capacity of the system to
facilitate quick response time to queries. Need for information sharing and outreach was mapped into the final
theme on the need for better communications (from MIIC to its users/stakeholders) which underscored the need
to inform users ahead of time on planned system upgrades/down time, to facilitate planning of clinic vaccinations.

Discussion

Results point to strong support of MIIC and recognition of its value and the services/tools offered. Almost all
participating organizations (12 of 12), which include 324 individual sites had access to MIIC in varying formats
embedded within their care delivery. These represent approximately 25% of the sites/clinics in the state and so a
reasonable indicator of the overall pattern. Majority of the organizations interviewed (10 of 12, 80%) had MIIC
access within their EHRs, but some of those did not have dynamic data exchange which supported data entry from
MIIC into EHRs. But, this issue should be resolved in the near future, as current version of the prominent EHR
product used in Minnesota (Epic) supports this functionality and organizations are upgrading to this version.

One of the findings was the systematic difference between private and public health clinics in their access and use
of MIIC and its perceived utility, with public health clinics/local health departments much more appreciative of a
public health information system such as MIIC. This is likely due to the patient population they serve, many of
whom have sporadic encounters with the healthcare system and have providers who are spread across locations
and systems resulting in an immunization record scatter. IIS serves as a hub to collate this vaccination history
across providers and locations and presents immense value to these settings. The appreciation of MIIC is also due
to the fact that low resource settings likely have EHRs with fewer capabilities such as clinical decision support
and hence rely more on MIIC services such as CDSi and various tools/reports (client assessment, vaccine
management).

As initiatives are being explored to increase the utility of MIIC CDSi, this study yielded important findings on the
main user base, who are primarily nurses in both clinical and public health settings along with support
professionals (e.g. front desk, scheduling, billing), with limited access by providers (e.g. physicians). The
literature on clinical decision support and national recommendations advocate for access during clinical
encounters/point of care. But the majority of settings in this study pointed to access of MIIC CDSi as part of pre-
visit planning. As per study participants, this timing of access seems to integrate better with their workflow as
vaccinations are typically administered during scheduled well-child visits for pediatric population. As the
recommendations are to access CDSi during the point of care, additional research needs to be done to understand
the obstacles (if any) to access the CDS tools during a clinical encounter. This is an important issue which will
affect the design and implementation of EHRs and their integration with IIS.

This study pointed to some system/functionality needs which required actions by MIIC program management.
The need for better communications was acted upon by MIIC leadership with regular email updates sent to
stakeholders on scheduled MIIC downtimes and also immediate information shared on unexpected data exchange
malfunctions so that an organization can re-submit their data. Though MIIC had communication mechanisms on
error corrections, the interviews pointed to the need for selecting the right professional at the provider end to receive
the messages and to address those errors.

The study emphasized the need for good quality of data in the IIS (MIIC in this study) as the forecasting is
dependent on IIS data and becomes irrelevant with incomplete data in the IIS. The issue of missing shots
impacting completeness of data identified by stakeholders is due to non-submission of data by some organizations
and efforts are being made to increase provider participation in MIIC. Likewise, the need for better data quality
in MIIC was addressed by creation of a data quality coordinator position whose responsibility is to monitor quality
of data and identify systematic errors with incoming data and also implement protocols for regular data quality
assessment. The increasing bidirectional movement of data across MIIC and EHRs due to capacity of EHRs to
support this data interchange highlights the increasing need to monitor quality of data to ensure data is correctly
being attributed to organizations which have the shot and those that incorporate and report them to IIS. These findings also supported the need to use a data quality monitoring tool on a regular basis for data validity checks.

One of the limitations of this study are that it did not cover all the sites that accessed MIIC CDSi. The participating organizations represent approximately one fourths of user base and so findings can be applicable to other sites that are similar in size and patient population. Participants were chosen based on their expertise and their position within the organization to share practice information from a system level, but it’s possible that there is variation across sites. The other shortcoming is that, after completion of this research, three of the main healthcare systems with hundreds of clinic sites have either upgraded their EHR product or switched to a new EHR platform and so the functionalities (specifically the capacity for dynamic data interchange across MIIC and EHRs) may have since improved.

Another limitation of this study is that it focuses on a single state IIS. MIIC is part of WIR consortium28 which is a collaboration of group of states on the same vendor platform as MIIC and is likely that some of these findings are applicable to them, but need additional studies for validation. Additional aspects which are unique to this study setting and can potentially limit generalizability is the predominance of integrated health care delivery network structure in the state and the market dominance by a single EHR vendor. Yet another limitation is that this research did not examine the role of third-party immunization clinical decision support29 and its role. This study focused on understanding the overall access and utilization of MIIC CDSi and additional studies are needed to understand the variability in CDSi across MIIC and third-party solution. The American Immunization Registry Association (AIRA)30, a membership and advocacy organization for IIS across the various states should share findings from this and other IIS studies to share lessons learned.

Conclusion

With the recognition of the importance of public health reporting and the recommendation to look up and use CDSi offered by IIS, there is a need to understand the current status of utilization. This study collected stakeholder feedback on access and use of vaccination history and MIIC CDSi with the intent of utilizing results for prioritizing system enhancements and program improvement. Research insights can be applied to other scenarios of public health decision support (e.g. case reporting) and other situations of HIT implementation and evaluation. The overarching goal is to enhance utility of IIS and its CDSi functionality and study will have potential implications for using IIS CDSi as a strategy to increase immunization rates and improve population health.

Acknowledgements

The authors would like to thank the various stakeholders from private health systems and from public health clinics who participated in this study for their time and valuable input.

Formative Evaluation of CareNexus: a Tool for the Visualization and Management of Care Teams of Complex Pediatric Patients

Pallavi Ranade-Kharkar, PhDc, MS1,2, Chuck Norlin, MD1,3, Guilherme Del Fiol, MD, PhD1
1Department of Biomedical Informatics, University of Utah, Salt Lake City, UT; 2Intermountain Healthcare, Murray, UT; 3Department of Pediatrics, University of Utah Health Sciences Center, Salt Lake City, UT.

Abstract
Complex and chronic conditions in pediatric patients with special needs often result in large and diverse patient care teams. Having a comprehensive view of the care teams is crucial to achieving effective and efficient care coordination for these vulnerable patients. In this study, we iteratively design and develop two alternative user interfaces (graphical and tabular) of a prototype of a tool for visualizing and managing care teams and conduct a formative assessment of the usability, usefulness, and efficiency of the tool. The median time to task completion for the 21 study participants was less than 7 seconds for 19 out of the 22 usability tasks. While both the prototype formats were well-liked in terms of usability and usefulness, the tabular format was rated higher for usefulness (p=0.02). Inclusion of CareNexus-like tools in electronic and personal health records has the potential to facilitate care coordination in complex pediatric patients.

Introduction
Children and youth with special health care needs (CYSHCN) generally have or are at a risk of developing chronic medical and mental health conditions, resulting in an increased need for specialized medical, therapeutic, equipment, family support, and other services. 15.6% (approximately 11 million) of the pediatric population has special needs and accounts for about a third of the total healthcare spending associated with children. Coordinating care for these medically complex patients is crucial for enabling efficient use of resources, reducing costs, enhancing communication between patient/family and provider, and improving patient/family and provider satisfaction.

Caring for CYSHCN often involves a large number of participants from disparate settings, working independently, and serving in various roles that may wax and wane in importance or need over the continuum of patient care. The clinical care teams often include the primary care physician and a number of specialists, care coordinators, therapists, and social workers. However, the care teams of CYSHCN also extend far beyond the hospital/clinic walls and may include schools; community resources such as support groups and family advocacy groups; cultural and charitable organizations; multiple payers and funding agencies; and family members, neighbors, and friends. In a previous study, we identified and described information needs of physicians, care coordinators, and parents to support care coordination of CYSHCN and categorized them into information goal types. One of the goal types we identified was care networking and we defined it as “building a patient’s care team or network, knowing team member identities and roles, and sharing pertinent information to enable activities/actions as a team”. Keeping track of who is involved in a patient’s care at any given time, what their roles are, their goals and feedback, and preferred contact information; and finding new care team members to fit patient and family needs, was described as extremely challenging by the interviewees. Because they lacked appropriate tools, physicians, care coordinators, and parents of CYSHCN resorted to workarounds such as spreadsheets, hand-written sticky notes, refrigerator magnets, and memorization to store and track care team-related critical information.

In spite of the great potential for electronic health records (EHRs) to help providers coordinate care, current EHR systems do not adequately support the needs of care coordination. Vawdrey et al. note that we need better tools to support care team-related information in commercial EHR systems. Usability of EHRs also falls short in supporting the unique needs of representing information about complex patients. A recent systematic review reported that lack of appropriate software functionality and poor user interfaces were linked to patient safety concerns. Electronic personal health records (PHRs) have been proposed as a strategy to support care coordination. However, few PHRs have been developed for the domain of pediatrics due to lack of standards for pediatric content and customizations needed for chronic conditions. With lack of PHRs to support care networking, parents of CYSHCN bear the burden of maintaining information about their child’s care team and repeating their “story” while coordinating care among a large and diverse care network.
In this study, we partner with care team members in key and complementary roles: physicians, parents, and care coordinators of CYSHCN, to gain insights into designing an application for clinicians and patients/families for the purpose of care networking. We iteratively design two alternative user interfaces to view, understand, share, and manage patient care team information. We then implement the designs and conduct a formative evaluation of the usability, usefulness, and efficiency of the user interfaces.

Methods

This study used a within-subject design comparing the interactions of physicians, parents, and care coordinators of CYSHCN with two user interface designs (graphical and tabular) of a prototype software we named “CareNexus” to accomplish goals and tasks related to creating and managing patients’ complex care networks. The study involved both, granular tasks designed to assess usability, and high-level tasks focused on solving a care coordination problem described in vignettes. The study addressed the following research questions: 1) to what degree are features offered by CareNexus to create, understand, and manage care networks of CYSHCN easy to use and efficient?; 2) how useful are the features offered by CareNexus?; 3) how do the graphical and tabular displays of the care networks compare in terms of usability and usefulness? The study was approved by the University of Utah Institutional Review Board under protocol #IRB_00096357.

CareNexus tool design

The design of CareNexus was guided by Information Foraging theory18, Shneiderman’s principles for information visualizations19, and Jakob Nielsen’s heuristics for user interface design20. The Information Foraging theory draws an analogy between a bird foraging for food and humans foraging for information. The optimal foraging effort seeks maximum “benefit” from minimal “cost” of information seeking by identifying rich information patches. We enabled users to optimize their information seeking effort by providing information patch enrichment (i.e. providing ways to get to the relevant content quickly and easily). We also applied Shneiderman’s visualization principles by offering an overview of information at the first level, then implementing zoom-in/zoom-out functions for the information, and finally providing information details on demand. Additionally, we have incorporated Nielsen’s principles for user interaction design to the CareNexus prototype.

The design of CareNexus followed an iterative design methodology based on rapid prototyping, analyzing, and refining cycles guided by feedback from representative users from each of the target user roles: physician, parent, and care coordinator. Tabular representation of medical data in the form of charts are common in current EHRs (e.g. Cerner™ uses tables to display patient care teams). This made the tabular design an obvious choice. A recent systematic review on innovative visualization of EHR data reported that color, lines, shapes, and visual diagrams have been effectively used to render patient data21. Thus, we opted to design a graphical interface that depicts the care team as a visual diagram as an alternative to the tabular format. We started off with “low-fidelity” prototypes in the form of whiteboard diagrams and software mockups. As the design matured, we transitioned to web-based “high-fidelity” prototypes using the AngularJS™ framework, Java™ RESTful Web Services, and MySQL™ database. We further incorporated the critique from human factors and usability experts into the mature designs.

The functional specification for CareNexus is derived from the results of our previous work focused on eliciting information needs and associated goals that are raised by physicians, care coordinators, and family members while coordinating the care for CYSHCN7. CareNexus is designed with the objective of supporting the information goal of care networking, specifically creating, understanding, and managing patient care networks or care teams. CareNexus does this by supporting previously identified goal sub-types of care networking: 1) care team building, 2) care team member identities, 3) contact information, 4) shared team knowledge, and 5) shared team action.

Participants and setting

Participants in the iterative design phase and the study were recruited from primary care sites that participate in pediatric Patient-Centered Medical Home (PCMH) Demonstration projects in Utah22. Each practice has a designated care coordinator and has one or more “family partners” who are actively-engaged parents of CYSHCN. The iterative user design phase included one of the co-authors (CN), one parent, and one care coordinator. For the formative evaluation, we recruited a purposive sample of 21 subjects (7 each of physicians, parents, and care coordinators) with the following criteria: 1) a minimum of 2 years of current experience caring for CYSHCN; 2) experience across a wide range of clinical and patient conditions; and 3) no previous exposure to the CareNexus tool. The participants were invited by email to join the study by the project director of the PCMH Demonstration and co-author CN. We determined the sample size by following recommendations from the literature23,24.
Case vignettes
The two case vignettes used in the study were adapted from the “Essential Information for Children with Special Healthcare Needs” project headed by the HL7 Child Health work group. The primary author contributed to this project by suggesting use cases and writing storyboards for the selected use cases. The case vignettes were representative of the clinical conditions, information needs, and challenges that often face this cohort of patients and are comparable in complexity. Each case vignette consisted of a narrative about the patient’s clinical and social context and a care coordination problem related to a current event or episode in her/his life that needed to be resolved using CareNexus. The two case vignettes were further customized to the role of the study participant (physician, parent, or care coordinator). The case vignettes and the associated data were synthetic and were approved by the users in each of the three roles who participated in the user interface design phase.

Procedure
The study was conducted either in an office setting at the work sites of the participants or at their homes. The two case vignettes and two interface designs resulted in four possible case vignette/display format combinations: 1) case vignette 1 + graphical format; 2) case vignette 1 + tabular format; 3) case vignette 2 + graphical format; and 4) case vignette 2 + tabular format. Each of the participants interacted with two of the four combinations in random order such that all participants interacted with both the displays and both case vignettes.

The study session began with a brief introduction of the study. In study part 1, the participants were asked to complete the following steps for their first case vignette/CareNexus display format combination: 1) usability tasks: perform 22 tasks (Table 1) distributed over the 5 goal subtypes of care networking; and 2) problem-solving: identify care team members to communicate with using CareNexus to resolve a problem related to care coordination for a current episode of care as posed by the case vignette. This was followed by a questionnaire that assessed the usability and usefulness of one display format of CareNexus. These steps were repeated for their second case vignette/CareNexus display format in study part 2. Finally, the study subjects were asked to rate the usefulness of a set of CareNexus features and provide open-ended comments and suggestions. The participants were not provided with a tutorial of CareNexus. The goal was to assess the intuitiveness, usability, usefulness, and efficiency of CareNexus without any prior exposure to the user interface of CareNexus. The user sessions were recorded using Hypercam, a screen capture software.

Data analysis
Using the video recordings from Hypercam, each of the usability tasks were coded for: 1) ability to carry out the usability task to successful completion, and 2) time to completion. Given that the data represented repeated measurements of ratings, where the user rated two different interface designs, a paired sample data analysis was used. Comparison between the ratings of the two interface designs was performed using mixed-effects linear regression, with repeated measurements nested within user, controlling for the covariates of perceived vignette complexity, experience of the study subject with the patient conditions in the vignette, and the sequence in which the interface designs were evaluated. We developed a 14-item questionnaire with Likert-scale response options (1=strongly disagree; 5=strongly agree) to assess the usability and usefulness of CareNexus. The questionnaire included five questions from the System Usability Scale and nine questions that measured self-perceived ability to understand the gist, create, and manage care networks and related information. The individual questions were aggregated into two composite scales: usability (questions 1, 3, 8, 12, and 13) and usefulness (questions 2, 4, 5, 6, 7, 9, 10, 11, 14) to maximize reliability and generalizability. Reliability analysis was performed using Cronbach’s alpha by aggregating ratings for the two user interface designs for the composite scales.

Results
CareNexus user experience
The design of the user interface of CareNexus required ten iterations that were performed before the formative evaluation. The resulting user interface of CareNexus with the graphical care network format for case vignette 1 is shown in Figure 1. Figure 2 shows the tabular care network display for case vignette 2.

The patient banner (section #1, Figures 1 & 2) gives a quick overview of the patient and indicates additional needs if applicable (e.g. need for a language interpreter). Section #2 below shows the event timeline with boxes intuitively labeled to indicate clinical events (e.g. outpatient, inpatient, and emergency room visits) and other significant events in the patient’s life providing information-patch enrichment. The start and end of timeline defaults to six months before and three months after the current date respectively. The user can view a wider or narrower timeline range by using...
Figure 1. CareNexus user interface with a graphical view of the care network for case vignette 1.

Figure 2. CareNexus user interface with a tabular view of the care network for case vignette 2.
the navigation menu buttons or the mouse wheel. Clicking on individual events, displays detailed information about the primary care team member involved in the event in the bottom left-hand side of the screen (section #4). Shared team knowledge of the patient demographics, clinical conditions, a quick reference to the contact information of the person most involved in the patient’s care, and a quick summary of the patient’s encounters aims to provide patient context efficiently and accurately.

Users can visualize the patient’s care network in section #3 (Figures 1 & 2). Knowing who is currently involved in the patient’s care, in what role, and how to contact them is vital to care networking. The care network is displayed either in a graphical (Figure 1) or tabular format (Figure 2). In the graphical format, the patient is shown in the center of the network and is surrounded by either the family (yellow), medical (green), or non-medical (blue) care network member nodes. The tabular format displays the care team members in a table sorted by status (“active” at the top, followed by “less active”, and finally “inactive”). The family network includes immediate and extended family members involved in the patient’s care. Care team members belonging to a clinic setting are categorized as medical network members (e.g. primary care physician, care coordinator, neurologist, and social worker). The non-medical team members include the extended care network such as the school, community support groups, and durable medical equipment providers. The color gradient of the nodes of the care network and the thickness and style of the connecting lines indicate closeness of the care team to the patient’s care. There are three levels of closeness or importance: 1) active (color: darkest, connecting line: bold and solid); 2) less active (color: lighter, connecting line: medium and solid), and inactive (color: grey, connecting line: medium and dashed). The closeness or importance of a care team member to the patient’s care network can be manually assigned or can be inferred based on whether the team member has been involved in the patient’s care within a certain time frame: 1) “active” indicates activity within the last 3 months; 2) “less active” indicates activity within the last 6 months; and 3) “inactive” indicates no activity for over 6 months. The label across the top gives a quick summary of the number of active, less active, and inactive care team members. Our design goal was to provide optimal cues to users to help them understand the gist of the patient’s care network and the ability to get more information on demand, per Shneiderman’s visualization principles.

The bottom left of the screen (section #4) shows details of the care team member with the team member identity and contact information of the selected care team entity (primary care team member involved in a timeline event or a member from the care network). This information display resembles a “business card” following Nielsen’s design principle of matching real world and software system representations. Next to it we display the status, recent appointments, patient care goals, and feedback (if applicable and available) of the care team member. Building and managing a patient’s care team (section #5) can be accomplished by using the search, add, update, and delete functionality conveniently co-located in bottom center of the screen. Users can update and/or delete only those care team members who have been added by them. Finally, shared care team actions are supported by providing information about who is responsible for which task, due date (if applicable), and the status of the task. The users can view all team members’ tasks and add/delete/update their own task list. Following Nielsen’s design principles, we have maintained simplicity and color/font consistency throughout the design of CareNexus and minimized the need for user recall by providing convenient tool tips.

Ease of use, efficiency and usefulness ratings
The study participants were able to successfully complete all of the 22 usability tasks (Table 1). The median time to completion was less than 7 seconds for all but 3 tasks (searching for and manually adding care team members, and identifying events took > 7 seconds). All users also successfully identified all the care team members needed to resolve the care coordination problems posed by the case vignettes. Users highly rated all CareNexus features with highest ratings for the timeline, team member business/contact cards, and most recent and next appointments (Table 2).

Comparison between CareNexus user interface designs

Cronbach’s alpha for the composite variables of *usability* and *usefulness* are given in Table 3. There was a significant lower mean usefulness rating for the graphical interface compared to the tabular interface, after controlling for complexity, experience, and the sequence in which the interfaces were evaluated (adjusted mean difference=−0.12; 95% CI: -0.22,-0.01; p=0.02). Although statistically significant, the differences are very small and may not indicate clinical significance. There was a non-significant lower mean usability rating for the graphical interface compared to the tabular interface, after controlling for the same criteria (adjusted mean difference=−0.12; 95% CI: -0.26,0.03; p=0.12). Given our sample size of 21 we had 80% power using a two-sided alpha 0.05 comparison to detect a paired sample standardized mean difference of 0.64, which represents a moderate to large effect size by Cohen's criteria.

Discussion

Pediatric patients with special needs have large care teams with members in various roles corresponding to different aspects of patients’ lives, such as treatment and management of health conditions, developmental challenges, educational needs, and financial support. Previous research in the domain of patient care teams has addressed availability of care team-related information in the inpatient setting, supporting team work within the same care setting, and tailored applications for the needs of patients with certain conditions. However, less has been done for designing clinician- and patient-facing applications to address the needs of medically complex patients that cross the boundaries of specific settings and conditions. The goal of our research is to address this gap by designing, developing, and evaluating two alternative user interface designs for a prototype of CareNexus, a tool to visualize, understand, share, and manage care team related information for complex pediatric patients.

The study participants highly rated the feature set and the overall user interface of CareNexus in terms of usability and usefulness. These findings are important based on the technology acceptance model (TAM) which stipulates that perceived usefulness and ease-of-use are predictors of actual use. Several factors may have contributed to these findings, including deriving the requirements from a systematic information needs analysis, the early involvement of representative users, an iterative design approach based on the information foraging theory, Shneiderman’s visualization principles, and Nielsen’s usability principles. All users completed 100% of the usability tasks (time to completion for 19 out of the 22 tasks was less than 7 seconds). The problem-solving segment of our evaluation approach encouraged the users to quickly grasp the gist of the care network, identify the care team member(s) relevant to the problem, and access their contact information. The patient event timeline was the highest ranked component of the application. Users found it to be a very intuitive and quick way to gain shared team knowledge about recent visits, issues, and current status of the patient’s care. The tabular format of the care network was preferred over the graphical format, however the differences in the ratings were small. Participants liked both the formats and users should be allowed to choose between the two formats, per individual preference, as suggested by one of our physician participants. Further research is needed to investigate if our findings regarding tabular versus graphical displays generalize to other applications as well as the different factors that may influence display format preferences. Display of three separate networks and the associated color coding made it easier for the users to identify care team members. Having the contact information along with the preferred contact readily available can be very beneficial, especially in emergent situations which was described as a need for this cohort of patients. Sharing the goals and feedback provides a way to create a shared sense of common ground between the team members. Finally, care team actions enable processes that require shared responsibility between care team members ensuring that members of the care team (including the parents) are “on the same page”. Viewing the care team actions and their status is valuable for all team members and may reduce the need for time-consuming and sometimes unreliable person-to-person communication.
The results of our formative evaluation are promising and warrant future work on: 1) analyzing the information sources for the care team-related information displayed in CareNexus, 2) developing algorithms to automatically populate applications like CareNexus, and 3) integrating CareNexus into EHR and PHR workflows. Future studies should also focus on extending the findings in this study to other patient populations needing chronic care management.

Limitations
The case vignettes used in this study were adapted from the use cases identified by the HL7 Child Health work group. Although they are representative of clinical and patient conditions of children with special needs, it is possible that different conditions may require other design features. The formative evaluation assumes availability of accurate and up-to-date care team information. High-quality care team data may not be readily available in real world systems and that may influence users’ perception of usefulness. Also, CareNexus is designed to be used in tandem with EHR and PHR systems. Further studies should investigate the usability, usefulness, and efficiency of CareNexus integrated in the user workflow.

Conclusion
We describe the design and formative evaluation of two alternative user interfaces of CareNexus, a prototype of a tool to view, understand, share, and manage patient care team information. We followed an iterative design approach guided by the information foraging theory, information visualization principles, and user interface design heuristics. In addition, feedback from representative users was incorporated early into the design. Twenty-one users participated in the formative evaluation of the resulting graphical and tabular user interfaces. Users highly rated the usability, usefulness, and feature set of CareNexus, and were able to complete the usability tasks in a short amount of time. The tabular format was rated higher for usefulness but the difference was small indicating that the users liked both the formats. Tools that enable understanding the gist of a patient’s care network across organizational boundaries, the temporal nature of care team relationships, details of contact information, goals and feedback of those involved in the patient’s care, and ability to find providers to match patient/family needs have the potential to facilitate care coordination and team collaboration.

Acknowledgements
This investigation was supported by the University of Utah PHR and Population Health Research Foundation, with funding in part from the National Center for Research Resources and the National Center for Advancing Translational Sciences, National Institutes of Health, through Grant 5UL1TR001067-02 (formerly 8UL1TR000105 and UL1RR025764). We would like to acknowledge the HL7 Child Health work group for allowing us to adapt their use cases for the case vignettes used in this study. Finally, we would like to thank the socio-technical team at the Department of Biomedical Informatics, University of Utah, for their valuable feedback on the user interface designs.

Abstract

There are many benefits of online patient access to their medical records through technologies such as patient portals. However, patients often have difficulties understanding the clinical data presented in portals. In response, increasingly, patients go online to make sense of this data. One commonly used online resource is health forums. In this pilot study, we focus on one type of clinical data, laboratory results, and one popular forum, MedHelp. We examined patient question posts that contain laboratory results to gain insights into the nature of these questions and of the answers. Our analyses revealed a typology of confusion (i.e., topics of their questions) and potential gaps in traditional healthcare supports (i.e., patients’ requests and situational factors), as well as the supports patients may gain through the forum (i.e., what the community provides). These results offer preliminary evidence of opportunities to redesign patient portals, and will inform our future work.

Introduction

The clinical data (e.g., laboratory results, clinician notes) contained in medical records have long been a product of, and central to, the interactions that take place between patient and physician in a clinical encounter. These data were traditionally created, updated, and used almost exclusively by physicians. However, research suggests that providing ready access to medical records facilitates patient engagement,1 which can lead to improved health outcomes and reduced costs.2 While patients have had the right to access these records since 1996,3 the process of requesting a paper copy has tended to be prohibitive and, once obtained, can soon become difficult to manage and are easily lost.4 To address these barriers, U.S. health IT policies such as Meaningful Use,5 and initiatives such as OpenNotes,6 have encouraged that patients be given direct, electronic access to their medical records. In response, many healthcare organizations have deployed patient-facing technology, commonly referred to as patient portals, connected to their electronic health record systems. The literature suggests that patient use of these portals may have numerous benefits, including improved quality of patient records,7 home monitoring infrastructure,8 satisfaction with patient-provider communication,9 and health status.10 However, despite these potential benefits, patients have not accessed the portals11 at the rates predicted based on the high level of interest.12 In fact, according to the 2015 U.S. Health Information National Trends Survey, only about 27% of Americans had accessed their health data online, including through patient portals, in the past year.13 Even more concerning is the significant disparities in use found among certain groups, including some minorities,11 adolescents,14 and incarcerated patients.15

So, why has ready access not resulted in more access? According to the literature, a key barrier to realizing the full potential of patient portals is the lack of useful information despite the abundance of data they make available. For example, a recent study found that many patients’ needs for online portals were not just for accessing the data, but for obtaining personalized and actionable knowledge.16 These needs, however, have not been adequately met in the pervasive patient portal design. Relatedly, low health literacy and numeracy, meaning a lower “capacity to obtain, process, and understand basic health information and services needed to make appropriate health decisions,”17 can be a barrier to patient portal use.18 Many portals present data to patients in the same or similar way that it is presented to healthcare providers; however, studies have shown that patients may have difficulty understanding medical jargons used in free-text document, such as clinician notes,18 and interpreting quantitative data, such as laboratory results.19 These findings suggest that current patient portals may have been designed at too high of a level of health literacy and numeracy, or do not provide enough, or the right, support to aid patient understanding.

At the same time, there is often not enough time during a clinical encounter to fully meet patients’ needs for knowledge. While it varies by healthcare setting (e.g., primary care, specialty care), there is evidence suggesting that, on average, physicians are spending less time with each patient – from over 20 minutes per patient in 1998, to
around 17, or even lower, in 2016.\textsuperscript{10,21} A related issue is that studies have found that some physicians frequently interrupt patients,\textsuperscript{22} which may make it difficult for patients to get their questions answered. These factors can also negatively affect the patient-physician relationship,\textsuperscript{23} which may reduce the likelihood that patients will trust their physician. In sum, while healthcare provider institutions are expanding patients' access to clinical data through patient portals, this technology often does not adequately meet patients' knowledge needs, and access to healthcare's traditional social supports,\textsuperscript{24} including informational, is shrinking.

Therefore, in order to actually use the available data for personalized decision-making, patients must often tap into supplemental sources of knowledge. Increasingly, this means searching online for general and/or individualized health information.\textsuperscript{25} In fact, according to one study, 72\% of U.S. internet users reported doing this.\textsuperscript{26} There are, of course, a variety of online resources of varying levels of interactivity and quality from which patients may choose, but health forums have been growing in popularity (e.g., MedHelp.org, CrowdMed\textsuperscript{26}). These forums provide users with a platform to ask their health-related questions, so that others (typically peer patients) can provide assistance.

Among the myriad of patient questions, we were particularly interested in questions accompanied by data that appeared to be directly copied from the individual's medical record, and pasted into the forum post (or in some instances transcribed; referred to just as copy/paste below). Examples of such data include laboratory results, vital signs, and excerpts from radiology reports and discharge summaries. This content is usually posted publicly, which provides an opportunity for researchers to understand the nature of patients' questions about their clinical data. This offers direct evidence of comprehension issues, as well as additional forms of support that may be needed. Similarly, the nature of the answers to these questions, especially those that patients find useful, point towards the supports those patients may gain through the forum discussions. While the insights from these analyses may have broader implications for patient-provider communication channels, in this study, we focused on their opportunities to improve patient portal design to better meet patients' needs.

In this study, we preliminarily assessed the feasibility of this approach by focusing on a particular type of clinical data, laboratory results, which are widely available and frequently viewed in patient portals,\textsuperscript{18} a common source of questions,\textsuperscript{27} and tend to be easier to identify in question posts. Similarly, we focused on MedHelp (medhelp.org), which is one of the most popular online health forums.

**Methods**

**Dataset:** All questions and threaded replies from MedHelp were downloaded in September 2016. This dataset contains over 2 million questions and over 8 million answers posted by over 2 million unique users on numerous health conditions (e.g., diabetes, asthma) and health-related topics (e.g., healthy recipes). Question posts on MedHelp are very diverse; for example, patients may present symptoms and/or laboratory results in order to determine whether a clinic visit is necessary, and/or request emotional support during a stressful time (see Figure 1).

**Identifying Potentially Relevant Posts:** Before we could address our research objective – to understand the nature of question posts containing laboratory results that seem to be copied/pasted from medical records, and their threaded replies – we first needed to identify relevant posts. We did this in four steps.

The goal of Step 1 was to iteratively develop a list of keywords, and determine the number of posts containing copied/pasted laboratory results (relevant posts) returned by each. To do this, we utilized the live MedHelp website. Specifically, for each keyword (e.g., “lab result help”), we reviewed the first 90 posts (3 pages) of the results to (a) count the number of relevant posts; and (b) examine the “Related Questions” section for additional keywords to test.

Since it is difficult to develop a comprehensive list of keywords, and missing keywords could result in missing relevant posts, in the second step, we sought to identify features (patterns) that distinguish relevant posts from other posts. To do this, we translated the three keywords with the highest number of relevant posts (“Lab,” “Blood work,” and “Profile”), and their common alternative spellings, into three queries in the Indri Query language.\textsuperscript{28} The final queries were run against an inverted index built over all MedHelp question posts. We then manually reviewed the retrieved results to identify the patterns indicative of copying/pasting (e.g., specific test name plus numeric result, such as TSH 0.11). During the review of the last 100 results (a total of 600 were reviewed), no additional general patterns were found, suggesting theoretical saturation had been reached.\textsuperscript{29}

In Step 3, we encoded the identified patterns as regular expressions in Python v2.7. These regular expressions were tested against the annotated corpus created in the second step, and iteratively refined until at least 80\% recall was achieved – i.e., if there are 100 relevant posts in the annotated corpus, at least 80 are retrieved.
In the fourth step, we applied the final regular expressions to the entire dataset, which returned 64,922 potentially relevant question posts – matched a pattern indicative of laboratory results copied/pasted from medical records.

Figure 1. Screenshot of a MedHelp forum post illustrating the copied/pasted laboratory results. Response to question superimposed and outlined in blue.

Analyses: We generated an initial random sample of 1,000 of the potentially relevant question posts, and then retrieved all their peer replies. At least two research assistants independently (1) reviewed posts for relevance, and (2) analyzed relevant posts, using a qualitative content analysis approach, until no new information was emerging (theoretical saturation). In addition, where possible, a “satisfactory” response(s) was identified based on the feedback of the person posting the original question (e.g., “Thanks for info explains a lot.”), and the codes assigned to these posts were eventually compared to the codes assigned to posts not identified as “satisfactory” responses. The content analysis team met weekly to discuss and merge category/theme lists; all disagreements were resolved through discussion. Importantly, if we had not reached theoretical saturation after reviewing all posts in the initial sample, we would have repeated this procedure until we reached theoretical saturation.

For (1), question posts were determined to be irrelevant, and therefore excluded, if they did not contain any laboratory results, or contained results that were not from the individual’s medical records (e.g., from a scientific study). Of the 400 question posts reviewed before theoretical saturation, 146 were relevant and, therefore, further analyzed (in 2). Likewise, when reviewing the threaded replies to relevant question posts, any duplicate posts or posts not attempting to answer the original question (e.g., using the thread to ask their own related questions) were excluded. Of the 500 reply posts reviewed before saturation was reached, 417 were eligible for further analysis (in 2), including 289 answers to questions and 128 replies from the original question poster.

Results

Question Posts

The reviewed sample of posts contained an average of 2.1 questions per post, with a range of zero questions (e.g., just providing an update) to six. Questions covered laboratory results not pertaining to any specified conditions, as well as to a wide range of identifiable conditions or concerns, including sexually transmitted infections (e.g., herpes); heart-related concerns (e.g., hypercholesterolemia); liver conditions (e.g., hepatitis); kidney and pulmonary function; hormone imbalances (e.g., testosterone); cancers (e.g., breast); and autoimmune (e.g. lupus) and thyroid disorders (e.g., hyperthyroidism). Furthermore, while some posts included questions exclusively about the laboratory results, many asked about laboratory results in the context of their medical history and/or symptoms. We present the results of this analysis in three sub-sections: Topics, Requesting, and Situational factors.

Topics: While some posts included questions pertaining to more than one topic, most (~71%) focused on one of the following topics: diagnosis/cause, management/treatment, laboratory report, test/diagnostic, risk, and prognosis (see Table 1). In addition, sub-topic categories emerged as more specific descriptors of patients’ questions. In this sample, questions were most commonly about medications, symptoms, and next steps. For example, the subject line of one post reads, “Please tell me what to do next.” In the body of this post, it becomes evident that she is requesting help “…pulling this [relevant medical history, laboratory test results, symptoms, etc.] info together…” in order to get a step closer to identifying the cause of her symptoms. Less common sub-topics include effect of treatment (e.g., potential adverse effect), comorbidities (i.e., existing diagnoses), timing (e.g., how far apart treatments should be), risk behavior (e.g., alcohol use with certain conditions), and life-style (i.e., diet and exercise).

Requesting: Several categories emerged describing what patients were requesting with their post to the MedHelp community; specifically, patients requested opinion, advice, generic information, emotional support, and personal experience (see Table 2). Requests for opinions and advice were by far the most common in this sample. Those requesting opinions tended to provide their laboratory results and, often, relevant medical history and symptoms, and ask the community to interpret it in some way (e.g., likely diagnosis). Those requesting advice were asking for actionable opinions, and a sub-set of these were asking for the community’s assistance in deciding between two or more, often treatment-related, options. In addition, less frequently, posters requested information that was not necessarily personalized to them; for instance, one patient wrote, “Looking for information about chest aches/pain…” Others included language indicative of distress, fear (e.g., ‘I am terrified”), or other emotions, and were categorized as requesting emotional support. Finally, some posters explicitly invited other patients to share personal experiences so that they could learn from them.

Situational factors: Two main situational factors emerged; specifically, (1) whether patients are posting prior to discussing their results with a healthcare provider or after, and (2) whether they have a diagnosis or not. These situational factors, as well as sub-categories and representative quotations, are summarized in Table 3.

When it was possible to identify the motivation, patients posting questions prior to a healthcare consultation (also referred to as pre-consultation) did so for several reasons, namely waiting, preparing, and determining the need for an appointment. Many patients were waiting for an appointment with their physician, which often was not for several months, but wanted answers or to take action now. These posts tended to exhibit language indicative of distress (as described above). Others were preparing for their upcoming appointment – trying to obtain information that they could utilize in their consultation. In one such post, the patient wrote, “My doctor is very easy to work with but endocrinology is not his specialty (Family Practice). Please provide what information I would need to share
with my doctor for any changes/revisions in my current medication.” Still others were trying to understand their results in an effort to determine if they needed to make an appointment with a physician at all.

Similarly, patients posted questions about their laboratory results to Medhelp after discussing them with their physician (also referred to as post-consultation) for variable reasons, including seeking a second opinion, clarification/explanation, answers or a way forward when their physician is at a loss (referred to as ‘Doctor does not know’ in Table 3), and assistance in making a decision when they have been offered options. In this sample, seeking a second opinion was by far the most common reason for post-consultation posts – patients wanted another opinion on their physician’s interpretations and/or recommendations. In many cases, patients seem to doubt, disagree with, dislike, feel uncomfortable with, or mistrust their physician or their physician’s conclusions. In other cases, they received conflicting opinions (e.g., from different specialists). Other patients just wanted clarification or explanation of information that they discussed with their physician. For example, in one post the patient stated, “I asked questions, but I did not understand what deciding factor determines continuing treatment.” On the other hand, some patients reported that their physician did not know what their results meant or what to do next. Often these patients were still experiencing bothersome symptoms, and they seemed to be seeking fresh ideas. Finally, some patients’ physicians had given them options, and they were struggling to make a decision.

</tr>
</tbody>
</table>

Finally, three different diagnosis statuses were identified in the reviewed posts – diagnosed: not questioned, diagnosed: questioned, and not diagnosed (See examples in Table 3). Some patients posting questions had a diagnosis that they did not question (at least in the post), and were instead often questioning management/treatment aspects, prognosis, or another aspect. On the other hand, some patients had been diagnosed by their physician, but had doubts as to whether that was indeed the issue, and as such often asked diagnosis questions in their post. Finally, there were patients that did not have a diagnosis, and then this tended to be the focus of their post as well. Some were receiving abnormal test results for the first time, and others had been searching for a diagnosis for a while.
Answers

In this sample, there were an average of 2.0 replies per question post, with a range of 0 to 16. The replies that addressed the original question poster provided information, advice/suggestions, opinion, emotional support, and personal experience (See Table 4). They also requested more information from the question poster.

Information: The MedHelp community provided information on a number of topics, including diagnosis/cause, tests/testing, potential seriousness/risk, prognosis, management/treatment, and resources. More specifically, answers provided information on how a diagnosis is made, common symptoms associated with particular diagnoses, and common causes of abnormal test results and/or symptoms. In addition, information on tests/testing was offered, such as the reliability and accuracy of testing methods, reliability of different laboratory values (e.g., TSH), different options for tests, whether tests are invasive and any required preparations (e.g., fasting), and generally what laboratory results mean. Some answers also included information on potential seriousness/risk and prognosis. Furthermore, the community provided information on management/treatment, including general treatment approach for a given condition (e.g., “...doctors typically just monitor it, no real treatment needed.”), goals of treatment (e.g., management, cure), explaining or comparing options, treatment safety/risk, and new treatment options. Finally, answers offered social support and informational resources (e.g., pointing to websites or other MedHelp posts).

Advice: Answers also provided advice/suggestions related to physician/medical professional, addressing/treating health concern, further testing, and more information. Many reply posts suggested that question posters discuss their questions, and information provided by the community, with their physician. They also sometimes recommended that the question poster see a specialist, get a second opinion, or get a new doctor all together. In addition, the community provided advice/suggestions on addressing/treating health concerns, including whether or not treatment is needed, specific types of medication and dosages to try, changes in medication and/or dosage, suggestions for how to proceed with treatment (e.g., timing), and diet and supplementation recommendations. Some answers also recommended additional tests that they feel the question poster should consider. Finally, many answers suggested that the question poster get more information, including by using search engines, going to sites/resources that they felt were particularly helpful, and asking lots of questions of their physician.

Opinion: In addition, community members provided first and second opinions on topics, including primary concern, interpreting test results, possible diagnosis/cause, seriousness/risk, prognosis, and management/treatment. In cases where people had comorbidities or multiple pieces of information that conflicted, some answers provided opinions on the priority; for example, one community member said, “You're focusing too much on the test results and not enough on how you are feeling.” The community also provided interpretations of laboratory results, often including their opinion on possible or likely diagnosis/cause or prognosis given their interpretation of the results (and symptoms and history, when provided). Finally, answers provided opinions on management/treatment such as whether they think a proposed treatment is appropriate, treatment (often, medication) and/or dosage they feel would be better, and the best way to make treatment decisions for a given issue (e.g., certain laboratory value).

Emotional Support: Replies from the community also provided emotional support through empathizing, encouraging, offering well wishes and congratulations, reassuring, showing concern or caring, and by indicating that the question poster is not alone – others have felt or experienced the same. Many of these were responding to posts where there was language indicative of distress (as discussed above) or another emotion (e.g., cautious excitement); therefore, whether it was bad news (e.g., tests are positive for a certain condition) or good (e.g., tests indicate the poster is pregnant), most responded in an emotionally supportive way (e.g., “Don't give up!”). In addition, even if the question poster did not appear to explicitly request emotional support, answers would often still provide it.

Personal Experience: Answers provided personal experiences in order to offer reassurance, or another type of emotional support, as well as to provide information, opinions, or advice. They tended to use their experience to support a claim or recommendation. For example, one community member wrote, “I didn't hear a heartbeat until i was 10 weeks. So... try not to worry too much.” While another answer provided the following support for her suggestion that the problem may be pulmonary, “I just had 4 days of intense fatigue and being short of breath. It wasn't until the chest ache and coughing kicked in that I realized it was my asthma being a brat.”

More Information: Finally, community members often asked follow-up questions and requested that the question poster provide more or updated information. Such replies suggest that, given the information provided, they could not help or would be able to help more with additional information.

<td>“Arm yourself with as much information as possible and make an informed decision.”</td>
</tr>
</tbody>
</table>

**Opinion (First or Second)**

| Primary concern | “I would think your experience of dealing with Narcolepsy, which is awful by the way, should be the primary concern here.” |
| Interpreting test results | “The low PTH suggests that the high Ca++ initially discovered was "non-parathyroid" origin but if it were a malignancy the Ca++ would typically be on the further rise.” |
| Possible/likely diagnosis/cause | “You have positive antibodies (autoimmune thyroid disease) - most likely this is early Hashimoto's.” |
| Prognosis | “I think you're going to beat it, yes I do and I haven't seen anyone relapse yet who has taken the triple therapy.” |
| Risk/seriousness | “Personally I would feel better if your CRP were also in the first quartile of risk (low risk <1.0)... facts are you have a high LDL cholesterol and a level of CRP that is above the lowest risk group.” |
| Management/ Treatment | “I think Vit D treatment is fine as long as Ca++ is monitored closely.” |
| Emotional support | “it just makes sooooo angry when docs act like that.I know if it were them feeling bad they would take the med!!” |
| Personal experience | “I have Geno 1A and also 1B and two doctors insisted on Intron.But again it's probably personal perspective.” |

**Sufficient answers:** The replies determined to be “sufficient answers,” based on the reply from the original question poster, suggested that the question poster felt somewhat reassured or relieved, perceived themselves to have an improved understanding, and/or that they had or were going to take a recommended action. The largest number of “sufficient answers” were in reply to thyroid- and liver-related questions; however, “sufficient answers” were identified in threads related to infectious diseases, pregnancy, autoimmune disorders, cancer, and unknown condition. “Sufficient answers” more commonly provided opinion and emotional support, and more specifically tests/testing information, as well as concern/caring and encouragement emotional support.
Discussion

The results of this study provide evidence that it is feasible to identify and characterize the nature of patients’ questions related to laboratory results, and to characterize the nature of the answers to these questions. Specifically, they revealed (1) a typology of patient confusion when viewing laboratory results, (2) patients’ social support needs, (3) the contexts of questions, as well as (4) the type of support that patients may gain, and find ‘satisfactory,’ from peers in online health forums. Similar categories have emerged from studies in the human-computer interaction and patient portal literature, beyond laboratory results and outside of peer-to-peer settings, suggesting that our findings are robust. However, our study had several unique aspects – including, a “target-rich” source of actual patient information and knowledge needs across multiple types of health conditions, and the classification of answers, which few studies have previously done – that resulted in a more thorough typology and novel findings. While our results are preliminary, they suggest potential opportunities to improve patient portals to better meet patients needs.

First, we found a typology of patient confusion about their laboratory results, which includes topics such as management/treatment. Although others have identified similar categories, their typologies were not as comprehensive. For example, when analyzing secure messages sent via a portal, Sun et al., found similar categories of questions aimed at patients’ healthcare teams, but we identified categories, such as risk, that they did not. We were likely able to more comprehensively identify types of patient questions because of our rich dataset, which uniquely situates this study to add to the current understanding of the types of patient questions related to their clinical data. For example, compared to Sun et al.’s study, we may have identified more clinical topics, because many patients seek information online first. In fact, Wright et al. reported that patients were much more likely to search the internet after viewing their problem list through a patient portal, rather than contacting their healthcare provider. As our results suggest, after searching online, some of these individuals may believe that there is no need to, or may choose not to, follow-up with their physician.

Second, we observed that patients had social support needs, such as informational, that they tried to meet through the forum. Other studies have reported similar categories; for example, Silence et al. analyzed advice solicitation in an online breast cancer support group, and identified five patterns, (1) requesting advice, (2) requesting opinion or information, (3) disclosing a problem(s), (4) announcing a plan of action, and (5) asking “anyone in the same boat?” Despite small differences, the overlap, as well as the fact that we identified our categories across a number of conditions, indicates robustness, and that our results may be relevant beyond this study setting and population.

Third, while other studies have peripherally reported situational factors, it emerged as a central theme in our study. For example, Powell et al. reported motivations for online information seeking, including perceived barriers to traditional information sources, as well as to seek reassurance, a second opinion, and a greater understanding. In addition, this study also found that most online health information seeking was associated with consultations, either in preparation for or to find additional information afterwards. In the context of our study, there appears to be some differences in the types of questions asked based on situational factors. We are in the process of extending this work by developing a model of the different health information needs in different situations.

Finally, while there is literature characterizing “best answers” on question and answer websites, to the best of our knowledge, our attempt to examine peer answers that patients perceive to be satisfactory in an online health forum is novel. The results of this pilot suggest that answers perceived to be “sufficient” by patients more often included opinion and emotional support, and they usually provided more specific information on tests and testing, as well as concern/caring and encouragement emotional support. This may be because these elements were better aligned with what question posters were requesting. In terms of the emotional support, it may also be that when answers showed concern/caring or offered encouragement, it elicited more positive responses from the question poster, regardless of whether it actually helped them gain a better understanding of their situations. Our future work will seek a more complete picture of the types of answers that patients find helpful and the underlying reasons.

Implications: These results provide preliminary evidence of opportunities to improve patient portal design. In terms of content, as discussed above, patients often search online first and may not follow-up with their healthcare provider; therefore, it is crucial to provide more of the information and knowledge that patients need at the point of viewing their laboratory results in patient portals. This could reduce the time and effort burdens often inherent in seeking medical information in the vast internet and, at the same time, ensure that they are consuming, and making decisions based on, accurate information carefully curated by their healthcare professionals. One way to provide more of the information patients needs may be better understanding differences in information needs based situational factors, which could offer an opportunity to provide more personalized content in patient portals, based on elements that are often available (e.g., appointment date). In terms of features, since patients tend to seek these
social supports in online communities, it suggests that they may be lacking in patient portals and their healthcare encounters, which could present opportunities for additional patient portal features. For example, supporting patients desire for personal stories from patients “in the same boat,” by allowing patients to opt-in to a social feature that enables finding similar patients and/or more fluid groupings based on similar information needs, could be beneficial.

**Limitations:** There are several limitations to this work. First, the emphasis was to comprehensively identify relevant themes and categories emerging from this rich dataset; therefore, posts were not double coded. Future work will include more quantitative analysis, and validation of qualitative findings. Second, while it is possible to identify posts with indicators that the original question poster perceived the answer to be helpful, there were a relatively large number of answer posts to which the original question poster did not reply. In addition, there may be other factors, independent of perceived usefulness of the answer, that affect how someone responds, including personality, culture, and level of emotional distress. Therefore, the results related to “sufficient answer” should be interpreted with caution, and warrant further investigation. Finally, in this pilot we focused on one type of clinical information and one online health forum. While there is support in the existing literature that these are crosscutting categories; however, the extent to which these results extend beyond this study setting is unclear. Based on the results of this pilot, in our future work, we intend to include the other, harder to identify and less frequently available types of clinical information (e.g., discharge summaries and clinical notes), as well as other online health forums.

Despite these limitations, this work provides direct evidence of patients’ comprehension issues related to their laboratory data. The results also highlight the types of supports they need, and the type that they are able to gain, and deem ‘satisfactory,’ through online health forums. This knowledge directly informs how patient portals can better provide social supports for patients. Finally, this study provides a foundation for our future efforts, including collaborating with patient portal stakeholders (e.g., patients, developers, administrators) to assess how this study, and follow-up studies, can be incorporated into the design and redesign processes to improve patient portals.

**Conclusion**

This pilot study provides evidence for the feasibility of (1) identifying online forum posts containing patients’ laboratory results copied/pasted from their medical record; (2) identifying question topics, patient support needs, and situational factors; and (3) characterizing what patient peers are providing and requesting in response. An extension of this work is currently underway, and will characterize the similarities and differences in information needs based on context. In addition, the results presented in this paper provide a foundation for future quantitative work involving computational methods. Ultimately, this line of work may lead to improving the design of patient portals, and the way that we present clinical data to patients. Such improvements may, eventually, lead to more patients being engaged in their healthcare and, as a result, improved health status and reduced costs.

A Semantic Parsing Method for Mapping Clinical Questions to Logical Forms

Kirk Roberts, PhD, Braja Gopal Patra, PhD
School of Biomedical Informatics,
The University of Texas Health Science Center at Houston, Houston, TX

Abstract

This paper presents a method for converting natural language questions about structured data in the electronic health record (EHR) into logical forms. The logical forms can then subsequently be converted to EHR-dependent structured queries. The natural language processing task, known as semantic parsing, has the potential to convert questions to logical forms with extremely high precision, resulting in a system that is usable and trusted by clinicians for real-time use in clinical settings. We propose a hybrid semantic parsing method, combining rule-based methods with a machine learning-based classifier. The overall semantic parsing precision on a set of 212 questions is 95.6%. The parser's rules furthermore allow it to “know what it does not know”, enabling the system to indicate when unknown terms prevent it from understanding the question’s full logical structure. When combined with a module for converting a logical form into an EHR-dependent query, this high-precision approach allows for a question answering system to provide a user with a single, verifiably correct answer.

Introduction

The wealth of information available in the electronic health record (EHR) of a patient can be both a blessing and a curse. While having the most information possible for a patient stored in the EHR is important for the many uses of EHR data (record keeping, billing, legal, research, etc.), the large amount of information can create difficulties for clinicians when they need to quickly locate specific information. For this reason, much focus has been placed on presenting clinicians with the most important information, either visually1 or in text2, 3. This is no replacement, however, for mechanisms to efficiently access any piece of information. Largely this is accomplished by (often cumbersome) graphical interfaces for structured information and textual search for unstructured notes. Textual search offers notable advantages: it is often quick to enter a query and far less training is required than vendor- and provider-specific graphical interfaces. While some effort has gone into a more semantic search to find structured data elements4, these methods still largely rely on a keyword-based approach that cannot deeply grasp the user’s information need in a manner that presents a single, verifiably correct response. Instead, a search engine-style listing of ranked results is presented, burdening the user with determining the relevance of each result in turn.

Instead of keyword queries, which are often ambiguous in regards to their precise information need, natural language questions provide a clear and intuitive form to query EHRs. For this reason, observational studies of clinician needs often use natural language questions as their representation of choice5, 6. Due to the utility of expressing information needs as questions, numerous automatic question answering (QA) methods have been proposed for medical data7, combining natural language processing (NLP) and information retrieval (IR) methods. However, comparatively little attention has focused on QA for patient-specific data in the EHR. Furthermore, the QA methods that have been proposed for EHRs are largely analogous to the keyword-based semantic search methods for general-purpose IR queries. This limits their abilities to search over structured data and furthermore limits their ability to provide a single, verifiably correct answer. For example, given the question “What are her three most recent glucose measurements?” a clinician would ideally want a single result (e.g., “145, 139, 156”) that can be verified (e.g., by providing proof the question was properly understood and links to the lab results in the EHR interface). Further, if a clinician were to ask a question without an answer (e.g., the patient only had two glucose measurements), or if the system did not fully understand the question (either through human error, e.g. a misspelling, or lack of system functionality, e.g. inability to understand “three most recent”) then appropriate responses can be shown instead of providing a list of completely incorrect search results.

To provide such an answer, the natural language question must be converted to a complete, semantically-grounded logical form using a pre-defined set of logical operations. While semantic grounding task such as concept normalization8 and semantic relation tasks such as semantic role labeling9 provide partial information toward a complete semantic grounding, they are insufficient in capturing the full meaning of a question. The NLP task for transforming natural
language into a logical form based on pre-defined logical operations is known as semantic parsing. While semantic parsing is a well-studied task in NLP, almost no work exists on semantic parsing for a task like EHR QA.

This paper presents a semantic parsing method for understanding EHR questions. As one might imagine, converting any form of natural language to a completely structured form is a difficult, NLP-complete task. To avoid the difficult task of enumerating the lexicon of logical operations, some semantic parsing methods utilize ungrounded logical forms\(^{10,11}\), where the words in the question themselves become the logical functions. However, this is generally only used for searching unstructured data, or assumes words are easily mappable to the database structure. This can further be problematic when mathematical operations (e.g., $\min$, $\text{less than}$) or knowledge-based operations (is positive, is significant) are mixed in with logical operations that correspond to fields in the database. As such, for tasks such as this, pre-defined grounded logical forms are preferable, as they are easier to convert to structured queries. Manually enumerating a pre-defined lexicon for natural language is largely intractable, so most grounded semantic parsing techniques thus focus on short texts (such as questions) and small domains, such as U.S. geography\(^ {12}\) (e.g., What states border Texas?). Even under closed domains, oftentimes thousands of manually annotated $<\text{question, logical form}>$ pairs are necessary to train a semantic parser to achieve satisfactory results. Our method, therefore, differs from many existing machine learning (ML) based semantic parsers due to the complexity of the domain and the difficulty of obtaining so many annotations. This is done by relying on existing clinical NLP resources and incorporating several rule-based elements to improve its customizability. Instead of performing semantically-embedded syntactic parsing as done by many semantic parsers (e.g., using a combinatorial categorical grammar (CCG) on the raw question input), the approach proposed here first leverages existing clinical NLP methods to simplify the question. Second, the simplified question is converted to a dependency-based tree structure. Third, a lexicon is used to convert lexico-syntactic sub-structures into logical operations, resulting in an initial set of logical trees. Fourth, a set of rules transform and then filter these trees. Fifth, a ML-based classifier chooses the best logical form tree for the question. Sixth, a separate classifier identifies the relevant temporal intervals for medical concepts in the question. Finally, the best tree is turned into a flat logical form and items withheld during the simplification step are substituted back in. We use a logical form designed to concisely represent the question while also being easily convertible to EHR query standards such as Fast Healthcare Interoperability Resources (FHIR). Examples of such logical forms are:

<table>
<thead>
<tr>
<th>Logical Form</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>$\delta(\lambda x. \text{has_treatment}(x, C0852255, \text{status}))$</td>
<td>How low has her blood pressure been?</td>
</tr>
<tr>
<td>$\min(\lambda x. \text{has_test}(x, C0005823, \text{visit}))$</td>
<td>What is the trend in hemoglobin?</td>
</tr>
<tr>
<td>$\text{positive}(\lambda x. \text{has_test}(x, C022885, \text{visit}))$</td>
<td></td>
</tr>
<tr>
<td>$\text{has}(\lambda x. \text{visit}(x, C0005823))$</td>
<td></td>
</tr>
<tr>
<td>$\text{min}(\lambda x. \text{has_test}(x, C0005823, \text{visit}))$</td>
<td></td>
</tr>
<tr>
<td>$\text{trend}(\lambda x. \text{has_test}(x, C0005823, \text{visit}))$</td>
<td></td>
</tr>
</tbody>
</table>

This paper addresses the critical second through fifth step described above—the actual semantic parsing steps. The first step can leverage any number of existing clinical NLP systems (e.g., MetaMap\(^ {13}\), cTAKES\(^ {14}\)); the sixth step is an important but tangential task to the semantic parsing; and the final step is a deterministic process re-incorporating the information extracted during the first step. Evaluating the semantic parsing steps in isolation enables identifying key issues in converting a natural language into a logical structure without the difficulties involved in error propagation from upstream components. Optimizing the semantic parser in the presence of errors in the first step and classifying the appropriate time intervals in the sixth step are both left to future work.

Background

As previously stated, numerous methods have been proposed for medical QA\(^ {7}\). Again, the bulk of these methods are not focused on patient-specific EHR QA, but rather on general medical knowledge or the scientific literature. Some works focus on questions asked by clinicians, while others focus on consumer questions (see Roberts et al.\(^ {15}\) for a brief discussion of these systems). The key reasons for the separation include the linguistic differences between medical professionals and consumers\(^ {16}\) as well as the appropriate information source (e.g., consumers are less likely to likely to understand scientific literature articles). Further, while QA for EHRs is less studied, IR for EHRs has received more attention\(^ {6,17-20}\).

QA methods for EHR data vary along a spectrum from keyword-based IR approaches to deep semantic approaches, though the only work involving a deep semantic approach that we are aware of falls under the project discussed in this paper. The IBM Watson system\(^ {21}\) uses a passage scoring method. While this is similar to IR approaches, QA-specific
The input question (Q) is first split into multiple questions via the Syntax Decomposition module, then each of the $n$ output questions are separately run through the remaining pipeline. After Concept Normalization, the question is simplified (SQ) by replacing concepts with consistent placeholders. A dependency parse is then generated from SQ and run through the semantic parsing components.

The dependency tree is run through the Lexicon, which produces all $N$ possible Lexicon Match Trees. Each of these is run through both generation rules (increasing the number of trees) and filtering rules (pruning trees), resulting in $M$ Logical Trees. A Tree Classifier then selects the best Logical Tree.

After the semantic parser, the concept CUIs are re-substituted back into the logical form, the TIME attribute is classified, and finally a query module uses the logical form as a template for interacting with the EHR (e.g., through FHIR queries).

Our current project aims to overcome the limitations of existing EHR QA methods to enable a true natural language interface for structured data in the EHR. We have previously described the structure of the logical form as well as an annotated corpus of $<$question, logical form$>$ pairs. The corpus furthermore contains gold-annotated concepts and other manual annotations in a layer-wise fashion to enable training the semantic parser on correctly simplified questions. There are three annotated layers: (1) a syntactic simplification step (i.e., question decomposition), (2) a concept recognition and normalization step, and (3) a logical form step (i.e., semantic parsing). We have further proposed an automatic method for syntactic simplification as well as an automatic method for distinguishing patient-specific questions (i.e., answerable with the EHR) and other types of questions (i.e., answerable with many of the existing QA approaches) so that multiple QA systems can be integrated into a single interface. In this work, we focus on the most critical NLP component of the overall project: the semantic parser that converts natural language into a logical form. Future work will cover the remaining tasks, such as mapping logical forms to FHIR queries for direct integration of a QA system into EHRs.

Materials and Methods

The overall QA framework for this project is shown in Figure 1. Most of the following subsections except the semantic parsing subsection describe elements of this framework at a high level, motivating certain choices made in semantic parsing and providing references to already-published descriptions.

1. Data

The dataset consists of 212 manually-annotated questions originally collected from actual clinicians by Patrick & Li. The dataset contains gold-annotated concepts and other manual annotations in a layer-wise fashion to enable training the semantic parser on correctly simplified questions. There are three annotated layers: (1) a syntactic simplification step (i.e., question decomposition), (2) a concept recognition and normalization step, and (3) a logical form step (i.e., semantic parsing). We have further proposed an automatic method for syntactic simplification as well as an automatic method for distinguishing patient-specific questions (i.e., answerable with the EHR) and other types of questions (i.e., answerable with many of the existing QA approaches) so that multiple QA systems can be integrated into a single interface. In this work, we focus on the most critical NLP component of the overall project: the semantic parser that converts natural language into a logical form. Future work will cover the remaining tasks, such as mapping logical forms to FHIR queries for direct integration of a QA system into EHRs.
function max. Most questions, roughly 97%, have only one λ-statement, while multi-λ questions can be particularly complicated for semantic parsers. For instance:

\[
\delta(\lambda x. \text{has treatment}(x, \text{C0087111}, \text{visit}) \land \delta(\lambda y. \text{is response}(x, y)))
\]

This logical form corresponds to the question “Did she have a reaction to the treatment?”. The second λ-statement is nested inside the first, essentially testing every treatment event \(x\) (\text{C0087111} is the high-level code for treatments) to see if any other event (denoted \(y\)) is a response to event \(x\). There is insufficient space here to discuss the reasoning behind every decision for the logical form annotations. We thus refer the interested reader to our previous work describing these decisions\textsuperscript{15,23}.

2. Initial Question Processing

The important insight behind the layer-wise approach is that while the concepts are present in the final logical form, they do not affect the structure of the logical form. As a result, the semantic parser need not understand the differences between “diabetes” and “hypertension”, only that “Does he have PROBLEM?” corresponds to the logical form \(\delta(\lambda x. \text{has problem}(x, \text{CUI}, \text{TIME}))\), where the UMLS code for the problem is substituted into the place of CUI. For this reason, the first two layers are referred to as simplification steps, as they reduce both the lexical and syntactic complexity of the question. Further, these steps correspond to clinical NLP tasks for which there is existing data. As a result, far less training data for the semantic parser is required. The layer-wise annotation on this dataset furthermore enables experimentation using gold standard simplification, isolating just the semantic parsing.

While the automatic methods behind these steps are beyond the scope of this paper, as previously stated, existing methods can largely be leveraged to perform this processing. A syntactic decomposition method, for instance, was proposed by Roberts\textsuperscript{24}. Concept recognition and normalization has been extensively studied, with both ML-based methods based on the SemEval task focused on disorders\textsuperscript{8} as well as rule-based methods such as MetaMap\textsuperscript{13}.

The final step prior to the semantic parser, which is performed automatically in this work, is the dependency parse. The Stanford dependency parser\textsuperscript{26} operates on the simplified questions. To ensure a proper dependency parse, the concepts in the simplified question are substituted with a part-of-speech appropriate replacement word. For example: a noun concept is replaced by the word “concept”; a past-tense verb concept is replaced by the word “ate”; and the reference to the patient is replaced by the pronoun “he” or “his” (if possessive). This replacement ensures a proper dependency parse on the simplified question, since replacing a phrase with a word from a different part-of-speech would likely result in an erroneous dependency parse. The original placeholders are then substituted back into the output dependency tree (e.g., “ate” is changed back to “concept” and “he” is changed back to “patient”).

To demonstrate the full extent of processing prior to the semantic parser, consider the following two questions:

**Lexical:** When was the patient most recently dialyzed? What was her lowest and highest blood sugar level?

**Syntax:** When was the patient most recently dialyzed? What was her lowest blood sugar level?

**Concept:** when was patient most recently vbd:procedure what was pos:patient lowest nn:procedure

**Dependency:**

![Dependency Diagram]

Note that the right-hand question is split into two questions, with the results of only one being shown here.

3. Semantic Parsing

The semantic parsing components are shown inside the box in Figure 1. The first component is a dependency tree-based lexicon. Note that most publicly available semantic parsers\textsuperscript{27,28} make use of a similar lexicon: while a lexicon can be learned directly from \(<\text{question, logical form}>\) pairs, such systems generally prefer the rely on lexicons for increased precision. In our case, since a high precision semantic parser is crucial, we thus follow suit.
The tree-based lexicon maps nodes and edges in the dependency tree to logical operations. The simplest case are individual nodes (i.e., single words/concepts):

<table>
<thead>
<tr>
<th>Node</th>
<th>Logical Operation</th>
</tr>
</thead>
<tbody>
<tr>
<td>concept</td>
<td>( \lambda x. \text{has}_{\text{concept}} )</td>
</tr>
<tr>
<td>lowest</td>
<td>( \text{min} )</td>
</tr>
<tr>
<td>temporal_ref</td>
<td>( \text{time}_{\text{within}} )</td>
</tr>
<tr>
<td>concept(der:the)</td>
<td>( \lambda x. \text{has}_{\text{concept}} )</td>
</tr>
<tr>
<td>done(aux:have, auxpass:been)</td>
<td>( \delta )</td>
</tr>
<tr>
<td>much(advmod:how)</td>
<td>( \text{sum} )</td>
</tr>
<tr>
<td>received(dobj:concept)</td>
<td>( \lambda x. \text{has}_{\text{concept}} )</td>
</tr>
</tbody>
</table>

Where null matches indicate words not useful for semantic parsing, but possibly useful for downstream tasks (e.g., “yet” is useful for time classification). Multi-word matches are also common. They are specified with the head node and specific edge types to dependent nodes:

<table>
<thead>
<tr>
<th>Multi-word Match</th>
<th>Logical Operation</th>
</tr>
</thead>
<tbody>
<tr>
<td>concept(der:the) ( \rightarrow ) ( \lambda x. \text{has}_{\text{concept}} )</td>
<td></td>
</tr>
<tr>
<td>done(aux:have, auxpass:been) ( \rightarrow ) ( \delta )</td>
<td></td>
</tr>
<tr>
<td>much(advmod:how) ( \rightarrow ) ( \text{sum} )</td>
<td></td>
</tr>
</tbody>
</table>

Note that while the overall focus of the system is on precision, lexicon building invariably must focus on recall. For this reason, multiple lexicon entries are often necessary for the same word (e.g., [was ⇒ null], [was ⇒ \( \delta \)]). The result is that most dependency trees have at least one overlapping lexicon match. When this happens, all possible combinations of lexicon matches are generated such that every node in the dependency tree is covered by exactly one lexicon match. A new tree is then created with nodes corresponding to the dependency relations (nodes and edges in multi-word matches are collapsed into a single node). Leaf nodes with null values are also discarded. These trees are referred to as lexicon match trees: the nodes contain logical operations, but the edges between those operations do not necessarily correspond to relations in the final logical form. The trees for the above examples include:

**Lexicon Match Tree:**

Note that while the two initial questions are quite different on the surface, by now the structures are quite similar.

At this point in the processing, questions without any lexicon match trees are considered unanswerable, as this means some part of the question has an unknown logical function. This is the source of the system’s high precision design: we would prefer the system returns answers to fewer questions than risk returning incorrect answers. Incorrect answers would result in diminished trust in the system by clinicians. When a question is unanswerable, the user can be presented with the unknown word(s) and be asked to rephrase the question.

The next component converts each lexicon match tree into zero or more logical trees. A set of rules using a grow-and-prune strategy is used. First, two “grow” rules generate new trees by manipulating related nodes in the initial lexicon match tree:

1. **FlipRule**: if a parent has one child, create a new tree with parent and child flipped (e.g., the tree \([A \rightarrow B \rightarrow C \rightarrow D]\) would also result in \([A \rightarrow C \rightarrow B \rightarrow D]\)).
2. **PromoteRule**: if a parent has more than one child, promote each child in a new tree (e.g., \([A \rightarrow B, C]\) would also result in \([A \rightarrow B \rightarrow C]\) and \([A \rightarrow C \rightarrow B]\)).

Trees generated by these rules are also run through the same rules, resulting in a final set of trees not only resembling the original lexicon match tree (which frequently contains nodes with multiple children), but also every possible unary tree (which are more typical of the logical forms in the dataset). Next, the “prune” rules remove invalid trees:

1. **NullRule**: null leaves are removed, and trees with null non-leaf nodes are filtered.
2. **TypeRule**: Every logical function has pre-defined input and output types. For instance, \( \lambda x. \text{has}_{\text{concept}} \) has no input and returns an \text{EVENTSET}; \text{latest} and \text{max} take in an \text{EVENTSET} and return an \text{EVENT}; \delta takes in an \text{EVENTSET} and returns \text{TRUE}/\text{FALSE}; and \text{time} takes in an \text{EVENT} and returns a \text{TIME}. Using these types, any tree that has an incompatible parent-child relationship (parent’s input must equal child’s output) is filtered.

These rules drastically reduce the number of trees, as the grow rules produce many invalid trees. As the trees are now compatible with logical forms, they are referred to as logical trees. Logical trees for the previous examples include:
Logical Tree:

```
  time
    latest
      λx.hua_concept
  min
    latest
      λx.hua_concept
```

This tree structure is useful for downstream processing, however, so they are not yet “flattened” into logical forms.

The final step in semantic parsing is to choose between the remaining logical trees. There are several statistical factors that dictate the true logical forms. The two most important are that some lexicon matches are more likely than others (e.g., “was” is more likely to be null than δ), and some arrangements of the logical form are more likely (corresponding to parent-child relations in the logical tree). For this reason, a ML-based approach using a support vector machine (SVM) is used. The two statistical factors described are the first two features considered by the SVM, along with a third feature emphasizing the importance of the top-level logical operation. The three features are:

1. **LexiconMatch**: IDs of the lexicon matches that were used to generate the lexicon match tree that, in turn, was used to generate the logical tree.
2. **ParentChild**: All parent-child pairs in the logical tree, including identifying the root and leaf nodes.
3. **Stem+Root**: The question stem (e.g., what, how) combined with the logical operation of the logical tree’s root node. For example, what-latest, how-many-count, when-time.

The SVM classifies all remaining logical trees for a question. The tree with the highest positive confidence is then selected as the output of the semantic parsing phase.

**4. Subsequent Question Processing**

After semantic parsing, several more steps are necessary. First, the TIME element needs to be classified, which can be done using traditional ML-based multi-class classification. Second, the concepts simplified after concept normalization need to have their CUIs inserted into their proper place (easily done with multiple concepts by tracking which logical tree node corresponds to which concept). This will produce the final logical form, which can be represented as a flat string.

To query an EHR, a query module needs to convert the elements in the logical form to either EHR-specific queries or functions within the module. For instance, given the logical form `time(latest(λx.has_test(x, C0392201, visit)))`, the query module might convert `λx.has_test(x, C0392201, visit)` into a FHIR query (likely multiple queries) to find all the blood glucose measurements occurring during the patient’s visit. Each of these results would be represented as an event, and the full set of events would be passed to the latest function to find the most recent matching event. Finally, that event would be given to the time function to return just that event’s timestamp.

Using this approach, a QA system can provide a single answer (resulting from the structured query and logical functions) that is verifiably correct in that a visualization of the logical form (for instance, see Figure 2) can be provided to the user to verify the system properly understood the question. If the question understanding was accurate, the answer should therefore be correct (at least from the NLP perspective, errors in data entry and EHR querying notwithstanding).

**Results**

We evaluate the semantic parsing accuracy on the questions with a leave-one-out validation to maximize data use (the small number of questions and features means this is still quite fast, around 15 seconds). Table 1 shows feature experiments to demonstrate the importance of each of the three features, along with several baselines. All methods reported in Table 1 use the same lexicon and logical tree rules, only the tree classifier is altered. The Stem+Root feature, which simply looks at the question stem and the root logical operation, has the highest performance. This is likely due to the type-based filtering rules: if the top-level logical operation is correct, this limits the potential children. Additionally, so many logical forms start either with latest or δ, after which the amount of ambiguity decreases, and the Stem+Root feature can identify high-likelihood root operations (e.g., is-delta, what-latest) and eliminate unlikely operations (e.g., what-delta, did-latest).

</tbody>
</table>

**Table 2:** Experiments removing various logical tree rules using best tree classifier.

Table 2 shows experiments to assess the impact of logical tree rules on the final result. Performance is hurt dramatically without the generation rules, achieving 56.8% and 72.1% without the FlipRule and PromoteRule, respectively. Removing both rules results in a performance of 50.7%. The filtering rules have far less of an impact on the final result. This makes sense as removing generation rules fundamentally limits recall. The filtering rules, however, are designed to help with precision, but the ultimate decision rests with the tree classifier. The NullRule, which removes logical trees with null nodes, removes trees that are easily detected by the SVM classifier, and so there is no effect on the final score. The TypeRule has some effect on the system, as without it the accuracy drops to 89.8%. While the classifier should ultimately learn inaccurate parent-child relationships, they can be quite sparse for some relations. So having a hard rule that forces agreement is useful. It also greatly speeds up the system: without the type rule, there is a mean of 206 and a median of 13 logical tree candidates per question. With the TypeRule, that drops to a mean of 11 and a median of 2 candidates. This further has the positive effect of reducing data imbalance, which likely has a positive impact on training the SVM.

To demonstrate the effect of data size, Figure 3 shows the leave-one-out accuracy (using all three features) with increasing percentages of the total data. With small amounts of data (<20%), there are random fluctuations in performance, as would be expected, but afterward there is a steady climb in performance. It appears likely that adding more data would continue to benefit the semantic parsing performance.

**Discussion**

The high performance of the semantic parser (>95%) on the annotated dataset demonstrates the potential for a high-precision question understanding system, converting natural language to a fully-structured logical form. However, the use of the lexicon means that the results reported above are high estimates of the performance of the semantic parser on unseen questions, since almost all questions had the necessary lexicon entries to generate their proper logical form. For this reason, the 95.6% accuracy is less of a measure of system accuracy than it is a measure of system precision: some unseen questions will contain unseen words, which have no lexicon match and therefore will return no answer at all (i.e., a false negative). Precision does not measure false negatives, however, so the results above are a decent estimate for precision. Recall, however, while not a focus of our method, would still be a concern if it were so poor that hardly any questions would be answered. The primary limitation of recall in our system is the lexicon: if it fails to find an entry for a term in the question, or the entries it does find fail to produce a valid logical tree, then no answer will be provided. Figures 4 and 5 provide a sense of the distribution of the entries in the lexicon. Figure 4 shows that the lexicon has a very long tail: around 20 lexicon entries are highly used when generating gold logical trees, while
dozens of entries are only associated with a single gold logical tree. Figure 5 shows that 72 questions rely on at least one lexicon entry that is not used for any other question. It is difficult to estimate recall exactly from these figures, but it would not be surprising if recall on unseen questions was in the 60-80% range, far below the high precision of the semantic parser. However, this assumes that users ask questions without knowledge of the system: over time a user would likely come to understand how to phrase questions based on the parser’s vocabulary.

Even on the annotated data for which we have a complete lexicon, however, the semantic parser is not completely perfect, so some discussion of the types of errors it makes is worthwhile. The most common type of error revolves around rare logical operations. For instance, the question “Is his Computed Tomography positive?” has the gold logical form \( \text{is\_positive(latest(\lambda x.\text{has\_concept}))} \). The predicted logical form, however, was \( \delta(\lambda x.\text{has\_concept} \land \text{is\_positive}(x)) \). The predicted form more closely resembles other uses of \( \text{is\_positive} \) in the data, but unfortunately in this case would actually answer the question “Does the patient have a positive Computed Tomography”, i.e., it will return true if any prior test is positive, whereas the original question is only interested in whether the most recent is positive. In order to maximize precision further, these rare predicates either need to be removed or generalized to a common concept.

Other, more difficult errors, involve some degree of ambiguity or implied answer type. While the intentional decision was made during annotation to take the questions as literally as possible, it was not possible to remove all real-world knowledge of the true intention of the question. For instance, the question “How high is his Troponin?” has the gold logical form \( \text{latest(\lambda x.\text{has\_concept})} \), which essentially is just asking for the result of the latest Troponin test. The phrase “How high” is roughly analogous to “What is the value of” in the question. While that interpretation can be added to the lexicon, the semantic parser still focuses on a strict interpretation of the phrase “How high” and predicts the logical form \( \text{max(\lambda x.\text{has\_concept})} \), i.e., “What is the highest Troponin level?”. Similarly, “How much sputum does he have?” is interpreted as the summation of all sputum tests (\( \text{sum(\lambda x.\text{has\_concept})} \)) and not simply the result of the most recent test (\( \text{latest(\lambda x.\text{has\_concept})} \)).

Many of these errors can be tolerated if the answer is placed in the proper visual context. For instance, the incorrect interpretation of the question about sputum level should result in a graphically produced answer that indicates there was a misunderstanding. In this case, not only showing a graphical query representation, but also having the actual answer that shows not just the sum, but all of the sputum tests below the sum, would be a good visual clue to the clinician that the question was misinterpreted. This is yet another case of how placing a noisy NLP system within a proper visual context...
interface can prevent NLP errors from propagating to clinical decision-making, and thus retain the trust of clinicians. Unlike most NLP systems, however, the logical forms created by the semantic parser provide an incredibly useful structure to visually represent information. NLP systems that rely on bag-of-words text categorization, for instance, are difficult to visually interpret beyond highlighting noteworthy words. Instead, the logical form, when displayed graphically as in Figure 2, allows the user to not only know an error occurred almost immediately, but also gives a strong clue of how to re-phrase the question in a less ambiguous manner. Such a trust-building combination of NLP and interface design can lead to a greater use of NLP to directly benefit clinicians in a real-time situation. Currently, however, most clinical applications that involve NLP focus on its offline use for research and administrative purposes.30 For the most part, this is largely due to the fact that NLP systems are not sufficiently precise to risk introducing errors into clinical decision-making. It is our hope, however, that methods like the one proposed here focus sufficiently on precision, while still offering substantial utility, that their adoption by clinicians will eventually take hold.

Conclusion

We have presented a semantic parsing method to convert clinical questions to a structured logical form. The method combines rule-based techniques (a lexicon and generation/pruning rules) to create tree-based structures that are then classified by a SVM classifier to select the tree corresponding to the best logical form. This semantic parsing method achieves an accuracy of 95.6% on a manually annotated set of questions, though as discussed this is probably better interpreted as the system’s precision. The method is intentionally high-precision, sacrificing recall in order to preserve user trust. Not only is the logical form approach an effective way to retrieve a single, verifiably correct answer, it also provides a useful opportunity to visualize the NLP prediction in a way that can further increase user trust. Future work on the semantic parsing includes expanding the number of questions, including questions with additional complexity. For the project as a whole, future work will focus on integrating the semantic parsing component into an end-to-end QA system, from natural language question to FHIR query.

Abstract

The terminological content of SNOMED CT, the world’s largest clinical terminology is linked to description logics expressions, which give support to consider SNOMED CT a formal ontology. The Terminology Quality Assurance (TQA) of such a terminology resource is hampered by errors in modeling, which act as a barrier for the successful use of electronic health records to ensure semantic interoperability. One application case is the new version of ICD, now in its pre-final form, the content of which is based on a subset of SNOMED CT. The ongoing alignment exercise has highlighted significant modeling issues in more than one third of cases that contrasted SNOMED CT concept model instances with the intuitive meaning given by their Fully Specified Names or synonyms lexically mapped to ICD-11 class names. We recommend prioritizing SNOMED CT TQA on the subset of the core SNOMED CT content to constitute the always true common ontology between SNOMED CT and ICD-11.

Introduction

SNOMED CT1 is the world’s largest clinical terminology with about 300,000 representational units, called concepts. They are linked to terms in several languages, with English providing the highest coverage. All lexical entities in SNOMED CT are named Terms. They include Fully Specified Names, Preferred Terms, and Synonyms. SNOMED CT concept are described and defined by expressions following a formalism called Compositional Grammar (CG)2, which can be interpreted according to description logics (DLs) which allows SNOMED CT to be considered a formal ontology. SNOMED CT is introducing itself as “a terminological resource which consists of codes representing meanings expressed as terms, with interrelationships between the codes to provide enhanced representation of the meanings.”

Nearly half of SNOMED CT’s concepts constitute the large Procedure and Clinical Finding hierarchies. They are not covered by any Terminology Quality Assurance (TQA) mechanisms apart from an abstraction network derivation methodology which focuses on internal consistency only3,4,5.

We here propose to assess the quality of SNOMED CT concept model by assessing its ability to support a formalization based not only on the closed world of SNOMED or ICD but on the open world assumption6 by taking the external example of SNOMED CT ICD-11 semantic alignment work.

As explained in7 this semantic alignment needs several steps: step 1 is a lexical map between the ICD-11 class name with textual definition and SNOMED CT Fully specified name or synonyms: step 2 is a tentative match between ICD-11 textual definition and SNOMED CT Compositional Grammar (CG) expressions2. Further steps as queries on pre-coordinated or post-coordinated SNOMED CT concepts to take care of ICD-11 inclusions and exclusions rules are out of the scope of this paper.

The purpose is to assess the quality of the inferred CG expressions candidates to the common ICD-11 SNOMED CT ontology by measuring the need of modification of CG expressions in order to represent ICD 11 class definitions if and only if there is a possible lexical map between ICD 11 class and pre-coordinated or post- coordinated SNOMED CT concepts. This is justified by the seemingly high rate of the same strings of characters in both systems: it allows to avoid the more complex issues when the same meaning is expressed by different strings of characters.
We do not consider the current pre-final version of ICD-11 as a gold standard for healthcare terminological resources and the total or partial omission of a SNOMED CT concept that seems necessary to ICD 11 external authority. We neither assess the clinical consistency of ICD 11 textual definitions. We assess only the ability of the existing CG expression(s) to represent the ICD-11 textual definition when lexically mapped to SNOMED CT concept description terms or if necessary to modify this concept model instance according to assumptions, rules, and standards that are specific to the SNOMED CT concept model.

**Material**

The ICD-11 Mortality Morbidity and Standard (ICD 11-MMS) is extracted from the WHO Browser (date: 31 Jan 2017). The semantic alignment principles explained above are performed with SNOMED CT content as displayed by the IHTSDO browser, corresponding to the SNOMED CT release of the same date, which includes:

1. Number of direct parents
2. Number of role groups
3. Number of children
4. Whether the concept is primitive or fully defined
5. Depth (distance from root)
6. Compositional grammar (CG) expression

The SNOMED CT specific compositional grammar (CG) is a set of rules that govern the way in which SNOMED CT expressions are represented as a plain text string. It is a syntax that supports a wide range of clinical meanings to be captured in a clinical record, without requiring the terminology to include separate concept for each case. Clinical expressions using SNOMED CT concepts can be of two types: pre-coordinated expressions, which use a single SNOMED CT concept identifier and post-coordinated expressions, which contain more than one SNOMED CT identifier.

The IHTSDO browser provides the representation in plain text and in a diagram. For example, the SNOMED CT concept 31978002 *Fracture of tibia*, a fully defined pre-coordinated concept, is defined using a CG expression as being equivalent to *Injury of tibia* and *Fracture of lower leg*, with *Associated morphology Fracture* and *Finding site Bone structure of tibia*. This definition is shown below in Table 1 using the SNOMED CT CG formalism, together with the transcription into DL Manchester syntax and in Figure 1 for the CG diagram displayed by the browser.

To enhance readability, concepts are noted in *Italics* and relations are noted in **Bold**.

</tbody>
</table>

**Figure 1.** The SNOMED CT concept Fracture of tibia (ID = 31978002) as a CG diagram

The purpose of this study is to assess the quality of the SNOMED CT CG inferred expressions of concepts candidates to constitute the common ontology between ICD-11 and SNOMED CT. We measure the rate of issues in...
modeling when the SNOMED CT concept model instance is not aligned with the Fully Specified Name of the SNOMED CT concept.

The study is limited to 428 classes from ICD-11-MMS, covering the circulatory system, and 522 ones covering the digestive system. We exclude ICD-11 codes ending with a "Y" or "Z" code (other specified or unspecified term at the subchapter level): 206 of such residual codes are in the circulatory chapter and 250 in the digestive chapter (see Table 3). Residuals assure that in ICD hierarchies all sub-hierarchies are fully exhaustive, although they have no clear meaning outside the context of the ICD hierarchy.

For this study, we focused on SNOMED CT concepts that can be lexically mapped to ICD-11 MMS classes either by one pre-coordinated SNOMED CT concept or by more than one post-coordinated SNOMED CT concept as stated in the introduction and explained in the following subsection. We analyze only the CG expressions of these candidate SNOMED CT concepts lexically mapped to ICD-11 MMS classes.

The work was done by two different knowledge engineering master students one in charge of the circulatory chapter and one in charge of the digestive chapter. Both chapters were supervised by the same senior ICD-11 and SNOMED CT expert.

Methods

Semantic interoperability is a crucial point for using SNOMED CT and ICD in parallel, e.g. to address clinical documentation, epidemiology, research and decision support use cases.

The first step is to perform a lexical map and in a second step a match of meaning between ICD-11-MMS classes, supported by their subclass hierarchies and text definitions and SNOMED CT concepts. Both terminologies are accessed by the web browsers made available by the respective maintenance organizations (cf. Figure 2 and Table 2).

We introduce the following symbols for the mapping types: M (refined by M1 and M2), A (refined by A1 and A2), P and Z. We consider the mapping of a SNOMED CT Concept $SC_i$, described by terms $ST_{i1\ldots n}$ to an ICD class $IC_i$, described by a name $IT_i$.

Lexical map

The following rules apply for lexical map

- If there is a full lexical map between the ICD-11 class name $IT_i$ and one SNOMED CT description $ST_{i1\ldots n}$, considered as pre-coordinated in SNOMED CT it is classified as M (for Lexical map) type.
- If there is no lexical map between any $IT_i$ and $ST_{ik}$, but if mapping can be achieved to the post-coordination of two or more descriptions $ST_{i1\ldots n}$ of $SC_k$, it is classified as A (for Addition map) type.
- If only a part of $IT_i$ of $IC_i$ can be lexically mapped to any $ST_{ik}$ it is classified as P (for Partial) type.
- Finally, if not even a partial lexical mapping between any $IT_{i\alpha}$ of $IC_i$ and $ST_{ik}$ is possible, it is classified as Z (for Zero) type.

Match of meaning

Subsequently, the CG inferred expressions $^2$ of $SC_i$ are analyzed to check whether they correspond to the totality of the textual definition and hierarchy inheritance of $IC_i$ and of defining and constraining axioms of one or more than one $SC_i$.

The following cases are distinguished:

- M (lexical match) type:
  1. This expression fully represents the meaning of $IC_i$, a complete match meaning is assumed: the classification is refined to M1.
  2. This expression does not fully represent the meaning of $IC_i$, a new expression is produced according to CG: the classification is refined to M2.

- A (addition map) type:
  1. These expressions fully represent the meaning of $IC_i$, a complete match meaning is assumed: the classification is refined to A1.
2. These expressions do not fully represent the meaning of $IC_i$, a new expression is produced according to CG: the classification is refined to $A_2$.

- **P type:**
  For $IC_i$ it is then necessary to create a logical representation based on one existing CG expression plus an extended de novo CG expression.

- **Z type:**
  For this $IC_i$ it is necessary to create a logical expression in accordance with SNOMED CT CG.

In the following, only M and A types will be analyzed.

The two most frequent lexical map types are M (M1 plus M2) for full lexical map with a pre-coordinated SNOMED CT concept and A (A1 plus A2) full lexical map with a post-coordinated SNOMED CT concept: 93.69 % for the circulatory chapter and 94.44% for the digestive chapter.

The most frequent type is M1 for for both
The less frequent types are Z for no possible lexical map for the circulatory chapter (0%) and P for partial lexical map for the digestive chapter (1.92%).

The other main differences between the two chapters are the higher rate for the match types A2 for the digestive chapter (19.92% against 3.04%): These differences can be explained by interrater differences (the work was done by two different knowledge engineering master students supervised by the same senior terminology expert) or quality differences between these two chapters either in WHO ICD 11 or in SNOMED CT or in both.

We found for these two chapters nearly the same percentage found on a previous work on the circulatory chapter with browsers based on WHO ICD-11 and SNOMED CT one year before the current study (31 January 31 2016).

The goal of our study is to measure the quality of SNOMED CT concept model for the SNOMED CT concepts candidates for a lexical map with ICD 11 class names and definitions i.e lexical map types M and A which correspond to more than 90% of ICD-11 classes for the circulatory and the digestive chapters.

As an example for M1 type ICD-11 DA 40.4 Perforation of esophagus is defined by: “perforation of esophagus is a penetration or hole of the wall of the esophagus, resulting in luminal contents in esophagus flowing into the mediastinum and/or thoracic cavity”.

The full lexical map is with SNOMED CT 23387001 | Perforation of esophagus (disorder) | which is a fully defined concept with the following pre-coordinated SNOMED CT inferred expression in Figure 4 and the diagram in Fig. 5.

Figure 4. Pre-coordinated CG expression for Perforation of Esophagus

```plaintext
37657006 | Disorder of esophagus (disorder) | + 51875005 | Gastrointestinal perforation (disorder) | + 300286002 | Lesion of esophagus (finding) |
| { 363698007 | Finding site (attribute) | = 32849002 | Esophageal structure (body structure),
  116676008 | Associated morphology (attribute) | = 36191001 | Perforation (morphologic abnormality) } |
```

Figure 5. Pre-coordinated CG diagram for Perforation of Esophagus

As an example for M2 type ICD-11 BA00 Essential hypertension is defined as “Essential (primary) hypertension, accounting for 95% of all cases of hypertension, is defined by ICD as high blood pressure for which a secondary cause cannot be found”.

The full lexical map is with SNOMED CT 59621000 | Essential hypertension (disorder) | which is not a fully defined concept but a primitive meaning that the SNOMED CT concept FSN has no full representation with the following pre-coordinated SNOMED CT inferred expression in Figure 6 and the diagram in Figure 7.

Figure 6. Pre-coordinated CG expression for Essential hypertension

As an example for M2 type ICD-11 BA00 Essential hypertension is defined as “Essential (primary) hypertension, accounting for 95% of all cases of hypertension, is defined by ICD as high blood pressure for which a secondary cause cannot be found”.

The full lexical map is with SNOMED CT 59621000 | Essential hypertension (disorder) | which is not a fully defined concept but a primitive meaning that the SNOMED CT concept FSN has no full representation with the following pre-coordinated SNOMED CT inferred expression in Figure 6 and the diagram in Figure 7.

Figure 6. Pre-coordinated CG expression for Essential hypertension
This is only the representation of hypertensive disorder, systemic arterial (disorder) which has the same representation and there is no representation of the ICD-11 class definition statement: a secondary cause cannot be found. We will present later how CG can represent this statement.

Table 3 shows how SNOMED CT concept model represents logically ICD-11 classes

### Table 3. Quality of SNOMED CT concept model to represent logically ICD-11 classes

<table>

<td>104/133</td>
<td>78.19</td>
</tr>
<tr>
<td>Poor quality Rate= (M2+A2)/(M1+M2+A1+A2)</td>
<td>107/401</td>
<td>26.68</td>
<td>199/493</td>
<td>40.36</td>
</tr>
</tbody>
</table>

To summarize the quality issue there is a rate of poor quality of 306/894 = 34.22 %

It is interesting to compare the poor quality rate to represent logically ICD-11 classes with the poor quality rate to represent SNOMED concepts which can be the rate of primitive SNOMED CT concept out of the candidates SNOMED CT concept to represent ICD 11 classes as shown in Table 4.

### Table 4. Primitive SNOMED CT concepts by map and meaning match types

```sql
<< 38341003 | Hypertensive disorder, systemic arterial (disorder);
  36370008 | Has definitional manifestation (attribute) =
  24184005 | Finding of increased blood pressure (finding);
  363698007 | Finding site (attribute) = 51840005 | Systemic circulatory system structure (body structure) |
```
The types with full map and meaning match (M1 and A1) have a low rate of SNOMED CT primitive concepts (from 0% to 33%) and the types with no full match (M2 and A2) have a high rate of SNOMED CT primitive concepts (from 81% to 100%). It can be considered that the quality issue with SNOMED CT concept model concerns mainly the rate of primitives with few exceptions.

Discussion
The semantic alignment between ICD-11-MMS classes and SNOMED CT concepts provides a good opportunity to trace the quality issues with the SNOMED CT concept model.

According to our study, 107 out of 401 SNOMED CT concepts (26.68%) in the circulatory chapter and 199 out of 493 SNOMED CT concepts (40.36%) in the digestive chapter from the Clinical finding hierarchy that lexically mapped to ICD-11 classes show modeling issues resulting in misalignments not only between ICD-11 MMS class meaning and SNOMED CT concept model instances, but as well between SNOMED CT Fully Specified Names and concept model instances. We here list some typical examples: As shown in Table 4 in most of the cases this is related to the high number of primitives, i.e. not fully defined SNOMED CT concepts for more than 80% of SNOMED CT concept candidates to lexically map with ICD-11 class names.

Misalignment between SNOMED CT concept FSN and primitive representation
In the example of Essential hypertension (ICD-11 class BA 00), which is the main category of Arterial hypertension which is one of the most frequent diseases in the world, Figure 7 shows that the existing SNOMED CT expression does not represent the lack of secondary cause, which is the meaning of “essential” or “idiopathic”. The CG provides the possibility to represent the lack of secondary cause by adding the following attribute and domain value: 370135005 | Pathological process (attribute) | 54690008 | Unknown (origin) (qualifier value) | and the diagram of Figure 8.

Figure 8. Actual SNOMED CT CG candidate representation of ICD 11 class BA 00 and proposed fully defined representation.
There are several other cases with the wording “of unknown etiology” or, e.g. as 85598007 | Constrictive pericarditis (disorder) | with no representation of “constrictive”, 373945007 | Pericardial effusion (disorder) | with no representation of “effusion”, 706882009 | Hypertensive crisis (disorder) | with no representation of “crisis”.

**Misalignment between SNOMED CT concept FSN and fully defined representation**

ICD-11 DA52.51 Allergic gastritis due to IgE-mediated hypersensitivity can be fully represented by the SNOMED CT concepts 1824008 | Allergic gastritis (disorder) | and 422076005 | Immunoglobulin E-mediated allergic disorder (disorder) |, both of which are fully defined. The role of Immunoglobuline E is not represented in the present version of the SNOMED CT concept model.

**Conclusion**

To answer the question of the title, *viz.* whether the application of the SNOMED CT concept model is sufficiently quality assured, we can state the following points as a route to an answer.

Semantic interoperability between a clinical terminology as SNOMED CT and a statistically aggregated classification as ICD-11 will be more and more necessary in the future.

The SNOMED CT concept model is a good opportunity to provide a logical basis to automate the coordination.

Problems in matching SNOMED and ICD are a way of highlighting quality issues when applying the SNOMED CT concept model.

We recommend prioritizing SNOMED CT TQA on the subset of the core SNOMED CT content by using ICD11 definition coming from WHO closed world.
This can contribute to develop a common SNOMED CT and ICD-11 ontology always true in an open world assumption6.

Abstract

Automated literature analysis could significantly speed up understanding of the role of the placenta and the impact of its development and functions on the health of the mother and the child. To facilitate automatic extraction of information about placenta-mediated disorders from the literature, we manually annotated genes and proteins, the associated diseases, and the functions and processes involved in the development and function of placenta in a collection of PubMed/MEDLINE abstracts. We developed three baseline approaches to finding sentences containing this information: one based on supervised machine learning (ML) and two based on distant supervision: 1) using automated detection of named entities and 2) using MeSH. We compare the performance of several well-known supervised ML algorithms and identify two approaches, Support Vector Machines (SVM) and Generalized Linear Models (GLM), which yield up to 98% recall precision and F1 score. We demonstrate that distant supervision approaches could be used at the expense of missing up to 15% of relevant documents.

Introduction

The placenta is the most important organ in human pregnancy. It plays the role of lungs and kidneys for the developing fetus, supplies substrates for its development, and regulates complex immune functions to allow the cohabitation of two different organisms - the mother and the fetus - during the pregnancy. Defects in the placentation process are known to be associated with a wide range of pregnancy related complications such as preeclampsia, uterine growth restriction, and premature rupture of membranes, fetal growth retardation, placenta abruption, spontaneous abortion, and fetal death. The association between defects in the placenta, the placentation process and most of the above-mentioned diseases was established in the 1950’s. More recently additional associations between the functionality of the placenta and other maternal/fetal diseases have become evident. For example, in gestational diabetes, adipokins, leptin and TNFα produced in placenta are implicated in gestational insulin resistance and possibly in insulin resistance in the adult life of the fetus through a process known as “fetal programming”. The functionality of the placenta influences maternal and fetal health and development and impacts future health for both mother and baby, not only during pregnancy but for the lifetime of both (1) (2) (3) (4). The study of the organ in real time using invasive procedures to sample the placenta and the placenta insertion site can be dangerous for the mother and the fetus, even with the use of guided imaging technology. Safer study approaches during pregnancy have only become available recently with the advancement of genetic and molecular sciences. The full potential of now-available biomedical research tools has not yet been applied to the study of the placenta. Recognizing the importance of multidisciplinary collaboration for the study of the placenta, the National Institutes of Health (NIH) through the National Institute of Child Health and Human Development (NICHD) established the Human Placenta Project (HPP) “to understand the role of the placenta in health and disease and to develop new tools to learn how it develops and functions throughout the pregnancy” (2).

Discovery of gene pathways and biochemical mechanisms that help explain disease causality can be facilitated by automated extraction of relevant information from the biomedical literature (5). One essential step in understanding complex pathways has been the compilation of disease-specific gene candidates extracted from the literature. Data analysis then makes it possible to create candidate gene assays and translate the results to the wet bench for biochemical research (6).

Our long-term goal is to extract genes, gene pathways, biomarkers, and related events from the human placenta literature to create a specialized human placenta gene repository and to identify pathways that can uncover target genes and gene therapies for pregnancy-related diseases. In this study, we present a machine learning approach to extract and identify sentences describing gene-disease relationships and gene and protein activity from a collection of studies in the placenta literature. We also make the collection of PubMed® (7) abstracts annotated for this study publicly available.
available. In addition, we evaluate if the manually annotated relations among genes, proteins and diseases could have been captured by the rules based on MeSH® indexing – human annotation of MEDLINE® abstracts by NLM indexers.

**Background**

Perch and Altman point out that all important biomedical knowledge is described in the published research literature, but to operationalize this knowledge we need computational algorithms that can efficiently extract, aggregate, annotate, and store information from the raw text (8).

To develop approaches for the automated extraction of genes and gene pathways studied in the human placenta, it is necessary to identify specific genes, their mechanisms of action, and related diseases in the human placenta literature. Having information on already-identified cause/effect relationships between genes and diseases should expedite the extraction process. Extraction of this information from the literature will allow the discovery of novel relationships as new genes are identified in the human placenta. Some hereditary aspects of such associations have already been explored in the clinical setting, where women who have developed pregnancy-induced hypertension or gestational diabetes appear to have a higher incidence and family history of chronic hypertension and Type II diabetes, respectively (1). Similar approaches to automated extraction of information from the literature have been useful in Alzheimer disease research: literature-based gene enrichment and prioritization tools were used for the discovery of novel genes related to Alzheimer’s disease (AD) (9) and protein-protein interaction networks constructed using data from literature sources, among others, were advantageous in providing objective prioritization of disease-gene candidate criteria (10).

The understanding of biological systems requires not only the ability to extract entities such as cells, proteins, genes, diseases, etc., but also to establish associations between different identified entities and cause/effect relationships (11). It is necessary to understand the role of each entity in a given relationship to establish a cause/effect association. Reports in the literature and shared natural language processing tasks have focused on DNA methylation (12), protein modifications (13), and gene expression mentions in anatomical locations (14), among others. Automatic sentence classification has been used to support evidence based medicine (15), for automatic extraction of clinically useful sentences in clinical evidence resources (16), and for automatic retrieval of abstracts on randomized controlled trials (17).

The goal of the current study is to develop approaches to facilitate automatic text identification of gene associations, their mechanisms of action, and their effects on diseases by employing automated extraction of entities, their roles, and the relationships reported in the human placenta literature. In this work, we present the annotated collection of documents needed for supervised machine learning approaches for extraction of the above information and a comparison of supervised and distantly supervised approaches for extraction of contexts that contain this information.

**Methods**

In our previous short communication (18), we described the dataset obtained for the study. In this section, we summarize information about the data and focus on the information extraction methods.

**Data**

The corpus was downloaded from PubMed on December 8, 2015, searching for: placenta AND (human OR woman OR women) AND (gene OR genes OR biomarker* OR polymorphism* OR enzyme*) AND (gestational diabetes OR hypertension OR preeclampsia OR pre-eclampsia OR eclampsia OR SGA OR growth restriction OR preterm OR HELLP OR acute fatty liver OR DVT OR anemia OR placenta abruption OR placenta previa OR stillbirth OR miscarriage) in the articles that have abstracts. The terms preeclampsia, hypertension, and other pregnancy and fetus-related diseases were included in the search because they are the most common causes of maternal-fetal morbidity in pregnancy. The search retrieved 428 MEDLINE citations. The search was specifically aimed at retrieving human placenta-related studies; however, the manual review revealed that only 300 documents referred to human placenta, while the remaining 128 were human placenta gene studies in animal models. The 128 documents with mentions of gene studies in animal placentas were excluded from the study.

**Manual Annotation**

We set out to annotate gene and protein activity events and all biomarkers, genes, and disease entities involved in the events, along with the roles the genes play in the events. We based our annotation schema on those developed for event annotation in the GENIA corpus (19) and for gene-drug relationships extraction (20). Table 1 presents the
entities and events annotated in our corpus, along with their counts. Events were marked as negated or speculation when clear negation or hedging was stated in the text. To differentiate between genes and proteins with the same name, we annotated entity mentions involved in increased or decreased levels or amount of events as protein. We annotated mentions involved in increased or decreased expression or activity of events as gene. We used BRAT online annotation tool (21) installed in a secured server and configured with the annotation schema designed for this study.

The four authors all with biomedical informatics experience and training--two physicians (DF and LR), a biologist (SM), and a cellular and molecular scientist (KG)--annotated the first 20 documents individually, reconciled the differences together, and finalized the guidelines for annotation. The remaining documents were annotated individually by two annotators each, and the differences were reconciled in pairs. We computed inter-annotator agreement using F1-score, as proposed by Hripcsak and Rothschild (22). The inter-annotator agreement between the pairs of annotators was fair. The agreement between the clinician and the geneticists was higher (58.5% on average), than between the geneticists whose F1-score was 40.3%. The better agreement between the clinician and the geneticists could be explained by learning, as for annotating the second half of the documents we paired the geneticists with the clinician, so the agreement between the geneticists was measured earlier in the process. The final modest scores reflect the difficulty of the task. The gold standard should not be affected by the modest initial agreement, as all differences were discussed and carefully reconciled in group meetings.

The resulting collection of annotated documents was then used for machine learning experiments to extract and identify sentences containing information about biomarkers and the activity of genes and proteins in the human placenta that are associated with diseases in different stages of pregnancy. Figure 1 shows an example of a fully annotated sentence.

Figure 1: Annotation of protein activity mention associated with disease in human placenta study. In this example, correlates is an event of type is-associated, and angionic regulators and oxidative stress biomarkers are entities of the type protein_enzyme and gene_family respectively. These entities have the roles of objects of the correlates event.

We explored two distant supervision approaches on the same collection as an alternative to manual annotation. We explored using the NLM PubTator web-based tool (23) to automatically annotate entity types: Disease, Species, Mutation, and Gene. We then compared the use of these automatically derived annotations as features in machine learning to manual annotation-based features.

We also explored exploiting MeSH indexing. Jimeno Yepes et al. demonstrated the use of MeSH headings and subheadings in extraction of gene-disease relationships (24). In the MeSH indexing process, NLM indexers assign headings (terms that describe the topic of the document) and subheadings (qualifiers) from the MeSH controlled vocabulary to MEDLINE citations. The subheading creates coordination among the headings, e.g., in the document PMID: 25305692 the indexing terms Pre-Eclampsia/genetics* and 14-3-3 Proteins/genetics* potentially indicate involvement of 14-3-3 Proteins in Pre-Eclampsia (disease); the asterisk indicates that both headings are the major topics in the article. For each one of the 300 documents we: 1) extracted indexing terms with the same subheadings; 2) derived indexing-based rules that establish associations among entities involved in the events presented in Table 1 and roughly correspond to these events; and 3) evaluated the relations against our gold standard as described below. Note that this approach is complementary to the initial PubMed retrieval strategy, which is recall-oriented and designed to find as many potentially relevant articles as possible. The MeSH indexing rules are geared towards finding specific relations in the set of the retrieved articles.
The following rules presented in the form subheading (Heading type, Heading type) capture associations corresponding to the events. For example, the rule genetics (disease, chemical) corresponds to association and finer grained events involving genes and proteins. In document PMID 11766889 this rule captures genetics (Pre-Eclampsia, HLA Antigens), which approximately captures the decreased_level_of event manually annotated in “A deficit in levels of the HLA-G3 transcript was observed in mild pre-eclampsia compared to normal placentas.”

- enzymology(disease, anatomy)
- enzymology(anatomy, cellular structure)
- biosynthesis(chemical, chemical)
- genetics(disease, chemical)
- genetics(disease, cellular structure)
- genetics(Physiological Phenomena, disease)
- immunology(anatomy, disease)
- immunology (Physiological Phenomena, disease)
- metabolism(disease, chemical)
- metabolism(anatomy, disease)
- metabolism(Physiological Phenomena, disease, chemical)
- pathology | physiopathology (disease, anatomy)
- pathology | physiopathology (anatomy, chemical)
- physiology (anatomy, chemical)
- physiology (Physiological Phenomena, chemical)
- physiology (Physiological Phenomena, anatomy)

We evaluated the correspondence between the associations captured by the above rules and the manually annotated gold standard (GS) as follows: 1) the MeSH-based association corresponds to at least one event in the GS (True Positives), 2) the events in the GS are not captured in MeSH indexing (False Negatives), 3) No events related to a disease are annotated in GS and the rules produced no associations (True Negatives), 4) A MeSH-based association has no corresponding events in GS (False Positive).

**Machine Learning**

We used R statistical software core package for data preprocessing and machine learning experiments, and the packages RTextTools, E1071, and MxNet for the machine learning experiments (25) (26) (27).

In the machine learning (ML) experiments, we used sentences with entities and events (963), sentences with only entity mentions (246), and a random sample of 200 sentences with no entity mentions or events. We used WordToVec filter to process the sentences eliminating English stop words, numbers, punctuation, and extra white spaces.

For classification purposes we used supervised machine learning algorithms known to perform well on text with settings briefly described below. We used a stepwise gradual approach adding features to measure performance with each of the ML algorithms. The features used for the stepwise approach were: bag of words, manually annotated events, entities, roles and attributes (negation and speculation). To test the distant supervision approach based on automatic annotation of entities, we used entities identified using PubTator, PubTator types and PubTator codes.

We used the R implementation of Support Vector Machine (SVM) (28) based on LibSVM with default settings for the radial kernel.

*Glmnet:* an R package that fits a generalized linear model via penalized maximum likelihood (29). We used the default settings with alpha set to 0.2, which makes it closer to ridge penalty.

*LogitBoost:* is an algorithm in R adapted to add a convex optimization to Boosting (30) that uses decision stumps, one node decision trees as weak learners (31).

*Max Entropy:* R implementation of Low-memory Multinomial Logistic Regression with Support for Text Classification. The regularizers were turned off in our experiments.

*Neural Networks:* (NNet) we used an R implementation of the single layer neural network with the default settings (32).
Evaluation

We evaluated Recall, Precision and F1 scores for extraction of sentences containing entities and events using 10-fold cross validation on the set of 963+246 + 200 sentences labeled respectively as containing events, entities only, and not relevant. We evaluated Sensitivity and Specificity for gene-protein/disease relations in MeSH indexing.

Results

A summary of the manual annotation of the entities and events in 300 documents is shown in Table 1.

The most commonly mentioned genes were LEP, PHLDA2, FLT1, PGF, STOX1, and VEGF. The LEP gene, which provides instructions for making a protein called leptin, is involved in the regulation of body weight, and in our collection it was associated with pre-eclampsia (33) (34). The PHLDA2 gene, generally associated with tumor growth suppression and placenta growth, was associated with placenta insufficiency and fetal growth retardation in our collection (35) (36). The FLT1, VEGF, and PGF (placenta growth factor) genes, known to be associated with development of embryonic vasculature, the regulation of angiogenesis, cell survival, and cell migration, were associated with pre-eclampsia and intrauterine growth restriction in our collection (37) (38) (39). The most frequent events were associations between gene mentions and the diseases preeclampsia and intrauterine growth retardation followed by HELLP syndrome and preterm delivery.

Extraction of sentences containing entities and events:

The results of classifying sentences as containing gene-placental mediated events, entities only, and not relevant are shown in Table 2. Adding manually annotated entities improved the results for all classifiers by at least 60%. For the automatically extracted entities, the boost was much smaller, and the difference in the improvements provided by the automated and manual entity annotation was preserved even when other manual features were added to PubTator annotations. The second visible improvement in the results is associated with adding the event annotations as features, whereas the roles and the modality features either do not contribute anything or slightly worsen the results.

Evaluation of MeSH Indexing-based event extraction:

Not surprisingly, MeSH headings contained the following diseases included in our search: *preeclampsia*, *HELLP syndrome*, *intrauterine growth retardation*, *gestational diabetes* and *premature rupture of membranes*. The chemicals included: *Nitric Oxide Synthase*, *Plasminogen Activators*, *Nucleic Acids*, *Nucleotides*, and *Nucleosides* among others. The most common subheadings were: *genetics*, *metabolism*, *physiology*, *pathology*, and *enzymology*. Three documents did not have MeSH indexing. One was published prior to the date indexing started for the publishing journal; the two others are in journals not indexed for MEDLINE. The non-indexed documents were discarded from the calculations. The sensitivity for the MeSH based association rules was 0.87 and specificity was 0.97. Table 3 presents the evaluation results.

Discussion

Our results demonstrate that an SVM or a GLM model can be used to reliably identify sentences containing information about genes associated with placenta-mediated disorders. Our collection provides a means to further extract several types of events, such as *increased/decreased activity* and *increased/decreased levels of*. Additionally, our exploration of MeSH indexing shows that MeSH headings used in conjunction with subheadings can be used to identify documents that establish gene or protein activity in certain diseases. MeSH controlled vocabulary does not include specific gene or protein terms, but it can be used in conjunction with entity annotation tools such as PubTator.

The field of genetic studies in the human placenta in real time has emerged in recent years due to availability of tissue testing on smaller sample sizes, which decreases the need for invasive intrauterine procedures that can be deleterious to the fetus and the mother. The Human Genome Project has made it possible to make important advancements in the study of genetic related diseases; knowledge grows every day on gene activity and physiology (40). With an estimated 19,000-20,000 human protein-coding genes, the task of finding genes associated with disease in the human placenta would be daunting without automated support. We have demonstrated that it is possible to use machine learning algorithms to extract knowledge from the literature in this field. As the literature grows and reports increase in size and volume, it is necessary to make use of automatic tools to guide the wet-bench research. Likewise, automatic extraction of genes, gene disease relationships, and activity allows mapping to annotated genetic databases for knowledge extraction and further guidance.
We show that even sophisticated literature searches alone are not sufficient to extract only human placenta studies: at least 30% of the studies retrieved by our search were researching human tissues in animal models. Our results also show that although distant supervision using the state-of-the-art tools such as PubTator for named entity recognition is possible, about 15% of the documents with gene mentions will be missed using this approach. Similarly, relying on MeSH indexing alone will also result in missing 13% of the relevant documents. However, MeSH indexing is an alternative source of high quality information that we plan to combine with the machine learning approaches in the future.

Limitations and Future Work

The largest limitation of the study is the size of the corpus and the paucity of some events, such as activates, stimulates, and suppresses. The collection, however, reflects the state of this area of research: a search on PubMed in January, 2017 retrieved 488 documents; only 60 more than the study corpus. The genetic human placenta literature is growing at a relatively slow pace, but we anticipate that as the knowledge increases, the rate will also increase. The specific events extracted from the identified sentences can be used to inform future research projects investigating gene pathways related to the identified gene-disease associations and potential precision medicine approaches for the mitigation of placenta-mediated disorders.

Conclusion

Our study demonstrates the possibility of automatic extraction of sentences containing information about genes associated with placenta-mediated disorders in the human placenta literature. We compare the performance of several well-known supervised ML algorithms and identify two approaches, SVM and GLM, which yield up to 98% recall precision and F1 score. We demonstrate that distant supervision approaches based on MeSH indexing and automatic extraction of entities could be used at the expense of missing up to 15% of relevant documents. Our annotation schema, guidelines, and the annotated documents will be available at https://bionlp.nlm.nih.gov/PlacentaCollection.

Abstract
Catheter-associated urinary tract infection (CAUTI) is a common and costly healthcare-associated infection, yet measuring it accurately is challenging and resource-intensive. Electronic surveillance promises to make this task more objective and efficient in an era of new financial and regulatory imperatives, but previous surveillance approaches have used a simplified version of the definition. We applied a complete definition, including subjective elements identified through natural language processing of clinical notes. Through examination of documentation practices, we defined a set of rules that identified positively and negatively asserted symptoms of CAUTI. Our algorithm was developed on a training set of 1421 catheterized patients and prospectively validated on 1567 catheterized patients. Compared to gold standard chart review, our tool had a sensitivity of 97.1%, specificity of 94.5%, PPV of 66.7% and NPV of 99.6% for identifying CAUTI. We discuss sources of error and suggestions for more computable future definitions.

Introduction
Catheter-associated urinary tract infection (CAUTI) is a common healthcare-associated infection (HAI) in the US, contributing to the deaths of up to 13,000 patients and costing at least $400 million annually.1,2 Especially in light of new reporting requirements and payment reforms penalizing hospitals for development of certain HAIs, CAUTI identification and prevention have become top priorities for hospitals.3-5

Despite the economic and medical importance of CAUTI, standardized measurement of CAUTI incidence is challenging for two reasons. First, the standard Centers for Disease Control and Prevention (CDC) National Healthcare Safety Network (NHSN) CAUTI definition is complex and subjective.6-8 Second, CAUTI surveillance has historically been done through manual chart review, which is subject to significant inter-observer variability and is resource-intensive at a time when infection control departments have fewer resources for surveillance.9-11 As of 2008, fewer than half of hospitals had an established, house-wide surveillance system for monitoring CAUTI.12

Given the need for cheaper, more reliable surveillance in the electronic health record (EHR) age, there has been a trend toward development of automated HAI surveillance tools.5,13,14 However, previous attempts to automate CAUTI surveillance have modified the NHSN definition to exclude subjective symptoms because they are not typically stored as coded EHR data.15-20 Some recent approaches have used natural language processing (NLP) to identify the presence of a urinary catheter and/or fever.21,22 However, to date no published approach has implemented the NHSN definition fully, including all subjective symptoms (e.g., urgency, dysuria).

We have developed an automated surveillance tool capable of applying the NHSN definition as written, using NLP to capture subjective symptoms documented in free-text clinical notes. Herein we describe our approach, characterize its performance compared to manual chart review, and present opportunities for improvement, especially in terms of a more computable and reliable definition of CAUTI.

Methods
We developed a CAUTI surveillance tool through an iterative process that involved a multidisciplinary team of infectious disease specialists, an infection preventionist (IP), quality improvement (QI) staff, a statistician, and a programmer. The study was conducted at the University of Washington Medical Center, a regional tertiary academic...
medical center serving five states. This effort was reviewed by the University of Washington IRB, who exempted this work from further IRB involvement due to its objective of improving healthcare quality.

Data sources and study population

Patient data from our EHR (a Cerner implementation known as “ORCA”) were deposited daily into a Microsoft Amalga UIS database, which our CAUTI surveillance tool queried as needed (Figure 1). Billing and University HealthSystem Consortium (UHC) data were obtained from a hospital administrative database. The study population consisted of all inpatients ≥18 years of age with length of stay ≥ 24 hours with a urinary catheter in place within 48 hours prior to a urine culture, from February 2010 through July 2011 (training set) and August 2011 through August 2012 (validation set). Within this population, no patients were excluded.

Figure 1. Data sources and study population. All data is discretely encoded except for items with a single asterisk (free text) or double asterisk (mix of discrete and free text). UCx: urine culture. ASB: asymptomatic bacteriuria

CDC CAUTI definition implementation

We sought to implement the NHSN definition⁶ as faithfully as possible using an iterative development process. Figure 2 graphically represents our resulting algorithm. We began by identifying all urine cultures during the training timeframe. We then examined documentation of urine output on indwelling urinary catheters (charted discretely by RNs in our EMR) surrounding each urine culture. Patients were included if a catheter was present within 48 hours prior to the urine culture (UCx). Other kinds of catheters (e.g., suprapubic, in and out, condom) and nephrostomy tubes were not included.

We then used urine culture and urinalysis (UA) data per Figure 2. We defined a positive UA as meeting at least one of the following: positive or trace leukocyte esterase, positive nitrite, pyuria, or bacteria visualized on unspun urine. Pyuria was defined as >5 white blood cells per high power field (based on our lab’s cutoff point). If the UCx identified 3 or more distinct organisms, or described “mixed flora”, the specimen was excluded for contamination. Fever was defined as temperature >38°C; if a fever was present, we looked at blood culture (BCx) +/- 72 hours from UCx.

If the BCx was positive with a non-matching (by genus) organism, the fever was considered to be caused by the organism growing in blood and did not count towards CAUTI. If the blood culture was negative or caused by a
matching (by genus) organism, it was considered to represent urosepsis and the fever counted towards CAUTI. If the blood culture was negative or caused by a matching (by genus) organism, it was considered to represent urosepsis and the fever counted towards CAUTI.

Urinary symptoms other than fever were extracted from clinical notes using natural language processing (NLP; described further below) or discovered from a discreetly encoded “genitourinary symptoms” (GU) field in our EMR. We looked for symptoms within +/- 48 hours of the UCx based on the logic of the NHSN Transfer Rule, assuming that a CAUTI takes at least 44 hours to develop from inoculation. The presence of fever or any allowable symptom (i.e. some symptoms like dysuria do not count while the urinary catheter is present) in either a clinical note or the discrete GU field defined a candidate CAUTI.

A candidate CAUTI was then excluded if it met any of the following criteria: if a matching genus was identified from any previous UCx within 14 days (then the CAUTI was considered incomplete treatment); if the reference UCx occurred up to 24h after admission (then the CAUTI was considered present on admission); if the reference UCx occurred up to 24h after urinary catheter insertion (then the CAUTI was considered present on insertion); if a CAUTI had previously been identified within the preceding 14 days (then the CAUTI was considered in treatment).

Natural Language Processing

In the final algorithm, all clinical notes associated with catheterized patients within +/- 2 days of the reference UCx were searched for positively asserted CDC symptoms (dysuria, urgency, etc.). We developed our NLP algorithm as follows: a random sample of 500 notes from the training period containing each symptom were returned and then cropped to the 100 characters before and after the symptom (resulting in a 200 character “substring”). On this training set of substrings, by manually examining the context around the symptom, “modifiers” were defined that qualify the symptom as present, absent, or

Figure 2. CDC algorithm (numbers in green circles represent number of urine cultures leaving each node); ASB: asymptomatic bacteriuria.
other. For example: complains of dysuria (present), denies dysuria (absent), or history of dysuria (other). Synonyms and variations of symptoms were also defined, e.g. “suprapubic pain”, “tender over suprapubic”. Intermediate terms were also defined that would be allowable between the modifier and the symptom, e.g. “[modifier] left-sided [symptom]”. By running this rule-based algorithm in a sequential manner (Figure 3), that is, first looking for neutral, then negative, then positive qualifiers, we were able to reduce false positives by removing negative and neutral uses from further consideration. We also assessed confidence based on proximity of the modifier to the symptom (closer is higher confidence); we only used high confidence results. See Table 1 for examples of modifiers defined.

Our EMR also has a discreetly encoded genitourinary symptoms field. Preliminary analysis showed poor agreement between this field and clinical notes/NLP, so both approaches were combined (union) in the algorithm for maximum sensitivity (see Table 2, bottom).

- direct (“denied…”), indirect (“no c/o of…”)
- direct (“complains of…”), indirect (“persistent…”), problem list (“#…”)

Validation and Analysis

We verified all data elements gathered by the tool against their corresponding entries in the primary sources (EMR, microbiology lab data) to ensure reliability. During the year-long prospective validation period, the tool was used in parallel to the IP’s existing workflow. This existing workflow was semi-automated in that the IP received a monthly report of patients with urinary catheters with positive culture results, and then conducted manual chart review on these patients. We compared the tool’s performance (sensitivity, specificity, PPV, NPV) to this “gold standard” of manual chart review. For the purposes of these analyses, we included only cultures ≥10^3 because any culture <10^3 would be excluded by the NHSN definition.

Results

The training set included 2460 cultures from 1421 patients; the validation set included 2547 cultures from 1567 patients. Table 2 provides patient demographics and hospital stay information as well as incidence of signs and symptoms of CAUTI, for all patients and for patients meeting various criteria (no growth, asymptomatic bacteriuria/ASB, CAUTI).

After the tool was adopted for routine use (at which time the existing parallel workflow ceased), the IP kept a log of all CAUTI cases identified by the tool which were subsequently rejected based on chart review. Out of 100 tool-identified CAUTIs, 62 were confirmed, resulting in a PPV of 62%. See Table 4 for top reasons for rejection of tool-identified CAUTIs.

</tbody>
</table>

We compared the sensitivity and PPV of the tool using fever alone vs all signs/symptoms (see Table 5). Using fever alone, the tool identified 64% of all cases, compared to 97% when subjective symptoms (from NLP and GU field) were incorporated. PPV increased slightly from 60% to 62% when subjective symptoms were included. We found that subjective symptoms tended to have lower sensitivity but higher PPV for CAUTI than fever (Table 6).

Discussion

We report a novel use of natural language processing to mine unstructured full text in clinical notes to find subjective symptoms indicative of CAUTI. With this method, we were able to apply the NHSN definition as written, and analyze how it applied to our population. We found our tool to have excellent sensitivity, specificity and NPV, and moderate PPV (67%), suggesting that, given its high sensitivity, it would serve as an ideal screening tool, eliminating the vast majority of potential cases while leaving a highly enriched set of potential cases (2/3 true CAUTI, 1/3 false positives) for manual confirmation. Our sensitivity (97%) was much greater than manual review which was found in a multicenter study to average just 59%. In addition, we estimate significant time savings of >100 hours per year based on elimination of review of 300 cases per year with time savings of 20 minutes per case; estimated cost savings are up to $10,000 yearly. Additional time savings would likely result from bringing all pertinent data (e.g., cultures, clinical notes) into one display for those cases which do undergo manual review.

In our population, we found objective data alone to lack sensitivity—36% of CAUTI cases had subjective symptoms without documented fever. Others have found as little as 0-10% decreased sensitivity when using objective findings alone. It is unclear whether different documentation practices, patient populations, or study methods led to these differences, however it is likely that removing subjective symptoms from the definition may have a disproportionate effect in different settings.

In comparing two sources of subjective symptoms in our EMR (clinical notes and a discrete GU field), we found they had little overlap (see Table 2, bottom). About 4% of patients had associated symptoms according to each method, but 6.8% had symptoms when both were combined. This finding should serve as a caution to hospitals that even if their EMR has a discrete data field representing GU symptoms, symptoms often may only be charted in free text notes.

Related work

Much progress has been made in developing automated surveillance tools, however previous work has been limited to use of diagnostic codes or objective clinical data to identify CAUTI. Due to poor coding consistency, ICD codes were found to be insensitive. Increased sensitivity has been obtained with the addition of objective clinical data such as presence of fever, culture and urinalysis results.

More recent approaches have used NLP to determine the presence of a urinary catheter, finding moderate sensitivity (65%) and PPV (54%) but high specificity and NPV (>99%). Branch-Elliman et al. also used NLP in this work to identify documentation of fever, however they do not present any data to show that discretely documented body temperature is unreliable. They state in online supplemental material that capturing symptoms using NLP was not
feasible due to variation in documentation practices. In their manuscript, they state that none of the 7 cases that were missed by their algorithm were attributable to subjective symptoms, and conclude that it remains unclear whether including subjective symptoms would improve their algorithm’s operating characteristics.

Gundlapalli et al.25 show the feasibility of using NLP to detect the presence of a urinary catheter as well as a full complement of urinary symptoms, however they do not appear to have incorporated their work into a functioning surveillance tool. Their results are encouraging, showing sensitivity of 50-63% and PPV of 96-97% in determining presence/absence of urinary catheter; and sensitivity of 100% and PPV of 97% in determining presence of urinary symptoms. They conclude that it is possible to reliably extract symptoms from clinical notes and recommend further work towards standardizing and structuring documentation to improve extraction of information necessary for surveillance.

In contrast to prior work, we used NLP only for capturing subjective symptoms; we did not attempt to extract language related to whether a catheter was present or whether a fever was documented because both of these data elements are already documented discretely and reliably in our EMR. It is unclear whether a mention of a “fever” without an accompanying body temperature reading should count as a qualifying sign. Additionally, discrete documentation of the presence of an indwelling urinary catheter is increasingly common in major EMRs to enable QI initiatives to track dwell times and prompt early removal of unnecessary catheters.26 Therefore, we suggest that future work would best be directed toward extracting urinary symptoms which are likely to remain, at least partially, in free text clinical notes. As mentioned previously, our EMR includes a discrete field for urinary symptoms but it was only 67% sensitive compared to an approach that also included NLP.

More computable definitions

Definitions for HAIs originated in the pre-EHR era in which computability was not a concern. For our work, we found the NHSN CAUTI definition to be difficult to apply algorithmically for two main reasons. First, it contains several subjective elements; most notably that symptoms should not be related to “another recognized cause”. We implemented this in such a way that if a febrile patient has a positive blood culture from a different genus than present in urine culture, we discounted the fever, but it was less clear how to handle, e.g., a contemporaneous positive sputum or wound culture. It was also challenging to define rules about what would disqualify subjective symptoms such as urgency, e.g., if the patient has a known history of an enlarged prostate. The second reason for difficulty in algorithmic implementation was a lack of specific detail around timeframes. For example, how near in time must a symptom be to a positive urine culture? How soon can a patient develop a second CAUTI? What if a patient has had a previously positive non-catheterized UCx with a matching organism—how much time must pass before the patient can be said to develop a CAUTI with the same genus?

Due to these limitations, different implementations and interpretations of the definition will lead to undesired variability in reported HAI rates; at the same time these rates have taken on increased significance as markers of care quality and factors impacting payment. We suggest that HAI definitions be reconsidered for digital implementation, especially if those definitions will be used for comparison between hospitals. Computable definitions should be both meaningful (capturing true rates of infection) and able to be applied uniformly across hospitals.

We recognize that an approach like ours is not feasible on a large scale across many institutions due to variability in documentation practices and technical resources. We would therefore recommend a simpler approach that maximizes the use of discretely charted data. To be most reliable and uniform, we suggest changes to documentation practices and to the CAUTI definition itself. Specifically, hospitals should ensure that urinary catheters and urinary symptoms are documented discretely (in addition to culture results, body temperature, etc), including ongoing training and QI activities to ensure this remains reliable. Including urinary symptoms (not just fever) is important because in our population they increased sensitivity considerably. The NHSN definition itself should be modified to minimize subjectivity by identifying specific allowable “other recognized causes”, especially for fever, given that it is so nonspecific (39% of our patient population with no growth on UCx had a fever). Because fever is so non-specific, we do not suggest removing “other recognized causes” from the definition entirely as this would trade off too much specificity for increased objectivity. Finally, the NHSN definition should spell out all relevant timeframes to enable an algorithmic approach to surveillance.
CAUTI surveillance will likely never be fully automated due to its inescapable subjectivity; tools like ours should strive to prescreen and rule out as many true negatives as possible to allow IPs to efficiently review the remaining cases. One reasonable step would be for the NHSN to establish criteria for definite (not requiring further review), probable (requiring further review), and non-CAUTI (not requiring further review) to standardize the types of cases that must be reviewed.

Limitations

Our study was limited to a single center and had a relatively small validation sample. Our NLP engine should be validated in other settings with different documentation patterns and patient populations. We used our best judgement about applying the “no other recognized cause” language and timing parameters that were not specifically articulated in the NHSN definition; more detail around these elements of the definition from the NHSN would improve objectivity and reproducibility of tools like ours. However, we found that even an experienced IP struggled to determine whether patients met criteria, suggesting that completely accurate discrimination of complex real-world patients will likely remain beyond the scope of this, or any, tool’s logic.

Future work

Future work should address implementation of similar tools across a variety of settings to identify sources of variability contributing to artificial inter-institutional differences in HAI rates. Such work could inform modifications to HAI definitions to make them more meaningful and uniform when applied electronically. Additionally, real-time prospective use of such tools should be explored to enable infection control staff to interact with clinicians while diagnosis and treatment is still ongoing to facilitate continuous quality improvement.

Conclusion

CAUTI is a common and costly healthcare-associated infection yet it is challenging to measure accurately due to the complexity and subjectivity of the NHSN definition. We demonstrate a novel use of NLP to fully implement the definition, including subjective symptoms found in clinical notes. Compared to manual chart review, we show excellent sensitivity and specificity in large part due to the inclusion of symptoms. Our tool has been adopted clinically, screening out the vast majority of potential CAUTIs and saving at least a hundred hours of chart review per year. Reflecting on our experience, we suggest a generalizable approach that maximizes the use of discretely charted data—requiring changes to hospital documentation practices and ultimately to the NHSN definition itself.

The Problems of Realism-Based Ontology Design: a Case Study in Creating Definitions for an Application Ontology for Diabetes Camps

James C. Schuler, BSc¹, PhD student and Werner M. Ceusters, MD¹
¹Department of Biomedical Informatics, University at Buffalo, Buffalo, NY, USA

Abstract

A requirement of realism-based ontology design is that classes denote exclusively entities that exist objectively in reality and that their definitions adhere to strict criteria to ensure that the classes are re-usable in other ontologies while preserving their ontological commitment. Building realism-based ontologies is therefore quite challenging and time-consuming, demanding considerable training. Although the top-level in the form of the Basic Formal Ontology (BFO) is worked out very well, and also the upper levels of certain domains, there is still a disconnect with the bottom-up or middle-out approach which is typical, and more practical, for application ontologies. Using the development of an application ontology for diabetes management in diabetes camps as an example, we present an overview of problems trainees in realism-based ontology design can be confronted with and offer some guidelines on how to deal with them in case no ideal solution is available.

Introduction

Realism-based ontology design¹ is often criticized as being too difficult². That it is difficult indeed is witnessed by the many ontologies that attempt adherence to the principles of Ontological Realism³ but then fail at one or other stage and do not become accepted as an Open Biomedical Ontologies (OBO) Foundry ontology⁴. There are at least two reasons for this difficulty. One is that ontological commitment in realism-based ontologies is exclusively towards what has (or once had) objective ‘mind-independent’ existence³. This includes entities and their types (the latter called ‘universals’), for example organisms and cells, and certain combinations thereof (called ‘configurations’; entities, universals and configurations all being ‘portions of reality’) such as all living and deceased diabetes patients. The second one is that definitions for representational units in realism-based ontologies must adhere to very strict criteria: each one must be defined by means of an Aristotelean definition which states all necessary conditions that are also jointly sufficient and satisfiable for some entity to be an instance of the class denoted by the representational unit¹. This is extremely important for reference ontologies, i.e. ontologies that are intended to be comprehensive for a given domain and that consist of representational units that can be re-used in other ontologies while preserving their ontological commitment to the original entities in reality. Representational units in the form of terms – in contrast to, for example icons or numerical identifiers – should also have general face validity independent of context⁵.

Concept-based ontologies such as SNOMED CT⁶, in contrast, require mere adherence to formal logical criteria and an ontological commitment not to reality, but to a ‘universe of discourse’. The advantage of concept-based ontology design is that the notion of ‘concepts as shared meanings’ is perceived as more intuitive and closer to the language used in the domains that are modeled than the quite ‘abstract’ notions of ‘universals’ and ‘portions of reality’ as employed by realists. While, for example, there is no place for terms such as ‘prevented abortion’ and ‘absent nipple’ in realism-based ontologies, they can be allowed in concept-based ontologies as, from such a perspective, it does not involve rocket-science to grasp their meaning. Therefore, metaphorically, conceptualists can ‘see’ both absent nipples and persons with absent nipples, while realists can in that context only see persons with absent nipples. While the challenge for conceptualists is not to misclassify prevented abortions and absent nipples as special kinds of abortions, resp. nipples, the challenge for realists is to find ways for formally describing in what way persons with absent nipples are different from persons with prevented abortions without resorting in these descriptions to absent nipples and prevented abortions⁷. Such considerations are very hard for trainees without a solid education in philosophy.

Whereas strict adherence to the realism-based principles is an absolute requirement for reference ontologies³, one might wonder whether that must also be the case for application ontologies, i.e. ontologies which are designed to accomplish some specified local task or application within a specific context. Application ontology development usually follows a bottom-up or middle-out approach: fundamental terms in the application domain are addressed first before moving up to more generic and down to more specific terms. One could argue that for such ontologies it is sufficient to introduce terms that have face validity only within the interface terminology⁸ of the intended application. One might even be tempted to simplify definitions to what is relevant for the logical semantics of the underlying
application as advocated by concept-based ontologies. With less stringent criteria advanced ontological and philosophical analyses can be avoided, thus leading to quicker development times. The drawback is, however, that such ontologies are more prone to contain errors\textsuperscript{9, 10}, and that formally underspecified terms with local face validity hamper their re-usability in other semantic applications so that data collected through them cannot automatically be merged and integrated with data coming from other applications, even if they cover the same domain. Therefore, it is still worthwhile to define the mid-level application domain representational units of application ontologies in terms of upper-level units from realism-based ontologies. Unfortunately, here lies an additional level of complexity for trainees in realism-based biomedical ontology design: whereas the top-level in the form of the Basic Formal Ontology (BFO) is worked out very well\textsuperscript{1}, there is a shortage of adequate mid-level representational resources that follow realism-based principles strictly, perhaps with the exception of the Ontology for General Medical Science (OGMS)\textsuperscript{11}.

In this paper, we demonstrate the sort of problems this introduces for trainees on the basis of a use case: an application ontology for glycemic control of attendees of diabetes camps. We offer some guidelines on how to deal with them in case no ideal solution is available. The goal is to identify and prioritize issues that needs to be addressed by experts to make realism-based ontology development more accessible.

**Background**

The American Diabetes Association (ADA) holds many residential camps (‘diabetes camps’) for children age 7 to 18 with diabetes throughout the United States. These are typical summer camps in the sense the campers do all the typical camp activities over the course of a week, including activities such as arts and crafts, singing songs, building campfires, performing skits, rock climbing, archery, athletics, eating meals in a dining hall, and participating in an evening program revolving around a theme for the week. The atypical aspect of these camps is that all of the campers, and much of the staff and counselors, have diabetes. These camps have been held for over 90 years\textsuperscript{12}.

Managing diabetes is a challenging task for many people with diabetes in a normal day-to-day scenario\textsuperscript{13}. Adding the spectrum of high activity and a different routine than normal at camp only increases the difficulty of diabetes management. To keep campers safe, the management of the campers’ diabetes is achieved by means of teams composed out of medical professionals (e.g., physicians, nurses, and pharmacists, and medical professionals in training such as medical, nursing, pharmacy, and physician assistant students), the counseling staff, and most importantly, the campers themselves. Presently at camp, medical professionals working with the campers record key data on paper forms which describe the camper’s glycemic control and management (Figure 1).

![Figure 1: The current paper-based medical records used at Camp Aspire](image)

The tracking of this data allows the medical professionals to perform analysis and make adjustments to the various aspects of care which determine glycemic control\textsuperscript{12}. Moreover, the tracking on records is important for communication between staff members, and engages staff to provide continuous safe and high-quality diabetes management.
The current state of medical record keeping and tracking of vital healthcare data at diabetes camp is archaic and thus ripe for innovation. The data tracked on paper medical records include, but are not limited to: time of observation, blood glucose level, carbohydrates consumed in grams, doses of insulin, basal insulin delivery rate, and urine/blood ketone level. The paper records are cheap, easily modifiable, and relatively secure. However, there are many downsides to their use. For example, paper records only modestly facilitate tracking and analysis of data and are ill-suited to detect patterns indicating potentially dangerous developments. Furthermore, the records can often be unreadable, and unavailable in a reasonable time frame in an emergent situation. Finally, there is no standard of use of paper records, or fields present in those records throughout the camps run by the ADA. Indeed, no two camps use the same forms for tracking of data (Figure 2). While each camp has its own unique forms, there is a standard within a camp, there is no standard between camps, as, for example, certain entities are referred to by different terms and possible ‘allowed’ values as instances. This lack of standard hinders research about diabetes management at all camps as data are not easily collated and analyzed what hampers the advancement in elucidation and understanding of the factors relevant to diabetes management in a camp setting and potentially places campers at risk for severe emergency events related to their diabetes. It is unknown to what extent an electronic medical record system implemented at a diabetes camp would impact the ease of recording and tracking data, elucidation of patterns in the data, and thus would increase the safety, care, and efficiency and efficacy of diabetes management at camp. With an ontology-based mobile app for diabetes care in such camps, this question might be answerable.

Methods

One option for the final assessment of students in the 500-level 3-credits course ‘Introduction to Biomedical Ontologies’ co-organized by the Departments of Biomedical Informatics and Philosophy of the University at Buffalo is the development of an ontology. The first author of this paper, a student in this course, being a regular collaborator at diabetes camps, envisioned the benefits of a small custom-made ontology-based electronic medical record app for glycemic control in such camps. It should be able (1) to support collecting, recording, presenting and managing data about the campers’ so that (2) the medical professionals would be able to analyze and interpret the data collected more easily. To keep it manageable, it would (3) allow collection of the data fields pertinent to the diabetes management of adolescents in a camp setting as, thus covering what is currently recorded on paper. This custom, micro electronic medical record would have less functionality than typical electronic medical records used in traditional inpatient or outpatient settings, but was hypothesized to have high value for use at diabetes camps. For reasons of reusability and comparability of data and integration with other relevant technologies, another design criterion envisioned would be (4) to keep the ontology – henceforth called the ‘Diabetes Camp Ontology’ (DCO) – underlying the system compatible
with the growing number of realism-based ontologies\textsuperscript{1}. The application would, for instance, be able to deal with the following scenario from camp which forms the core of the relationship between a camper and the medical staff, and the majority of what is currently recorded in the paper records: ‘\textit{Rob Smith checks his blood sugar when he wakes up on Monday. His sugar is 208. Rob’s medical staff for the week, Jim, records his blood sugar and based on this blood sugar, calculates Rob needs to take 2.8 units of insulin, and Rob takes his insulin. Immediately afterward, Rob Smith goes to the dining hall to eat breakfast. At breakfast he eats 65 grams of carbohydrates. Based on the number of carbohydrates Rob eats, Jim calculates Rob should deliver 4.3 units of insulin, so Rob does.’’ Such a scenario would be recorded in the paper records as displayed in Figure 3, a part of the form displayed in Figure 1.

In a first step, the student collected from the available paper record templates of various diabetes camps all the data elements used for the campers’ follow ups. In a second step, he inspected existing ontologies for the presence of representational units denoting types of entities in terms of which the entities represented by the terms that were collected could be described following the provisions of the Relation Ontology\textsuperscript{15}. Whenever in a feeder ontology an representational unit was found that denotes an entity also referenced by one of the collected data elements, that representational unit became part of the DCO, otherwise, a new representational unit was defined.

The resulting ontology and the documentation thereof – a short paper and presentation were part of the assignment – was then inspected by the instructor for adherence to realism-based quality principles\textsuperscript{1-3} and the total effort graded. At that stage, it became clear that failure to adhere was not only because of gaps in understanding on the side of the student, but also because of gaps in the available resources. The definitions and terms of the application ontology were therefore afterwards in a short turn-around modified and improved in discussion with the instructor to the extent possible and then analyzed together with the student’s arguments for his decisions with the goal (1) to find out what problems this student – and perhaps, to be determined through future studies, students in general – encountered with the application of realist principles, (2) to determine the root causes for these problems, and (3) to propose ‘easy fixes’, if any at all, that can be applied to definitions so that the corresponding classes, despite coming from an application ontology, can be more reliably, though not necessarily automatically, compared with relevant ones in other application ontologies within the same or a closely related domain.

Results

Building this application ontology turned out to be a difficult task and several issues were encountered. The biggest problem was not only to find adequate ontologies, but also adequate terms within them. The Basic Formal Ontology (BFO)\textsuperscript{4} as a top-level ontology, and the Information Artifact Ontology (IAO)\textsuperscript{16}, the Ontology for General Medical Science (OGMS)\textsuperscript{11}, the Ontology for Biomedical Investigations (OBI)\textsuperscript{17}, and the Ontology of Medically Related Social Entities (OMRSE)\textsuperscript{18} as high-level domain ontologies turned out to be good choices despite the wide range of incompatible options for existing representational units (RU) to choose from. Whereas the ‘middle-out’ development approach, i.e. starting with terms that need to be part of the interface terminology of the application in line with the envisioned scenarios, provided a good basis, way more terms than originally anticipated needed to be included as well and this for purposes of (1) crafting adequate definitions – a challenge in its own right, (2) providing additional functionality to the app as compared to what is possible with paper forms and (3) the ones required to drive the logic of this app. A major challenge was to identify the exact ontological types of the entities that figured in the scenarios we had in mind, a problem which not only seems to be a problem for students and trainees in realism-based ontology development, but also for the experts. For the purposes of this paper, detailed analyses are limited to representational units and definitions related to camps and the roles played by participants (Table 1) and to blood glucose levels and insulin administration (Table 2). For each RU, a textual definition precedes a semi-formal definition. The latter uses the formatting principles of the Relation Ontology\textsuperscript{15}: (1) each representational unit starts with the acronym of the ontology in which it is included, (2) SMALL CAPS is used for types, (3) \textit{italic bold font} for formal relationships. This formatting is, where important for correct understanding what we are referring to, also used in the discussion section.

Discussion

Finding relevant domain ontologies. Several projects report to have attempted the creation of an ontology for diabetes, its treatment, its complications or its diagnosis often with the eventual end goal to create clinical decision support systems to aid in numerous diabetes related issues for both patients with diabetes and healthcare providers\textsuperscript{19-25}.

</table>

The existence of them may raise the question whether yet another diabetes ontology is needed? Closer inspection reveals that only few have potentially pertinent terms and relations\textsuperscript{26, 27}. Unfortunately, rarely do these projects follow the realism-based guidelines and only one\textsuperscript{28} expresses interest in following guidelines to become a part of the OBO Foundry. While all are meaningful work within a concept-based approach and for their own specific uses, none encapsulate the reality of diabetes care and management in a camp setting. Therefore, for our purposes, a new realism-based ontology with high potential for integration with OBO Foundry compliant ontologies to address the specific needs of serving as a model of reality of caring for children with diabetes in a camp setting is indeed needed.

What terms to include? In line with the purposes the ontology has to serve, a first type of representational units to be included are those that represent entities to which the terms from the interface terminology of the application stand in an aboutness relation\textsuperscript{16}. This includes entities referenced by the terms on the paper forms used in diabetes camps, as well as the ones for which the application might offer some possible values. How clear cut this might seem, it isn’t in light of the specific ontological commitment of the BFO and the ontologies that intend to be compatible with it. An example is what is denoted by the abbreviation ‘BG’ on the form in Figure 1, i.e. blood glucose levels, and what is expected to be entered as values to denote a specific blood glucose level. One could allow just numbers such as ‘98’ and ‘289’, standing for ‘blood glucose level of 98 mg/dl (milligrams per deciliter)’ and ‘blood glucose level of 289 mg/dl’ resp. But does BFO commit to the existence of numbers with objective, ‘mind-independent’ existence? This is to say, if we write ‘98’, does this term denote some $x$ in reality? If so, would that $x$ be an instance of the type number?

</table>

Or would that x be a type itself so that there are entities which are instances of that x. Are then 98 apples, a heart rate of 98 beats per minute and a blood glucose level of 98 mg/dl all instances of x? Trainees might have these questions, yet find no answers in available documentation, or perhaps even more confusing, different positions which nevertheless all fall under a realist perspective. It is of course here that pragmatism comes into play by leaving out anything not directly relevant to the application while still staying under the realist perspective. So it is documented that BFO commits to entities on the side of the patient that are of types such as ‘blood glucose level of 98 mg/dl’ – they existed before anybody knew about glucose in blood, how to measure it, etc. – and all these entities are also of the type ‘blood glucose level’. Because blood glucose level is a quality, it allows convenient reasoning and accurate representations of reality at instance levels. For example, consider an instance of camper, Rob Smith. Rob Smith’s blood glucose level exists, and is an instance of blood glucose level for all the time during which Rob Smith exists. At some time, t₁ = 7:30 am, Rob Smith’s blood glucose level instantiates a blood glucose level of 208 mg/dl. At some later time, t₂ = 10:30 am, Rob Smith’s blood glucose level instantiates a blood glucose level of 115 mg/dl. Software can deal appropriately with these issues without the need to overload the ontology.

Should one include terms such as ‘hyperglycemia’ or ‘hypoglycemia’? These are medical terms describing blood glucose which often have strict definitions and cut-off values in certain settings and situations which often dictate action or treatment protocols. For example, in the emergency department of a hospital if a patient’s blood glucose is described as ‘hypoglycemia’ (physiologically low), it might prompt a provider to obtain some sugary food or drink for the patient to raise the blood glucose level back to ‘euglycemia’ (physiologically normal). Kids attending diabetes camp may have different blood glucose levels which they describe as ‘high’, ‘normal’, or ‘low’, a statement often referring to a blood glucose level in some range of blood glucose levels which is decided by the child’s physician. Furthermore, ‘High glycemia’ and ‘hyperglycemia’ do not always coincide, and neither ‘normal glycemia/euglycemia’, and ‘low glycemia/hypoglycemia’. One might be tempted to include terms such as ‘within target range blood glucose’, ‘above target range blood glucose’, and ‘below target range blood glucose’. But then, targets might be different for each patient. Thus in two distinct kids might inhere blood glucose levels which are of exactly the same determinate type, yet one could be within target, while the other one wouldn’t be. The issue here is that such terms when used on the form of some patient are not ‘just’ about the blood glucose level of that individual patient, but also
about the population of human beings or about the disease course of that patient as defined in the OGMS\textsuperscript{11}. When it is decided to use these terms, it is mandatory that the ontology contains a second type of representational units, i.e. those which are required to provide adequate ontological definitions\textsuperscript{29}. But there is not always the need for these terms to become also part of the interface terminology of the application.

The third type of representational units to be included are those required for the app to add additional functionality as compared to what is possible with paper forms. Thus it is critical for the functioning at diabetes camp and the representation thereof in the ontology for the app that certain roles be defined and used in precise manner. For example, when reviewing the records of diabetes management at camp, it is important to know who ordered what dose of which medication, as certain roles confer certain powers to individual persons to make certain decisions regarding the diabetes management of campers. Consider the following: a medical director of a diabetes camp may order all injections of insulin be cut by 25\% for a certain day because there will be a large amount of activity in the afternoon. This action by a medical director will likely result in the campers’ blood glucose level remaining in a safe range, as activity and insulin both act to decrease blood glucose level. A specific general medical staff working with a specific camper may decide that camper should cut the dose of an injection by 25\%, but cannot order such a change on a camp-wide scale. In table 1, D5 and D6 are examples of roles. Important subtypes of DCO:DIABETES CAMP MEDICAL STAFF ROLE include: diabetes camp medical director role, diabetes camp medical coordinator role, diabetes camp lead medical staff role, and diabetes camp general medical staff role. This then leads to the introduction of a fourth type of representational unit: the ones required to drive the logic of the application. Again, care must be taken, to the extent possible, that these units denote entities a realism-based ontology can commit to. In this case, it can be achieved by reference to entities of the type BFO:RELATIONAL QUALITY, such as the relational quality of authority between a person in whom an instance of diabetes camp medical director role inheres and other human beings in whom instances of other diabetes camp medical staff roles inheres. Analogously, there is a relational quality of authority between a person in whom an instance of diabetes camp medical coordinator role inheres and other human beings in which instances of other diabetes camp medical staff roles inheres, except for the person in whom an instance of diabetes camp medical role inheres. This allows to create an authority hierarchy among the diabetes camp medical staff.

Finding relevant mid-level ontologies. A major problem trainees are confronted with when attempting to define mid-level classes of their application ontology in terms of existing classes in other ontologies is the wide range of options, unfortunately mostly incompatible ones, which are suggested when searching through ontology repositories such as the BioPortal (http://bioportal.bioontology.org/) and Ontobee (http://www.ontobee.org/). Even more possibilities become available through literature searches.

Clearly diabetes camps in particular and camps in general are organized. Does that make such camp an ‘organization’? Over 30 existing ontologies use that term for a variety of distinct entities, the most frequent ones being: (1) the process of organizing something, e.g. organizing AMIA 2017, (2) the result of such process, e.g. the conference AMIA 2017 itself, and (3) some collection of people (and for some ontologies also other entities such as buildings, statutory documents, …), such as (3a) those involved in organizing in the first sense, e.g. the AMIA 2017 Organization Committee and (3b) everything involved once AMIA 2017 is ongoing such as its attendees, hosts, people involved in preparing the halls and rooms, etc. The student, in our use case, selected option (3a) which is the one at first sight suggested by the OBI, but with which the instructor, as we will explain further, disagreed (Table 1, D1a and D1b).

A similar situation occurs for ‘blood glucose level’ where the term is used to denote (1) an act of measuring glucose levels, (2) the value obtained through such measurement or (3) a quality of the blood independent of whether it is measured or not. In this case, the student correctly included all three types of entities in his analysis and definitions (Table 2, D9). Although several of the terms presented in the Clinical Measurement Ontology\textsuperscript{26} may be of use to this work, including ‘blood glucose level’ itself, the OBI describes better the relations between the various entities. For example, the original OBI publication describes in great detail the process of collecting a sample of blood and analyzing the glucose content in the sample\textsuperscript{17}. Thus, this ontology contains a class for OBI:MEASURING GLUCOSE CONCENTRATION IN SERUM so that the resulting output DCO:BLOOD GLUCOSE READING could be defined as a IAO:SCALAR MEASUREMENT DATUM which is linked to the former through the relationship has\textunderscore specified\textunderscore output.

Decisions on which ontologies to build further on should not only be taken on the basis of suitability of individual representational units for one’s purpose, but on the quality of the ontology as a whole. Acceptance of the ontology in the OBO Foundry is often used as a quality argument but it needs to be taken with a pinch of salt. So was at some point the Vaccine Ontology\textsuperscript{30} (VO) considered useful for the DCO. However, the VO considers the USA and Canada subtypes of ‘country’ rather than instances, which is too egregious a mistake for the quality label to be taken serious.
For the use case described, several ontologies with realism-based foundations are used. OMRSE is an ontology ‘cover[ing] the domain of social entities that are related to health care, such as demographic information and the roles of various individuals and organizations’\textsuperscript{18}. Notably, subtypes of the OMRSE:HEALTH CARE ROLE include OMRSE: PATIENT ROLE and OMRSE:HEALTH CARE PROVIDER ROLE as used in D5 and D6.

The OBI\textsuperscript{17} turned out to be very useful for many definitions, for example to address ways in administering insulin. Historically, insulin is introduced into the body via a subcutaneous route. Most campers use insulin pumps, and a minority use insulin pens or syringes. Insulin pens are made of cartridges of insulin and a screw top upon which one can screw a needle to inject the insulin. Insulin pumps are small (pager-size and shape), battery-operated entities which can push insulin held in a syringe through a tube. The tube is inserted into the hypodermis of a person with a needle. A similarity between the two methods of insulin injection is that insulin pumps and insulin pens all have as part an OBI:SYRINGE. A key difference is that every instance of insulin pump has part some instance of OBI: COMPUTER. Since there are several sorts of insulin pumps, it is important for the diabetes camp medical staff to be aware of the manufacturer of a camper’s insulin pump, and what model it is, such that the medical staff will then be able to navigate the appropriate menu options in the envisioned application. For example, Rob Smith’s Medtronic Paradigm 751 would be an instance of DCO:MEDTRONIC INSULIN PUMP MODEL PARADIGM 751, which is a subtype of DCO:MEDTRONIC INSULIN PUMP, which is a type of DCO: INSULIN PUMP (Table 2, D10) which OBI:is manufactured by value Medtronic Minimed which itself is an instance of OBI: ORGANIZATION. Whether a DCO: CAMPER receives insulin via a DCO: INSULIN PUMP or DCO: INSULIN PEN, he or she is participating in the process OBI: SUBCUTANEOUS INJECTION.

The IAO makes it possible to keep entities on the side of the patient and caregivers, e.g. blood glucose levels, strictly separate from entities to describe such entities, e.g. blood glucose readings on the screen of a glucometer. So there is IAO: SETTING DATUM defined as ‘a datum that denotes some configuration of an instrument’. Insulin pumps are devices with programmable settings. Examples of settings which are programmed by a user include: insulin to carbohydrate ratio, correction factor (sensitivity), basal rates, and blood glucose level targets. The DCO includes these terms referring to the analogous setting datum as subtypes of a new term DCO: PUMP SETTING DATUM (Table 2, D10), which itself is a subtype of an IAO: SETTING DATUM. These setting datum provide the information to determine how much insulin should be given in a given situation, for example based on current blood glucose level of a camper and carbohydrates eaten by a camper. Other representational units based on IAO include DCO: BLOOD GLUCOSE READING (Table 2, D9) as a subtype of IAO: SCALAR MEASUREMENT DATUM.

Deciding what types of entities selected terms denote. This aspect of realism-based ontology development is undoubtedly the hardest nut for trainees to crack as it does not allow objects to be ‘anything perceivable or conceivable’ as advocated in concept-based approaches\textsuperscript{31}. So it would be tempting to create subtypes of OBI: SUBCUTANEOUS INJECTION for what terms such as ‘food bolus injection’ and ‘correction bolus injection’ would denote. A food bolus injection would be administered when a camper eats carbohydrates, and a correction bolus injection when a camper’s blood glucose is high. However, it is easy to conceive two processes of bolus injection which are of exactly the same type (same sort of needle, same concentration, same type of injection site, …) whereby only the intention of the clinician would be different, but such intention is not part of the process of injecting. Or consider a carbohydrate count as subtype of IAO: SCALAR MEASUREMENT DATUM on the argument that such count is the result of a measurement of carbohydrates in food eaten. Carbohydrates are counted based on standard guidelines from the FDA and the nutrition labels on food. A standard may be: a medium size apple has 15 grams carbohydrates, and 1 slice of bread has 15 grams of carbohydrates. The question the trainee has to answer here is whether this method is more and estimate than a measurement, and whether OBI accepts estimates as kind of measurements.

As a last example, an important consideration when giving an injection of insulin is the location of the injection on the body. This is important to know, as different spots on the human body absorb insulin to varying degrees. For example, insulin injected into the abdomen is absorbed faster into the bloodstream than insulin injected into the buttocks, and a camper’s blood glucose level may be influenced by choosing to perform injections into certain locations. One could follow the example of the Vaccine Ontology\textsuperscript{30} (VO), a domain ontology which represents the entities in reality as pertaining to vaccines and vaccinations. Since vaccines can be given in various locations in the human body and via various methodologies, for example, an injection of a vaccine into the deltoid muscle of the arm, or an inhalation of a vaccine through the nose, the VO defines a VO: VACCINATION SITE, and a subtype VO: VACCINE INJECTION SITE. Thus in a similar way DCO: INSULIN INJECTION SITE is defined (Table 2, D12, D13). The question to be answered here is whether such terms denote truly extra entities or whether such terms are mere ‘ways of talking’. After all: there is no injection site in BFO sense unless the injection has been given and one can therefore not use it to describe where an injection is to be given; the ‘site used for injection’ is simply a body part. It is a bit different for inhalation, because in that case, the body part (nostril, mouth, …) is indeed a site in BFO sense. But would that site
behave suddenly an instance of ‘insulin inhalation site’ after inhalation of insulin? What did change after the inhalation that warrants this? It is acceptable, for pragmatic reasons, to introduce what are called ‘defined classes’ for these purposes, but the resulting ontologies are then not ‘realism-based’ in the strict sense as defined by some authors.

Closely related to this is determining whether entities are types or instances. Instances, also called ‘particulars’ or ‘individuals’, are entities that carry identity and do not come in various sorts. Canada and the USA are instances: there are no two different kinds of Canada or different kinds of USA. Is ‘Camp Aspire’, acronym for ‘Always Sharing Priceless, Inspirational, Rewarding Experiences’ as organized by the ADA a type or an instance (Table 1, D4)? Interestingly, that there is another ‘kind of’ ‘Camp Aspire’, acronym for ‘Autism Social Skills Program for Interaction and Relationship Education’ organized by the Autism Society of Central Illinois is not an argument for typehood but a simple case of homonymy. But that the ADA ‘Camp Aspire’ is organized annually, in distinct locations and at some locations at different times are all arguments for typehood, each specific camp, at a specific site and during a specific time period being an instance of that type. And of course, both the ADA ‘Camp Aspire’ and the autism ‘Camp Aspire’, which also is organized multiple times, are instances of DCO:CAMP. This raises the question whether ‘camp’ should indeed be defined in DCO, or whether it should not move up to a higher level in the hierarchy of domains.

What if the experts don’t know? To what ontology a representational unit ideally belongs is not a clear cut matter. It is proposed that the distinction between occurrents (entities that evolve, such as processes) and continuants (entities that don’t have temporal parts), and, amongst the latter, between independent continuants (e.g. objects) and dependent continuants (e.g. qualities, roles, functions, …) should be a guide. The Gene Ontology has been used as an example of how that would work. But what if even the experts disagree – or can’t decide – about what the highest subsumer of some type might be. It was tempting to define DCO:CAMP (Table 1, D1) as a type of OBI:ORGANIZATION until the fine print was read: ‘The definition summarizes long email discussions on the OBI developer, roles, biomaterial and denrie branches. It leaves open if an organization is a material entity or a dependent continuant, as no consensus was reached on that. The current placement as material is therefore temporary, in order to move forward with development.’ (http://www.ontobee.org/ontology/OBI?iri= http://purl.obolibrary.org/obo/OBI_0000245). Also using OBI:HOMO_SAPIENS to denote human beings is not unproblematic as experts seem to disagree about whether this OBO-term just lacks face validity by using the name of a specific species (an individual) for a type or truly represents a species. The difference is important as there are no different kinds of homo sapiens (yet?).

Conclusion

Building realism-based ontologies is a daunting task. Although the first version of BFO was created fifteen years ago, the current version consists of a mere 35 classes with a maximum hierarchy depth of 5. This is not only because BFO as top-level reference ontology is by design restricted to representational units which are relevant to all domains and thus is expected to be rather small, but also because of the extremely detailed philosophical analyses that were required to bring it into its present shape. Although not the same level of philosophical enquiry is needed for application ontologies, it cannot be avoided. The number of realism-based ontologies is growing enormously, but so also the number of inconsistent uses, even incompatibilities. Although ‘Building Ontologies with Basic Formal Ontology’ is a useful resource, it does not contain all the answers to practical questions trainees are confronted with.

Abstract

Breast cancer is the most common cancer among women. DESIREE is a European project which aims at developing web-based services for the management of primary breast cancer by multidisciplinary breast units (BUs). We describe the guideline-based decision support system (GL-DSS) of the project. Various breast cancer clinical practice guidelines (CPGs) have been selected to be concurrently applied to provide state-of-the-art patient-specific recommendations. The aim is to reconcile CPG recommendations with the objective of complementarity to enlarge the number of clinical situations covered by the GL-DSS. Input and output data exchange with the GL-DSS is performed using FHIR. We used a knowledge model of the domain as an ontology on which relies the reasoning process performed by rules that encode the selected CPGs. Semantic web tools were used, notably the Euler/EYE inference engine, to implement the GL-DSS. “Rainbow boxes” are a synthetic tabular display used to visualize the inferred recommendations.

Introduction

Breast cancer is the most common cancer among women in France with about 50,000 new cases per year. After having doubled between 1985 and 2005, the incidence rate of breast cancer seems now to be stabilized. However, if it is decreasing for women aged 50-79 that benefit from the nationally organized screening, it has increased of more than 60% for the women aged 30-39 and 40-49\(^1\). With 12,000 deaths per year (figures consolidated in 2012), the mortality rate of breast cancer in France is decreasing. Breast cancer is one of the cancers with the best survival rate at five and 10 years (87%, resp. 76%). This may be explained by the evolution of therapeutics and the development of endocrine and targeted agents as well as to the reduction of menopausal hormone therapy prescription. However, breast cancer comprises a complex and heterogeneous group of diseases at the clinical, morphological, and molecular levels. For some of the subtypes, especially the triple-negative and HER2+ breast cancers, margins for improvement are both possible and necessary\(^2\).

Clinical practice guidelines (CPGs) are elaborated to provide best evidence-based recommendations for the management of patients with specific conditions. Studies showed that implementing oncology CPGs does improve clinical outcomes in both overall and recurrence-free survivals\(^3\). This is especially true in the case of breast cancer\(^4\). However, despite the publication of CPGs and the provision of state-of-the-art recommendations, cancer management remains subject to variable practices, and poor levels of compliance with oncology CPGs are observed\(^5,6\). For instance, Wöckel et al. reported a 51.9% guideline adherence rate for the complete treatment received by primary breast cancer patients\(^6\).

In the last decade, organizational measures such as multidisciplinary tumor boards (MTBs) have been introduced to promote quality in care delivery to cancer patients\(^7\). The aim is to gather the various cancer specialists (surgeons, medical oncologists, radiologists, pathologists, radiotherapists, etc.) to promote the collective discussion of cancer patient

*The DESIREE project has received funding from the European Union’s Horizon 2020 research and innovation programme under grant agreement No 690238.
clinical cases and the decision of the best care plan for the patients. MTBs are expected to improve CPG implementation and to help capture cases for clinical trials. If studies on cancer care generally associate multidisciplinary tumor boards with improvements of guideline compliance rates\textsuperscript{8–10}, daily practice in MTBs is hampered by the complexity of the disease and the vast amount of patient and disease data available. Implementing CPGs is difficult since a high case load is actually discussed in MTBs and individual cases usually only receive a very limited amount of time for review. Thus, the impact of multidisciplinary tumor boards has been questioned\textsuperscript{11}, suggesting that decision support tools could improve MTB efficiency.

Indeed, CPGs are usually developed by health professional societies and national health agencies as textual documents in a narrative format. The sole dissemination of narrative guidelines poorly helps CPG implementation and has almost no impact on physician decisions\textsuperscript{12}. On the contrary, embedding CPGs in clinical decision support systems (CDSSs) has shown some benefit on the improvement of physician decision compliance with CPGs\textsuperscript{13,14}. Different prototypes of CDSSs supporting the management of breast cancer patients have been developed. However to the authors’ knowledge, only few systems have been routinely used to support decisions made for actual breast cancer patients in real life breast MTBs or breast units (BUs), and only some of them evidenced they were improving compliance of BU decisions with CPGs. Among them, we can mention MATE\textsuperscript{15} which uses the PROforma language, OncoCure\textsuperscript{16} based on Asbru-encoded protocols of pharmacological therapies for breast cancer, and OncoDoc\textsuperscript{17,18} that offers to navigate through a knowledge base structured as a decision tree to obtain patient-specific recommendations. Different formalisms have been proposed to translate the narrative recommendations into computer-interpretable guidelines\textsuperscript{19}. More recently, research works using web semantic approaches have been conducted, e.g. Abidi \textit{et al.} proposed to use ontologies in a rule-based reasoning process to manage breast cancer patients\textsuperscript{20}.

However, all previous propositions only rely on the modeling and implementation of a single CPG applied to a unique pathology, in this case breast cancer. Other research works have developed solutions to handle the concurrent application of different CPGs in order to manage patients with comorbidities that need different treatment regimens. Wilk \textit{et al.}\textsuperscript{21} have proposed a framework based on first order logic to represent CPGs and to mitigate possible adverse interactions (drug-drug or drug-disease) between the recommendations provided by the different CPGs. Galopin \textit{et al.}\textsuperscript{22} have implemented an ontological reasoning process to allow for the flexibility necessary to deal with patients suffering from both hypertension and type 2 diabetes. In these cases, CPGs are reconcile on the basis of competition.

DESIREE is a European-funded project\textsuperscript{†} which aims at developing a web-based software ecosystem for the personalized, collaborative, and multidisciplinary management of primary breast cancer by BUs. DESIREE would offer guideline-based, case-based, and experience-based\textsuperscript{23} decision support. The system is expected to be used by the clinical partners of the consortium on actual breast cancer patients and in real life BUs. In this perspective, we have translated the different contemporary breast cancer CPGs that clinical partners are implementing in their BUs in a computer-interpretable format. The aim is then to reconcile breast cancer CPGs on the basis of complementarity and to concurrently apply all of them. The idea is to avoid the CDSS silence observed when no recommendation is issued for a clinical case not covered by single CPGs, and to extend the clinical coverage of the CDSS by considering additional breast cancer CPGs.

In this paper, we present the guideline-based decision support system (GL-DSS) of DESIREE and describe how we used a domain ontology as the conceptual and terminological structure on which relies the reasoning process performed from the rules that model the selected breast cancer CPGs. We also propose an original visualization of the output of the concurrent application of CPGs as “rainbow boxes”\textsuperscript{24}.

**Material and methods**

**General design of the GL-DSS and basic workflow**

The aim of the GL-DSS of DESIREE is to provide state-of-the-art guideline-based recommendations structured as action plans issued from multiple breast cancer CPGs for any clinical case discussed by BUs. Informed BU participants may then choose to comply of not with one of the options provided. Since patient clinical cases discussed during BUs may be more or less complete, and because clinical data and reasoning process may be described at various levels

\textsuperscript{†}http://www.desiree-project.eu

1511
of abstraction, we chose to use semantic web tools allowing for subsumption. A data model and a knowledge model
dedicated to breast cancer management were consistently developed. The data model relies on a standard entity-
relationship model. The Breast Cancer Knowledge Model (BCKM) is a specification of all concepts that have been
identified for the management of breast cancer patients, structured as an OWL ontology. It enables the multi-level
description of patient cases and recommended action plans. The BCKM is a central static resource shared by all
data-oriented modules and components of DESIREE, so that they can be semantically interoperable.

To elaborate the knowledge base of the GL-DSS, the first step of the method was to select the different breast cancer
CPGs to be used. Once validated by the clinical partners of the DESIREE consortium, each of the considered CPGs
has been first structured as a set of human-readable decision rules, then encoded into a formal model-driven rule
language (NRL). Each formalized CPG was then processed in order to check its consistency regarding the BCKM and
to generate an internal computer-interpretable representation of the rules in the N3\textsuperscript{25} notation\textsuperscript{1}.

In the DESIREE project, a patient data repository, part of the DESIREE Information Management System (DESIMS),
constitutes a local breast-cancer-specific Electronic Medical Record (EMR) to store all patient cases according to the
common data model. In order to be interoperable beyond the DESIREE system, we decided to align both the knowl-
edge and the data models with standard reference terminologies to address semantic interoperability, and we chose the
FHIR messaging standard for communicating with external components to warranty syntactic interoperability\textsuperscript{26}.

Finally, we expected the GL-DSS to be used in real life BUs for actual patients. Thus, we needed to demonstrate
the good performance of the system and chose to use a fast and powerful rule based inference engine (Euler/EYE\textsuperscript{27}).
The GL-DSS module is implemented as a servlet providing web services through the use of a REST API. Figure 1
illuminates the different internal components of the GL-DSS, the external resources, and data flows. At run time, the
GL-DSS queries a FHIR server, linked to DESIMS, for patient data. Then, it converts the received bundle of FHIR
resources into an internal N3 representation. On the basis of N3 rules and of the N3 version of the BCKM, the
inference engine produces new facts, including the set of recommended action plans, which are returned to the user.

Clinical practice guideline collection and structuration

Various CPGs have been published for the management of breast cancer both at the international and national levels.
Our goal was to identify up-to-date CPGs that would be implemented within the GL-DSS module of DESIREE. The
selection criteria were: primary breast cancer; no restriction on the management step (including diagnosis, therapy,
and follow-up); published in English, or in the languages of the project’s clinical partners (Spanish and French);
most recent version when several versions existed. We conducted a search through different on-line resources: (i)
biomedical literature, using PubMed, (ii) international and national web repositories of CPGs including governmental
health care agencies (e.g. NGC, G-I-N, NCI...),\textsuperscript{5} (iii) websites of professional societies and associations, health care
institutions (e.g. NCCN, ESMO, ASCO, SEOM...), and (iv) custom local CPGs used as references by clinical partners’
BUs.

Eight CPGs were finally validated by the clinical partners of DESIREE and chosen for implementation within the
project: two NCCN guidelines Version 2.2016 “Breast Cancer” and “Genetic/Familial High-Risk Assessment: Breast
and Ovarian” [English]; the ESMO guidelines published in Annals of Oncology published in 2015 [English]; the
SEOM clinical guidelines for early-stage breast cancer published in 2015 [English]; three CPGs from the Paris public
hospitals (AP-HP), guidelines for “breast cancer management” (2016), for “fertility preservation” (2016), and for the
“management of cancer and pregnancy” (2014) [French]; the Onkologikoa’s breast cancer guidelines 2016 [Spanish].

Each CPGs has been structured by a medical oncologist specialized in the management of breast cancer as human-
readable IF-THEN decision rules. The rules built have been double-checked by a public health physician. Then, they

\textsuperscript{1}N3 is a compact and human readable syntax for RDF serialization but it has several features that go beyond a serialization for RDF models,
such as support for RDF-based rules. It currently has the status of a W3C submission whose specifications dated back to 2011 can be found at
http://www.w3.org/TeamSubmission/2011/SUBM-n3-20110328/

\textsuperscript{5}NGC = The National Guideline Clearinghouse (http://www.guideline.gov), G-I-N = Guideline International Network (http://www.g-i-n.net),
European Society for Medical Oncology (http://www.esmo.org), ASCO = American Society of Clinical Oncology (http://www.asco.org), SEOM =
Spanish Society of Medical Oncology (http://www.seom.org).
have been normalized to comply with the domain concepts defined by the breast cancer knowledge model.

*The Breast Cancer Knowledge Model*

The purpose of the knowledge model is to provide a common reference and terminology for all modules and components with the guaranty that clear, unique, and accredited concepts and definitions are being used. All the relevant concepts used for a patient case description and for the reasoning process are stored in a single place as an ontology in the OWL format. The choice to define a specific terminology focusing on the breast cancer domain was mainly made in order to be able to easily add new concepts. Nevertheless, the model remains tightly coupled with some existing established authoritative terminologies such as the NCI thesaurus, LOINC, and SNOMED CT, to further warranty semantic interoperability with potential hospital information systems (HISs) or EMRs. Alignment is maintained through links whenever it is possible by means of systematic annotations (see figure 2). All the relevant clinical procedures, possible examinations, clinical findings, and observations are present in the model.

The ontology also accounts for the breast cancer data model which includes the main concepts such as Patient, Side, and Lesion which are the main entities characterized by series of parameters or attributes, and allows for the description of a breast cancer patient case. Consequently, from the decision support point of view, the BCKM ontology is divided into two main hierarchies. The first one contains all the concepts specific to the DESIREE environment, namely the concepts used to define the entity parameters, and the second one contains all reference concepts defined in the breast cancer domain. The reference concepts are mainly used as potential values for the former DESIREE concepts.
Decision rules formats

We followed the approach promoted by the HL7 CDS group on the notion of “knowledge artifact” to represent rule sets. Rules are first encoded in a formal language, human readable, and possibly editable by some trained clinicians. We used NRL which is a model-driven language allowing to write logical expressions matching model components and rules, independently of any implemented inference engine. In our approach, the BCKM ontology acts as the reference model; an XSD model is automatically derived from the OWL model to feed the NRL parser that validates rule specifications. NRL has already been used to manipulate clinical information models and is similar to the GELLO language. NDL rule sets are then transformed into an XML representation, depending on the model, but independent from the source format (NRL) and the target computer-interpretable format. This intermediate representation is close to the HL7 Clinical Decision Support Knowledge Artifact Specification and is used to be shared by other modules (e.g., the experience-based DSS). Another transformation yields an N3 representation of the NRL rules which is the target computer-interpretable format.

Data representations

Patient-related data is stored outside the GL-DSS, within the DESIMS component. Input and output data exchange with the GL-DSS is performed using FHIR. No specific FHIR profile was defined and only standard FHIR resources were used, mainly Patient, Observation, Condition, BodySite, and Specimen. In order to preserve the data model through the FHIR transport, the main assumption has been that the observation resource was used to convey parameter-value pairs of the model. DESIREE codes defined in the DESIREE namespace of the knowledge model are used to particularize these observations and make them describe the same concepts as those used by the GL-DSS. Once parsed and decoded from the FHIR messages, patient data are converted to N3 notation and the data model is instantiated as a set of triples. This N3 representation is matched with the N3 executable rules by the inference engine at run time.

Execution engine

To combine rule-based reasoning and ontological reasoning, we adopted Euler, more specifically the EYE implementation by De Roo et al. This provides the system with description logic (DL) reasoning facility along with some classical logic powerful features. Euler is notably using Notation3 (N3), it is directly interoperable with the knowledge model since it belongs to the same family of semantic web tools able to deal with graphs of triples. Moreover, it appeared to be among the fastest reasoners with a full OWL-DL.

In the GL-DSS module, the engine is fed with a set of N3 rules and a set of N3 facts produced from the patient data.
according to the knowledge model concepts and properties. It takes the full knowledge model as additional input and using a generic query it then saturates the knowledge base until no more new triple can be produced generating new inferred facts. The content of the triple store is then explored in order to build new recommendations that have been produced with the basic concepts and building primitives from the knowledge model.

**Visualization of recommendations**

In order to display the multiple recommendations that may be produced by the different CPGs, we adapted the rainbow boxes visualization technique designed by Lamy et al. for the comparison of drug properties. It performs overlapping set visualization, a visualization problem that considers elements and the sets made out of these elements. The objective of the visualization is to clearly display which elements a given set includes, and which sets a given element belongs to, to facilitate the discovery of new knowledge such as similarities between elements or sets.

Rainbow boxes represents the elements in columns and each set is displayed as a rectangular labeled box that covers the columns associated with the elements belonging to the set. The boxes are stacked vertically as pieces in a Tetris game, and ordered by size (largest ones at the bottom). “Holes” can occur in a box when the elements belonging to a given set are not in consecutive columns. However, columns are ordered using a heuristic algorithm that minimizes the number of holes.

The presentation of multiple recommendations can be seen as an overlapping set visualization problem where each recommendation is a set of therapeutic units. Thus, in this context, a set is a recommendation and an element is a therapeutic unit. Therapies are grouped in six categories (pre-operative chemotherapy, pre-operative endocrine therapy, surgery, post-operative chemotherapy, radiotherapy, post-operative endocrine therapy) displayed from left to right, and each of the four types of therapies (surgery, chemotherapy, radiotherapy, endocrine therapy) were distinguished by color hues. In addition, some recommendations have a temporal dimension, e.g. chemotherapy with Adriamycin-Cyclophosphamide followed by Docetaxel. Color saturation is used to emphasize the first step of the recommendation.

**A case study**

As an illustration of how the GL-DSS operates, we present a case study processed with two of the breast cancer management CPGs that were selected in the DESIREE project, namely the 2016 version of NCCN CPGs “Breast cancer” and the 2016 version of AP-HP CPGs “Breast cancer management”. Both guidelines have been formalized as human readable IF-THEN rules by an oncologist specialized in breast cancer.

We consider the case of a patient, aged 67, diagnosed with an invasive bifocal breast cancer of the lower outer quadrant of the left breast. The first lesion is 35 mm, the second 12 mm, and the distance between the two is 18 mm. There is no clinical axillary lymph node (cN0). The two lesions have the same pathological profile: Estrogen receptors (ER)=95%, Progesterone receptors (PR)=40%, HER2-, SBR 3, and KI67=25%. The patient has no contra-indication to chemotherapy. Patient data is transmitted using a FHIR message to the GL-DSS and translated into the N3 format. Some preliminary inference rules are triggered to enrich the patient profile and assess the postmenopausal status, the TNM staging as T3 N0 M0, the stage as IIA, and the positive hormonal receptor status (HR). Figure 3 displays an excerpt of NCCN and AP-HP rules triggered on this patient case. NCCN guidelines recommend two management strategies, either surgery (lumpectomy and sentinel node excision or mastectomy and sentinel node excision) or systemic therapy: endocrine therapy with aromatase inhibitors or chemotherapy with the proposition of two different protocols (AC followed by Paclitaxel and TC). In the same way, AP-HP guidelines propose both surgery and systemic therapy (see figure 4). However, both surgeries and systemic therapies are different: AP-HP CPGs recommend a surgery by mastectomy with axillary dissection, there is no recommendation of endocrine therapy, and if some of the chemotherapies are those recommended by NCCN CPGs, there are two additional protocols.

The rainbow boxes visualization of the case study is displayed in figure 5. The box label indicates the guideline(s) leading to the recommendation. When both CPGs produce the same recommendation, there are two labels, and thus the box is larger. Consequently, it is easy to determine at a glance the most consensual recommendations. Similarly, the use of color makes it easy to see that most recommendations involve chemotherapy. It is also noticeable that all these chemotherapies include Cyclophosphamide.
We have developed the GL-DSS module of the DESIREE project applied to the management of breast cancer patients.

**Discussion**

We have developed the GL-DSS module of the DESIREE project applied to the management of breast cancer patients. The aim was to process the reconciliation of contemporary CPGs developed on a given pathology on the basis of complementarity to extend the coverage of patient profiles for which the GL-DSS provides recommendations. Although BU clinicians would have the opportunity to tick the CPGs they want to select to feed the GL-DSS, they may chose to work with all of them to reduce the silence of the system or see when different CPGs are consistent.

The choice of developing the knowledge model as an ontology presents two major advantages on top of providing a unique vocabulary to all the DESIREE project components: on the one side, the model resolves multilingual issues through label language tags, which is strongly required in an international project and, on the second side, the inference engine benefits from the ontological reasoning capabilities of the ontological model in addition to those provided by the rule engine. For instance, the use of the subsumption relationship leads in some cases to decrease the number of rules that have to be written and permits to match parameter values expressed at various levels of abstraction. In the same way, the issued recommendations may have different levels of specialization depending on the granularity of the information contained in CPGs for a particular patient case.

Different approaches have been developed to represent and execute CPGs\(^\text{19}\). However, in the case of breast cancer management, the choice of IF-THEN rules is appropriate to represent CPG contents since patient clinical data are easily formalized and recommended actions are given as care plans described at a high level of abstraction (to be refined and implemented by care providers outside the BU. In the same way, the temporal nature of CPG recommendations is easily represented by the ordered sequence of the therapeutic steps that compose the recommended care plan. We
could have chosen the HL7 Clinical Decision Support Knowledge Artifact Specification to define Condition-Action rules but we considered the standard was not stable enough to be used in an international project stressed on the production of outputs and outcome measures. In addition, a end-user formal language would still have been required, but we considered the standard was not stable enough to be used in an international project stressed on the open world assumption and the degraded performances obtained on a real scale with these techniques, we preferred to use the NRL language which accepts any declared information model like our BCKM, instead of using existing dedicated formalisms (like GELLO or Arden Syntax). IF-THEN rules have been manually built which sets the issue of the scalability of the approach. If natural language processing (NLP) methods to semi-automatically extract IF and THEN parts of rules have been proposed, the result is not yet satisfactory and solutions for the development of structured CPG contents should rely on the initial authoring of CPGs in these formats.

As for the execution engine, using tools from the semantic web domain as a base should have led to some kind of solution based on SWRL rules associated to a classical OWL reasoning engine to produce inferences. However, because of the lack of expressiveness of the latter, the impossibility to deal with non monotonicity and negation within the open world assumption and the degraded performances obtained on a real scale with these techniques, we preferred to adopt an alternative solution with Euler/Eye which does not have these limitations. When running the GL-DSS, the different CPGs are operated, which may lead to intra and inter-CPG conflicting recommendations. Only intra-CPG conflicts are resolved in the way proposed by. The resolution of inter-CPG conflicts are left to BU participants.

Currently, only two CPGs have been implemented, and work is still in progress with the other CPGs. It’s only when all CPG rule bases would be developed that we will be able to assess the performance of the semantic reasoner Euler/EYE and validate the choices we made. In addition, further evaluation is needed to assess the use of rainbow boxes to visualize the set of concurrent recommendations provided by the different CPGs.

Figure 4: Recommendations inferred by NCCN and AP-HP guidelines on the patient clinical case.
Figure 5: Rainbow boxes visualizing the eight recommendations obtained for the case study. Therapies are presented in columns and there is one recommendation per rectangular box (not one per line). One box includes a hole in the Docetaxel column. Colors identify the four categories of therapies (green, yellow, red, blue), the temporal dimension (the vivid part of a box corresponds to the first step, while the dimmed part corresponds to the other steps if any), and the guidelines (black and white labels).

Acknowledgments

Abstract

The growing amount of data describing historical medicinal uses of plants from digitization efforts provides the opportunity to develop systematic approaches for identifying potential plant-based therapies. However, the task of cataloguing plant use information from natural language text is a challenging task for ethnobotanists. To date, there have been only limited adoption of informatics approaches used for supporting the identification of ethnobotanical information associated with medicinal uses. This study explored the feasibility of using biomedical terminologies and natural language processing approaches for extracting relevant plant-associated therapeutic use information from historical biodiversity literature collection available from the Biodiversity Heritage Library. The results from this preliminary study suggest that there is potential utility of informatics methods to identify medicinal plant knowledge from digitized resources as well as highlight opportunities for improvement.

Introduction

Evidence from archaeological studies demonstrate the existence of knowledge regarding plant use even before writing had evolved.¹ Over centuries, such knowledge has been transferred both verbally as well as in the form of written text or scriptures. One of the oldest mentions of medicinal plant use dates back to 2600 BC written on clay tablets in cuneiform describing approximately 1000 plants.² Although the term “ethnobotany” was coined in 1895,³ long before that time, botanists and physicians were traveling to diverse destinations to collect and document plant use knowledge. An example of one of the early documentations of such information is *De Materia Medica*, written by Pedanius Dioscorides, a Greek physician, pharmacologist, and botanist, between 50 to 70 C.E.,⁴ which remained the core of western pharmacopoeia as late as 1865.⁵ His accounts of around 600 plants were based on travels to the Mediterranean. Since then, a rich repository of data has been compiled from accounts of botanical explorations across the globe aimed at collecting specimens and documenting their cultural use. Botanical explorations reached their peak during the 19th century and, by the latter part, drew interest of academicians who recognized the importance of systematic examinations of indigenous societies and their knowledge of plant use.⁶ Studies of the historical use from such texts have aimed to show correspondence between textual and present day folk traditions as well as guide discovery of potential medicines.⁷

Due to the impact of modernization, there is a loss of traditional knowledge transferred over generations. A major goal of ethnobotany is to document and investigate the knowledge about plant use by indigenous communities. Ample evidence exists that reflect the success of natural products research (aimed at drug discovery) directed by knowledge gained from ethnobotanical explorations.⁶ Considering the diminishing corpus of knowledge of traditional culture, it is imperative to document and preserve elements of indigenous knowledge.⁷ As a result of one such contemporary effort, the Palau and Pohnpei Primary Health Care Manuals were written based on information gathered from The Republic of Palau and Pohnpei State, Federated States of Micronesia, both island groups in Micronesia. Such documentation of traditional botanical knowledge is important both in terms of conservation of biodiversity and for supporting public health.⁸ Cataloguing plant species information and their respective use in treating ailments is an essential task that remains challenging. The information present in historical texts can complement contemporary ethnobotanical studies.⁹,¹⁰ However, historical texts need to be in computer-analyzable form to facilitate the identification of relevant knowledge. One such supportive initiative is the effort being led by the Biodiversity Heritage Library (BHL).¹¹ The BHL houses digitized versions of biodiversity literature covering 115,124 titles. The digitization of text describing medicine provide opportunities to carry out analyses over different periods of time.¹² Automated analyses and integration of data from such sources with contemporary biomedical data may lead to the generation of testable hypothesis as well as provide preliminary support for bioprospecting studies.
Extracting relevant information from digital archives can help mobilize information that would otherwise remain sequestered. Use of controlled vocabularies, such as the Medical Subject Headings (MeSH) in biomedical domain, has been shown to aid efficient retrieval of relevant information. In the biodiversity domain, approaches have focused on highlighting and leveraging the species-centric nature of how knowledge is sought in the discipline. Use of “taxonomically intelligent” approaches has been shown to facilitate retrieval and linking of organism-specific information across resources. There have been significant advances in the biomedical domain with the development of automated methods aimed at gaining insight and hypothesis generation from narrative data. In addition to tools and algorithms for mining the text, due consideration has been put into the development of ontologies and terminological resources. Natural Language Processing (NLP) systems have been developed that determine concept equivalence of terms or phrases from unstructured text by mapping to standardized terminologies. NLP systems have also been developed for mining entity-relation extraction (e.g., BioMedLEE and SemRep). The main approaches in biomedical entity recognition involve lexicon-based, rule-based, and machine learning based methods, with combinations of these approaches resulting in better performance. Potential applications of such methods in the biodiversity domain has been described by Thessen et al. Availability of annotated corpora is important for training NLP tools to derive key patterns that can be used subsequently. NLP tasks have benefited from the availability of annotated corpora in biomedical domain. However, the lack of similar resources, including annotated corpora, make retrieval of knowledge from biodiversity texts challenging.

This study aimed to test the feasibility of using biomedical terminologies and NLP tools to extract therapeutic information from contemporary and historical ethnobotany texts. The ability of the NLP tool MetaMap to extract and normalize mentions of medicinal use to Unified Medical Language System (UMLS) Metathesaurus was evaluated, focusing on plants identified from the ethnobotanical surveys of the Micronesian islands of Palau and Pohnpei. The results from this study reveal the challenges and opportunities regarding the applicability of informatics based methods for supporting large-scale analysis of historical texts, such as those that are included in the BHL. The experience gained from this preliminary study motivates the need for developing efficient strategies for reliable extraction of medicinal use information from historical texts.

Methods

The primary goal of this study was to examine the feasibility of applying biomedical text mining tools and methods to facilitate the extraction of plant-associated therapeutic indications from historical texts. A reference standard based on the manual annotation of Primary Health Care Manuals (PHCMs) provided the basis for optimizing the approach and further evaluation. Following evaluation of the approach, historical text pertaining to the plant list from PHCMs was analyzed for possible therapeutic uses. A general overview of the steps of the developed pipeline is depicted in Figure 1.

Annotation of Primary Health Care Manuals. The Primary Health Care Manuals (PHCMs) document indigenous knowledge related to plants commonly used for medicinal purposes for selected medical conditions on Palau and Pohnpei. These documents were a result of extensive ethnobotanical surveys carried out as a part of the program, Biodiversity and Human Health in Micronesia. The health conditions included in these manuals were selected based on frequent diagnoses by traditional healers and from the data collected during the surveys. These manuals serve as a reference for those interested in the use of plants for healing by cataloguing traditional medicinal knowledge attained first-hand from the field explorations. The Palau and Pohnpei PHCMs each include medicinal use information for more than 80 plant species. The botanical uses described covers use of individual plant species as well as recipes involving combinations of herbs. The scope of this study focused only on descriptions of medicinal use involving individual herbs.

A reference standard was developed that consisted of therapeutic annotations associated with individual plants mentioned in the PHCMs. An annotation guideline was used to direct the annotation process of PHCMs, which were organized into individual text files consisting of one plant per document. Each individual plant document included: (1) Local Name(s), (2) Scientific Name, (3) Family, (4) Description of Herb, (5) Traditional Uses, (6) Pharmacological Properties, and (7) Toxicology. The scope for the annotation process was limited to the sections Traditional Uses and Pharmacological Properties. The annotation “therapeutic indication” was used to include all single or multi-word expressions that related to the medicinal use of a given plant of interest. In addition to specific medical conditions (such as disease or symptoms) medically-relevant terms (e.g., “anti-bacterial”, “analgesic”, and “stypic”) were also included. If a given plant species was described as active against certain organisms (e.g.,
microbes or parasitic worms) those were also annotated. The annotation was performed using Stanford Manual Annotation Tool\textsuperscript{26} in batch mode, which resulted in a tagged document that was parsed using a program written in Julia.

![Figure 1: Study Overview.](image)

Figure 1: Study Overview. Text from PHCMs (Palau and Pohnpei) were manually annotated to create a reference standard against which MetaMap output was evaluated. A custom filter was designed by optimizing the combination of semantic types to achieve highest F-score. This custom filter was used to distill the MetaMap output for plant related texts identified from BHL to identify potential treatments that were manually examined.

Extraction and Optimization of Biomedical Concept Identification. The individual descriptions associated with plants from the PHCMs (Palau and Pohnpei) were processed using MetaMap, with plant associated mentions of UMLS concepts and their respective semantic types being extracted by a Julia program. The processed output was used to generate and optimize a semantic type filter that to identify UMLS concepts of interest. A default filter for concepts based on those that belonged to the UMLS Semantic Group ‘Disorders’ was used\textsuperscript{27}. The MetaMap output was compared to the output from manual annotation, and the correctly identified UMLS Concepts were grouped by semantic type. A cutoff was defined that included semantic types that accounted for at least 5% of correctly identified concepts entities. All possible combinations of the semantic types that were within the cutoff criteria were analyzed relative to the reference standard, calculating Precision, Recall, and F-score. The combination of semantic types with highest F-score was selected as custom filter. The optimized custom filter obtained from Palau dataset was used for evaluation of MetaMap output from Pohnpei dataset and vice versa. Finally, the semantic types from the custom filter obtained from both dataset was merged and all combinations were tested on the combined Palau and Pohnpei dataset. The concepts from filtered MetaMap output was compared to manually annotated PHCM reference standard. The best performing (according to F-score) semantic type combination was used as the final custom filter for further use.

semantic type combinations on MetaMap processed Palau dataset identified a combination of ten semantic types: acab, antb, bact, dsyn, fngs, inpo, lbtr, patf, sosy, and virs. This combination accounted for a maximum F-score of 52.8 (Precision: 43.52 and Recall: 67.12). This custom semantic type filter when applied on MetaMap processed Pohnpei dataset resulted in an F-score of 45.39. The optimum custom filter obtained from MetaMap processed Pohnpei dataset consisted of eight semantic types: antb, bact, dsyn, fngs, inpo, moft, sosy, and virs. This combination was selected as it resulted in a maximum F-score of 45.39 (Precision: 35.18 and Recall: 64.24). When applied to the MetaMap processed Palau dataset this custom filter resulted in a F-score of 47.85 (Precision: 37.41 and Recall: 66.76). This custom filter was same as the one derived from semantic type optimization on Palau dataset. A comparative evaluation using a default filter (semantic types included within the semantic group ‘Disorder’) resulted in F-score of: 27.41 on Palau dataset; 28.31 on Pohnpei dataset; and 28.61 on combined dataset. A summary of Precision, Recall, and F-score obtained from optimum custom filters and default filter is presented in Table 1.

**Treatments Identified from BHL.**
For the 129 distinct plant species identified, 72 BHL texts were identified after filtering based on subject keywords followed by scope of text containing mention of plant names (217 text segments). Manual evaluation of MetaMap output with custom filter resulted in identification of 14 distinct treatment indications associated with six plants from 14 different BHL titles. The resulting indications are listed in Table 2 along with their respective BHL barcodes. The true indications identified from BHL accounted for 17.54% of total associations. An additional 24 distinct treatment indications associated with nine plants were identified that belonged to semantic types ‘phsu’ and ‘fndg’ (Table 3). From the associations identified with these two semantic types the true indications described in BHL texts accounted for 11.70%. Table 4 lists the titles, links to BHL texts and DOIs for the barcodes mentioned in Tables 2 and 3. Additional treatments were identified from BHL which add to the list compiled from ethnobotanical survey of Palau and Pohnpei (as described in PHCM). A comparative list of such treatments are presented in Table 5.

**Discussion**
Starting from generational transfer of knowledge through verbal means to ancient documentation by explorers, it is important to preserve historical knowledge for guiding future discoveries. The field of pharmacognosy has benefitted by historical leads from such sources\(^\text{[10]}\). Since the need for systematic investigation of indigenous plant

use knowledge has been recognized, ethnobotanists have been generating data from indigenous cultures around the globe. The process of ethnobotany includes field surveys, interviews, collection of specimens, documentation, and analysis to elucidate plant use pattern within the context of human civilization. Search for existing records and literature related to a given identified plant species is an essential part of the process. In light of the growing amount of data being accrued from surveys and digitization of historical texts, cataloguing and indexing of plant use knowledge remains an essential task to support the needs of ethnobotanists and medical historians. Having scalability in implementation of automated pipelines for such tasks may result in ease of analysis of plant use patterns, which in turn may benefit in distilling bioprospecting studies. This study sought to test the feasibility of using biomedical NLP tools and terminological resources for automated extraction of plant related therapeutic indications from ethnobotanical and historical texts.

The development of automated pipelines for extraction of plant related medicinal use information from ethnobotanical and historical texts is fraught with challenges. A major challenge is the lack of annotated reference corpora for training and evaluating NLP approaches. A contribution of this study is the manual annotation of PHCMs (Palau and Pohnpei) that can be used to support the development and evaluation of NLP tools for ethnobotany. The annotation of therapeutic indications from these manuals reveal range of descriptions for describing therapeutic use of medicinal plants. For the purpose of evaluation and optimization of the pipeline developed in this study, the concepts identified by MetaMap were organized and combined according to the UMLS Semantic Network. The UMLS Semantic Network reduces the more than one million concepts in the UMLS Metathesaurus into 133 semantic types that are further grouped into 15 semantic groups. After applying the cutoff value used in this study, 25 and 22 different semantic types, respectively from Palau and Pohnpei PHCMs, were identified over which the relevant concepts were distributed. Such spread over different semantic type categories reflects the diverse nature of terms or phrases used to describe medicinal uses of plants within these texts. Owing to the diverse spread, an optimization approach was used in this study to filter noise while still retaining relevant therapeutic information. The efficacy of such filter is evident from the significant improvement in F-score.
over the default filter that only included the semantic group ‘Disorder’ (see Table 1).

Several interesting medicinal applications were identified from the BHL texts analyzed in this study (Tables 2 and 3). The year of publication for the identified titles ranged from 1874 for the oldest to 1919 for the most recent (see Table 4 for list of identified BHL titles). A comparative view of treatments from PHCMs and associated titles identified from BHL is presented in Table 5. There were few medicinal uses that were common: *Allium cepa* is described in BHL title to stimulate digestion and PHCM mentions its use for gastrointestinal issues; *Barringtonia racemosa* in BHL title has use in skin diseases and PHCM lists its use for skin rashes; the anthelmintic potential of *Carica papaya* is also common between BHL title and PHCM. Additional therapeutic use information for related species were also visible in the defined scope of text such as the use of *Terminalia chebula* for diarrhea, dysentery and in bilious disorders.

The scope of text analyzed was defined as a paragraph containing the mention of plant name. Although interesting therapeutic indications related to the PHCMs plant list were identified, future work is needed to further investigation of individual texts for designing custom templates specifying relevant scope of text (e.g., document, page, section, paragraph, or sentence). Also, use of co-reference resolution methods and techniques for analysis may potentially be beneficial. Additionally, correction of optical character recognition (OCR) output text will be essential for contemporary NLP systems to map concepts correctly. The plant species names can be used as an identifier for integrating information, but there may be challenges involving ambiguity and use of alternative name(s) (‘synonyms’). Future work may be more inclusive by using a collection of synonyms and vernacular names associated with a given plant for identifying relevant texts. Similarly, there may be challenges in terms of correlating words or phrases used in historical text to describe different disorders as well as their respective synonyms and variants into canonical medical concepts. Future work might therefore aim to include semantic libraries for improving the recall of relevant biomedical concepts, including the use of methods for automated lexicon generation. Finally, approaches for developing entity name reconciliation services may be used for better aligning name strings (e.g., from iPhylo) with collaborative knowledge bases such as Wikidata (or the now deprecated, but still accessible, Freebase). Such services may allow for the building of custom knowledge graphs for obtaining answers to questions of interest.

This study highlighted several challenges and opportunities in text mining historical data available in resources like the BHL for identification of potential therapeutic leads. The results and insights gained in this study serve as a foundation upon which a bridge between historical plant-based knowledge (which include those described in biodiversity texts) and contemporary biomedical application can be built. In particular, the success of this feasibility study demonstrates the potential for automated cataloguing of medicinal plant specific information from ethnobotanical and historical data sources such BHL using existing biomedical NLP resources. It is anticipated that the approach demonstrated here can be used on other relevant sources of historical medicinal plant knowledge, such as the collection of health related historical material maintained by National Library of Medicine’s History of Medicine Division.

**Conclusion**

The process of cataloguing medicinal plant use information by ethnobotanists has largely relied on manual searching of records from surveys and biomedical literature. Historical evidence about medicinal use of plants from archival sources may be a valuable addition to the existing pipeline of cataloguing information. Automated methods can support this process of distilling large amounts of text descriptions to extract meaningful information. This preliminary study demonstrated the potential of informatics methods for extraction of plant-associated medicinal use information from historical biodiversity literature archived in the Biodiversity Heritage Library. In addition to identification of historical medicinal use leads, several challenges were highlighted that provides insights for how to adapt biomedical terminology and approaches.

Abstract

Patient socioeconomic data is not usually included in medical records nor easily accessible to clinicians, yet socioeconomic disadvantage can be an important guide to disease management. This study evaluated the neighborhood-level Area Deprivation Index (ADI), a measure of neighborhood socioeconomic disadvantage, as a factor in diabetes mellitus prevalence. Electronic health records at an academic hospital system identified 4,770 Medicare beneficiaries. Logistic regression of diabetes diagnosis (ICD9=250.x) against ADI quintile, age, gender, and race/ethnicity found all these patient characteristics to be significantly associated. Diabetes prevalence was lowest in the least disadvantaged quintile of neighborhoods after adjusting for age, gender, and race/ethnicity. The positive non-linear association of diabetes prevalence with ADI demonstrates the power of this index to practically quantify socioeconomic disadvantage. The ADI may be suitable for clinical decision support, and for informing the policy changes which are needed to reduce socioeconomic disparities in diabetes prevalence and other health outcomes.

Introduction

Epidemiological significance of diabetes mellitus

One twelfth of the world’s population has diabetes mellitus, including 10.8% of Americans¹. In the United States (US) alone, diagnosed diabetes costs $176 billion annually in direct medical costs and another $69 billion annually in decreased productivity². Diabetes incidence rates are rising, with 1.9 million US adults newly diagnosed with diabetes in 2010³.

Education, occupation and income are independently associated with a 25-30% decreased risk of type 2 diabetes⁴. Lower subjective social status (the individual’s perception of his or her position in the social hierarchy) is also associated with increased risk of diabetes⁵, as are depression⁶ and lower self-efficacy and social support⁷.

Prevalence of the disease varies by ethnic group⁸, but disparities are more strongly associated with socioeconomic status than with race or ethnicity⁹. The least well-off suffer a disproportionate share of the burden of diabetes¹⁰, and children who live in poverty are more likely to develop type II diabetes as adults and more likely to die from it earlier¹¹,¹². The association between socioeconomic status and diabetes mellitus is worldwide, in low-income countries as well as high-income countries¹³.

Limitations of existing approaches

Clinicians need additional training and tools to assess and respond to social determinants of health at the point of care¹⁴. However, because patient income and education are often not part of the medical record, nor often discussed directly during care delivery, clinicians must infer socioeconomic status from available data, such as patient neighborhood of residence. The Area Deprivation Index (ADI), is a geographic, area-based measure of the socioeconomic deprivation to which census-defined neighborhoods (i.e. census block groups) are exposed¹⁵. Addition of this socioeconomic risk factor to more traditional individual-level clinical data such as age, gender, and race/ethnicity could improve the understanding of diabetes risks in individual patients and patient populations.

Objective of the current study

The objective of this study was to develop and evaluate a clinically useful tool for more practically identifying the social determinants which impact diabetes prevalence in a patient population.
Methods

Study population and setting

The study population comprised 4,770 primary-care patients at the University of Missouri who were 65 years or older and enrolled in Medicare (US federal health insurance for the elderly and disabled) on September 1, 2014. All patient diagnoses, demographics, and other clinical attributes were retrieved from University of Missouri Health System medical records.

Data collection

This study used an updated and refined 2013 ADI developed by the University of Wisconsin School of Medicine and Public Health (AJK). This 2013 ADI uses data from the 2009-2013 American Community Survey to construct a factor-based ADI score from 17 census block-group level markers of socioeconomic status for each neighborhood of interest (Table 1).

</tr>
</tbody>
</table>

Because the ADI is an index rather than a concrete measure such as income or percent of households, it is not associated with a defined unit of measure. Differences between index values must be interpreted in relation to the range of index values in the data set. For these reasons, the possible ADI scores for Missouri were calculated for each
Census block group and grouped into quintiles, with both the ADI score and the ADI quintile assigned to each member of the study population. Figure 1 shows the resulting map of ADI quintiles for the state of Missouri.

Figure 1. Missouri Area Deprivation Index (ADI) quintile by Census Block Group.

Statistical methodology

Diabetes mellitus, the outcome of interest, was defined as the presence of any 250.x ICD-9 code in a patient’s EHR record. Because that outcome is a binary categorical value (either present or absent), logistic regression was used to test the association between ADI and diabetes, adjusting for patient age, gender, and race. Diagnostic plots of the empirical log-odds of diabetes against ADI quintiles indicated that relationship is not linear, and so ADI was treated as a nominal scale variable. Integer age in years was treated as a continuous variable. Gender was treated as a categorical variable, with “female” and “male” being the only two values recorded for this study population. Race/ethnicity was also treated as a categorical variable with two values, “White/Non-Hispanic”, and “Other”. The data source included eight possible values for race/ethnicity, but because the “White/Non-Hispanic” category included 88% of the study population, all other categories (“American Indian or Alaskan Native”, “Asian”, “Black or African American”, “Hispanic”, “Native Hawaiian or other Pacific Islander”, “Other race”, and “Unknown race”) were reclassified as “Other”.

Results

All the variables tested were found to be statistically significant with \( p < 0.05 \), as shown in Table 2.

</tbody>
</table>

* p<0.05, ** p<0.01, *** p<0.001

A graphic visualization of the percent of patients with diabetes mellitus (DM) within each ADI quintile (see Figure 2) clearly shows a positive but non-linear association of increasing DM prevalence (ranging from less than 25% to more than 35% in the study population) with increasing ADI (i.e., increasing neighborhood deprivation.).

Figure 2 shows visible differences in diabetes prevalence between patients from the least disadvantage neighborhoods (quintile 1), from the most disadvantaged neighborhoods (quintile 5), and from neighborhoods in the middle (quintiles 2-4). However, pairwise comparison of the five quintiles found statistical differences only between quintile 1 and all other quintiles, as shown in the Table 3.
Table 3. Analysis of effects in the logistic regression model

| ADI Quintile Comparison | Odds Ratio | Pr > |t| |
|-------------------------|------------|------|---|
| 1 v 2                   | 1.3198     | 0.0013** |
| 1 v 3                   | 1.3461     | 0.0012** |
| 1 v 4                   | 1.2928     | 0.0171*  |
| 1 v 5                   | 1.3886     | 0.0261*  |
| 2 v 3                   | 0.9804     | 0.8307   |
| 2 v 4                   | 1.0208     | 0.8487   |
| 2 v 5                   | 0.9505     | 0.7304   |
| 3 v 4                   | 1.0412     | 0.7176   |
| 3 v 5                   | 0.9694     | 0.8355   |
| 4 v 5                   | 0.9311     | 0.6532   |

* p<0.05, ** p<0.01

The low statistical significance of the apparent increase in diabetes prevalence for quintile 5 may be partly due to the relatively small sample size of this quintile, comprising only 5.7% of the study population. This limits power significantly.

Discussion

Fulfillment of study objective

The positive non-linear association of diabetes mellitus prevalence with neighborhood disadvantage, as measured by the Area Deprivation Index (ADI), indicates that ADI could be a useful tool for converting patient address into a significant predictor of diabetes prevalence in a patient population.

Additional findings

In this study population, the prevalence of diabetes in the least disadvantaged neighborhoods (ADI quintile 1) is significantly lower than all other neighborhood quintiles after adjusting for age, gender, and race/ethnicity. Quintiles 2 through 5 were not statistically different. The statistical equivalence of quintile 5 with quintiles 2 through 4 may be due to relatively small size of quintile 5, or may show an approximate equivalence between diabetes prevalence at moderate and high levels of neighborhood socioeconomic disadvantage.

Limitations of the current study

Because the study was limited to a single academic health center in mid-Missouri, and to Medicare enrollees over 65 years of age, these results may not be generalizable to other populations. Because nearly 90% of the study population was non-Hispanic White, the important characteristics of race and ethnicity may not adequately tested by this study. Furthermore, as previously stated, relatively small sample size in the most disadvantaged neighborhood quintile limits our statistical power and our ability to draw conclusion for this group.

Directions for future research

Repeating this study with a larger patient population, and with a population sample more representative of the entire US, may add to the understanding on how neighborhood disadvantage by ADI could be harnessed in diabetes care and population health efforts.
Conclusion

This study demonstrates the power of the Area Deprivation Index (ADI) to quantify neighborhood socioeconomic deprivation into a single index for use in predictive analytics. The ADI may be suitable for clinical decision support, as well as for informing the policy changes which are needed to reduce socioeconomic disparities in diabetes prevalence and other health outcomes. In addition to confirming the existing literature in finding an association between neighborhood socioeconomic deprivation and the prevalence of diabetes mellitus, this application of the ADI adds new findings to our understanding of health disparities. Most strikingly, the association of neighborhood socioeconomics with good health was strong in this population only for those residing within the highest levels of privileged neighborhoods; middle-class neighborhood status granted no measurable protection from the diabetes health disparities that affected residents of the poorest and least privileged neighborhoods. Clinicians and population health managers armed with a simple and unobtrusive measure of neighborhood socioeconomic status, based not on private financial data but simply on patient address, may be able to more effectively screen for, prevent, and manage diabetes in individual patients and managed populations. This is an important idea worthy of future research and study.

Leveraging Collaborative Filtering to Accelerate Rare Disease Diagnosis

Feichen Shen, Ph.D., Sijia Liu, M.S., Yanshan Wang, Ph.D., Liwei Wang, M.D., Ph.D., Naveed Afzal, Ph.D., Hongfang Liu, Ph.D.
Department of Health Sciences Research, Mayo Clinic, Rochester, MN, USA

Abstract

In the USA, rare diseases are defined as those affecting fewer than 200,000 patients at any given time. Patients with rare diseases are frequently misdiagnosed or undiagnosed which may due to the lack of knowledge and experience of care providers. We hypothesize that patients’ phenotypic information available in electronic medical records (EMR) can be leveraged to accelerate disease diagnosis based on the intuition that providers need to document associated phenotypic information to support the diagnosis decision, especially for rare diseases. In this study, we proposed a collaborative filtering system enriched with natural language processing and semantic techniques to assist rare disease diagnosis based on phenotypic characterization. Specifically, we leveraged four similarity measurements with two neighborhood algorithms on 2010-2015 Mayo Clinic unstructured large patient cohort and evaluated different approaches. Preliminary results demonstrated that the use of collaborative filtering with phenotypic information is able to stratify patients with relatively similar rare diseases.

Introduction

In the USA, rare diseases are defined as those affecting fewer than 200,000 patients at any given time\(^1\). According to research conducted by Rare Disease Day\(^2\) and the National Organization for Rare Disorders (NORD)\(^3\), to date, there are over 7,000 known rare diseases inflicting 30 million Americans (nearly 1 in 10), more than half of whom are children\(^2\). However, due to the lack of scientific knowledge and clinical experience for rare diseases, most patients with rare diseases are frequently misdiagnosed or undiagnosed. In addition, only 5% of those diseases have corresponding treatment plans\(^2\). Therefore, there is an urgent need to accelerate the diagnosis of rare diseases as well as explore the science behind them.

Almost 80% of rare diseases are genetic\(^2\) and the first step towards rare disease research and diagnosis is to identify patients with similar phenotypes, where a phenotype refers to a clinical observable sign or symptom. Multiple studies have reported on studying rare disease phenotyping. To facilitate the discovery of genotype-phenotype association, the Human Phenotype Ontology (HPO)\(^4\) was developed to capture human phenotype information and is one of the most representative efforts that conducts phenotype-oriented analysis for rare disease differential diagnosis. The current version of HPO contains more than 116,000 annotations for over 7,000 rare diseases. To understand genotypes for rare diseases, Phen-Gen\(^5\) provides a method to combine phenotypes and patients’ sequencing data with domain knowledge in order to locate genotypes for rare disorders. Other efforts, PhenomeNET\(^6\) and PheWAS\(^7\) leveraged phenotypic information to discover genotype-phenotype associations that can be applied to prioritize genes for rare diseases.

Meanwhile, in the era of e-commerce, collaborative filtering techniques\(^8\) are popularly applied to recommend products to a customer based on customers with similar purchase preferences or other interests. The problem of diagnosing a patient with a disease based on patients’ phenotypic information is very similar to recommending a product to a customer, and therefore it is natural to propose the use of collaborating filtering for disease diagnosis. For example, given the hypothesis that disease prediction is achievable through analyzing phenotype and disease history, CARE provided an individualized healthcare framework by analyzing ICD-9-CM codes in patient’s medical history\(^9\-11\). Similarly, Steinhaeuser and Chawla proposed a combined disease network and collaborative filtering to perform disease prediction on structured patient data\(^12\).

In this study, we proposed a patient based collaborative filtering system enriched with natural language processing (NLP) and semantic techniques to assist rare disease diagnosis based on phenotypic information extracted from free-text clinical notes. Specifically, we extracted the Unified Medical Language System (UMLS)\(^13\) concepts using MetaMap and used terms in the Human Phenotype Ontology (HPO)\(^4\-14\) and the Genetic and Rare Diseases Information Center (GARD)\(^15\) based on dictionary lookup to preprocess 2010-2015 clinical notes from Mayo Clinic Rochester campus. We then used a patient based collaborative filtering framework for rare disease diagnosis and compared four similarity measurements and two neighborhood algorithms.
In the following, we first introduce materials used in this study. Next, we describe the methods used to build the framework and conduct the evaluation. We then present the results followed by discussion. Lastly, we conclude and discuss potential future directions.

**Materials**

*Clinical Data Collection*

We collected all clinical notes during the years of 2010 to 2015 generated at Mayo Clinic Rochester campus. The resulting corpus contains 12.8 million clinical notes corresponding to 729,000 patients. We limited our annotation to sections containing problems and diagnoses.

*The Unified Medical Language System and MetaMap*

The Unified Medical Language System (UMLS), developed at National Library of Medicine (NLM), is an integrated knowledge base that involves key medical terminologies and related resources. There are three components in the UMLS, the Metathesaurus, Semantic Network, and Specialist Lexicon. The Metathesaurus lists all clinical concepts integrated from over a hundred of terminological resources. A unique identifier, Concept Unique Identifier (CUI), is assigned to each medical concept. Each concept can be associated with one or more semantic types defined in Semantic Network. MetaMap is a configurable application for mapping biomedical text to the Metathesaurus. Here, we applied MetaMap with the UMLS version 2015 to extract UMLS concepts from clinical notes as a preprocessing step.

*Human Phenotype Ontology*

The Human Phenotype Ontology (HPO) has been developed as a controlled vocabulary for phenotypes by mining and integrating phenotype knowledge from medical literature and ontologies. HPO also provides associations with other biomedical resources such as Gene Ontology. HPO contains four sub-ontologies focusing on different annotation areas: Phenotypic Abnormality, Mode of Inheritance, Clinical Modifier, and Mortality/Aging. HPO and the UMLS have been cross-referred and we limited phenotype concepts extracted from clinical notes only to UMLS concepts that are cross-referred with the HPO released on September 2016. We only considered concepts from HPO sub-ontology Phenotypic Abnormality (HP_0000118) and its descendants, consisting of 11,721 phenotypes.

*Genetic and Rare Diseases Information Center*

The Genetic and Rare Diseases (GARD) Information Center is a program initiated by the National Center for Advancing Translational Sciences (NCATS) and funded by the National Institutes of Health (NIH). GARD extracts information from NIH resources, medical textbooks/databases, literature and the Internet to aggregate knowledge of rare or genetic diseases and group them into 32 categories. In the current version, GARD contains 4,560 diseases. We limited rare diseases extracted from clinical notes only to UMLS concepts that can be mapped to GARD.

**Methods**

Figure 1 shows the overview of our system workflow which includes two modules: i) a preprocessing module leveraging NLP and semantic processing techniques to identify patients with rare diseases and collect their phenotypes; and ii) a collaborative filtering model to recommend similar patients and possible disease recommendations.

*Preprocessing Module*

We first extracted problems and diagnoses from clinical notes using MetaMap. We kept UMLS concepts from the following semantic types: Disease or Syndrome (dsyn), Neoplastic Process (neop), Mental or Behavioral Dysfunction (mobd), Anatomical Abnormality (anab), Congenital Abnormality (cgab), Injury or Poisoning (inpo), Finding (fndg) and Sign or Symptom (sosy). To limit our analysis to only patients’ phenotypes and rare diseases, we conducted another refinement round on preprocessed UMLS terms to only keep phenotype-related concepts in HPO and rare diseases in GARD. For patients with rare diseases, we collected their phenotypic information within the last twelve months of the first mention of rare diseases.

*Patient based Collaborative Filtering Module*

In traditional user-based collaborative filtering, user preference data with various features describe different angles of user interests. Similarly, in the clinical domain, we considered patients as users and leverage large clinical cohorts to extract phenotypes as items for each patient. In contrast to rating-based recommender systems in which
preference score matters, we considered patient profile with phenotypes as binary inputs, that is, the relationship between patient and phenotype is either yes or no.

This module was designed on top of a user based collaborative filtering engine consisting of similarity measurements and neighborhood algorithms. Specifically, in this study, we applied Tanimoto coefficient similarity (TANI)\textsuperscript{18}, Overlap coefficient similarity (OL)\textsuperscript{19}, Fager & McGowan coefficient similarity (FMG)\textsuperscript{20}, and Log likelihood ratio similarity (LLRS)\textsuperscript{21} as four similarity measurements for binary data to calculate patients’ similarity based on phenotypes. Each measurement is feasible for different recommendation tasks, and as we did not have any \textit{a priori} reason to prefer one measurement over another, we tested all four methods.

Let $|\text{Phe}_i|$ and $|\text{Phe}_j|$ be the total number of phenotypes, and $|\text{Phe}_i \cap \text{Phe}_j|$ be the number of common phenotypes between any two patients $i$ and $j$. Tanimoto, Overlap and Fager & McGowan coefficient similarity are defined as shown in Equations 1, 2, and 3, respectively.

\[
\text{TANI}(i,j) = \frac{|\text{Phe}_i \cap \text{Phe}_j|}{|\text{Phe}_i| + |\text{Phe}_j| - |\text{Phe}_i \cap \text{Phe}_j|} \quad (Eq \ 1)
\]

\[
\text{OL}(i,j) = \frac{|\text{Phe}_i \cap \text{Phe}_j|}{\min (|\text{Phe}_i|, |\text{Phe}_j|)} \quad (Eq \ 2)
\]

\[
\text{FMG}(i,j) = \frac{|\text{Phe}_i \cap \text{Phe}_j|}{\sqrt{|\text{Phe}_i| + |\text{Phe}_j|}} - \frac{1}{2 \sqrt{|\text{Phe}_i| + |\text{Phe}_j|}} \quad (Eq \ 3)
\]

Log likelihood ratio similarity is built based on Shannon entropy\textsuperscript{22}. Given an event $X$ with its possible value $x_i$, Shannon entropy is defined in Equation 4.

\[
H(X) = - \sum_{i=1}^{|X|} P(X = x_i) \log P(X = x_i) \quad (Eq \ 4)
\]

In Shannon entropy, let $p_{ij}$, $p_\eta$, $p_\gamma$, $p_\Pi$ denote probabilities of common phenotypes shared by both patient $i$ and $j$, patient $j$ but not $i$, patient $i$ but not $j$, and neither patient $i$ nor $j$, respectively. The Log likelihood ratio (LLR) between any two patients $i$ and $j$ can be defined as shown in Equation 5.

\[
\text{LLR}(i,j) = 2 \times (H(p_{ij} + p_\eta + p_\gamma) + H(p_{ij} + p_\eta + p_\Pi) - H(p_{ij} + p_\eta + p_\gamma + p_\Pi)) \quad (Eq \ 5)
\]

As a result, Log likelihood ratio similarity (LLRS) between patient $i$ and $j$ is defined in Equation 6.

\[
\text{LLRS}(i,j) = 1 - \frac{1}{1 + \text{LLR}(i,j)} \quad (Eq \ 6)
\]
We also applied two commonly used neighborhood algorithms in collaborative filtering for given similarity metrics to recommend patients. One is K Nearest Neighbor (KNN), where the neighbors included are the k nearest neighbors. The other is Threshold Patient Neighbor (TPN), where a similarity threshold t is used to select neighbors.

Evaluation

This proposed system was implemented in Java with Eclipse Standard/SDK version Luna 4.4.0 running on 64 bit Linux CentOS 6.8 servers hosted by Mayo Clinic. We used the Apache Mahout framework to establish the environment for implementing the collaborative filtering framework. We evaluated eight different experimental groups formed as: 1) TANI with KNN; 2) LLRS with KNN; 3) OL with KNN; 4) FMG KNN; 5) TANI with TPN; 6) LLRS with TPN; 7) OL with TPN; 8) FMG with TPN.

To determine the best k and t, we first conducted a 10-fold cross validation for each experimental group. For each round, we randomly selected 90% data for training and the rest 10% for testing. To deal with binary preference value (i.e. either yes or no to a phenotype), for a specific patient, the Apache Mahout framework considered phenotype preference values as the summation of all his/her neighbors who also have the same phenotype. To determine the best k for KNN and t for TPN, we compared those estimated preference values with patients’ actual phenotype binary values (0 or 1). Specifically, for each predicted value \( p'_i \) and its corresponding actual value \( p_i \), we applied root-mean-square error (RMSE) on the total n results across all patients as shown in Equation 7.

\[
RMSE = \sqrt{\frac{\sum_{i=1}^{n}(p'_i - p_i)^2}{n}} \quad (Eq 7)
\]

We then computed second derivative for each RMSE function to select the optimal k and t at the biggest second derivative value. For function \( y=f(x) \), second derivative \( sd \) can be used to detect the concavity of a graph as shown in Equation 8.

\[
sd = \frac{d^2y}{dx^2} \quad (Eq 8)
\]

After the optimal k and t for each experiment was confirmed, the system returned a number of neighbors for each patient ranked in descending order by similarity scores.

To evaluate the performance of patient recommendation, we used information retrieval techniques to evaluate all ranked recommendations. We selected k recommended patients for KNN and all patients with similarity higher than t for TPN. We considered each patient as a query and their neighbors as a group of ranked recommendations. In addition, we used patients’ diseases as a gold standard to validate their similarity and considered a recommendation as an optimal one as long as the recommended patient affected similar rare disease(s). The confusion matrix in Table 1 generally depicts how to evaluate the system performance. According to Table 1, precision, recall and F measure can be computed as shown in Equations 9, 10 and 11. To analyze the performance and observe the trade-off between precision and recall, starting from top ranked patients, we divided them into ten portions and plotted precision-recall curves for each experiment. In addition, we calculated precision-recall area under curve (PRAUC) for each case. Moreover, we computed mean average precision (MAP) for recommendations of all patients. As shown in Equation 12, for each query \( q \), we computed average precision \( AveP \) over all relevant answers and calculated summation of \( AveP \) for all queries then divided by the number of total queries \(|Q|\) to compute the MAP.

To further evaluate performance for individual rare disease prediction, we assigned similarity scores of recommended patients to their corresponding rare diseases and accumulated all similarity scores for each disease. We considered the rare disease with the highest accumulated similarity score as the final diagnosis to evaluate performance for rare disease prediction. We used the optimal algorithm to conduct the evaluation. Precision, recall and F measure were computed for each rare disease as evaluation outputs.

Here we applied three level matching criteria to determine if two rare diseases are similar or not. The first one is string matching. That is, we compared two diseases directly by checking their exact names. Considering each physician might use different terms or concepts to make a diagnosis, the use of strict string matching would probably miss some semantically similar diseases. The Systematized Nomenclature of Medicine – Clinical Terms (SNOMED-CT) groups comprehensive medical terminologies with a semantic hierarchy in a standard manner. Therefore, as a second level matching, we mapped diseases to SNOMED-CT and considered two diseases to be
related if they contributed to a common ancestor node within 3 hierarchical generations\textsuperscript{31}. In addition, to have broader rare disease similarity checking in terms of categorization, we used the GARD dictionary and considered two diseases have a close relationship if they were listed in the same rare disease category. Therefore, for different matching criteria, definitions of relevant or not in confusion matrix are different.

\]

Results

After pre-processing, there are about 31,000 patients with at least one rare disease diagnosis. After removing rare diseases affecting only one patient, the final data set includes about 29,000 patients with 437 rare diseases (29 out of 32 GARD categories) and 2,400 phenotypes. In addition, 24,000 patients were diagnosed with only 1 rare disease and 5,000 patients were diagnosed with 2 rare diseases.

Figure 2 shows statistics of rare diseases in our clinical notes with GARD categories. Unique count indicates the number of unique rare diseases in each GARD category, and category coverage shows the percentile of rare diseases out of the total number of rare disease in each GARD category. The category with the biggest unique count is Rare Cancer consisting of 155 diseases, for instance, lentigo maligna melanoma and papillary thyroid carcinoma. In terms of category coverage, Autoimmune Autoinflammatory Diseases is the highest one with 45.45% (5 of 11), which includes autoimmune hepatitis, cretin syndrome, addison’s disease and so on.

Figure 2. Statistics of rare disease in clinical notes with GARD categories.
Root-Mean-Square Error for Optimal Threshold Selection

For different similarity measurements with KNN, Figure 3(a) plots the relationship between RMSE and the increasing number of neighbors from 2 to 30. Since KNN selected the closest \( k \) nodes incrementally, more neighbors will be included with \( k \) increased even though they do not locate within an absolutely close distance, which should increase the error. We found that with \( k \) increased, RMSE for LLRS had a fastest increase rate after optimal \( k \), indicating that LLRS is too sensitive to the change of \( k \). RMSE didn’t change obviously for OL and FMG, which shows that these two similarities with KNN are not capable of differentiating neighbors and non-neighbors. RMSE for TANI slightly increased RMSE after its optimal \( k \), suggesting that TANI+KNN is able to group neighbors in a moderate way.

Similarly, Figure 3(b) depicts the relationship between RMSE and patient similarity threshold varying from 0.01 to 0.99 for different similarity measurements with TPN. Generally, RMSE decreased as we increased patient similarity. The reason is that criteria for neighbor selection became higher when we increased the user similarity, which resulted in more precise neighbor detection and thus decreased the error. We found that RMSE for LLRS stayed stable until similarity threshold \( t \) became relatively higher, which indicates that LLRS is less sensitive to similarity threshold. We also found that curves for TANI, OL, and FMG had the similar trends but OL started with the highest RMSE and FMG started with the lowest RMSE. TANI had the moderate RMSE at the beginning and reached its optimal threshold \( t \) before OL and after FMG.

As a result, the best \( k \) and \( t \) for each combination are given in Table 2.

Performance for Patient Recommendation

Figure 4 shows precision-recall curves for 8 experiments and PRAUC for each matching criterion. We found that GARD matching yielded the best performance overall, and SNOMED-CT semantic matching always performed better than string matching. There is no significant difference between TANI+KNN and TANI+TPN for each of the three matching criteria. Specifically, TANI+TPN contributed to the best PRAUC for string matching while TANI+KNN led to the best PRAUC for SNOMED-CT and GARD matching. LLRS was suboptimal and LLRS+KNN outperformed LLRS+TPN with all three matching criteria. In contrast, PRAUC indicated that FMG+TPN performed better than FMG+KNN. OL contributed to relatively lower PRAUC than other three similarity measurements, OL+KNN performed slightly better for SNOMED-CT and GARD matching while OL+TPN was more suitable for string matching.

Table 3 shows mean average precision for patients with all their recommendations. MAP scores showed consistent performance with what PRAUC evaluated. But the only difference is that MAP scores indicated that TANI with
KNN performed slightly better for string matching while TANI with TPN was slightly better for SNOMED-CT and GARD matching.

**Performance for Rare Disease Prediction**

Here we chose TANI with KNN as the optimal algorithm and applied it on 24,000 patients with only one rare disease. Scatter plots in Figure 5 describe prediction performance for different matching criteria. There are 417 rare diseases in total. For these diseases, string, SNOMED-CT and GARD matching found 49.4%, 56.6%, and 92.1% correct predicted rare diseases, and weighted micro-average F measure for them are 0.4, 0.44, and 0.71 respectively.

Table 4 shows the top five diseases with the best F measures for each matching criterion. To protect patients’ privacy, any rare disease with affected cases less than 10 were marked as <10. We found for some diseases, the unique features affecting very few patients may contribute to a high prediction performance. For example, there were less than 10 patients with *ichthyosis bullosa of siemens*, but the prediction F measure with string matching is 0.8. All these patients have symptom *ichthyosis*, some of them have *ichthyosis* and *hyperkeratosis*, and some others have *ichthyosis* and *congenital bulous ichthysiform erythroderma*. These phenotypes grouped as unique combinations that can help diagnose *ichthyosis bullosa of siemens*. Meanwhile, with 1,380 affected patients, *abdominal aortic aneurysm* had a high F measure with string matching. However, not all rare diseases with a relatively large number of affected patients yielded the same performance. For instance, *meningioma* had 1,476 affected patients, but prediction F measures for it is only 0.44.

For string matching, some rare diseases didn’t get any correct predictions, such as *cadasil* (<10 patients) and *myotonic dystrophy* (25 patients), the reason is that those diseases not only had a small group of affected patients but also didn’t show unique groups of symptoms and signs. Due to the semantic hierarchical processing, SNOMED-CT matching had a slightly better performance than string matching. It was able to predict some diseases that string matching considered as non-relevant, such as *acquired von willebrand syndrome* (<10 patients) and *acute disseminated encephalomyelitis* (<10 patients). What is more, GARD gave predictions based on category and all top 5 predictions are 100% predicted. This indicates that phenotypes can help to infer similar type of rare diseases. Although such prediction cannot identify the exact rare diseases, similar rare diseases within the same category can still give clues for physicians to make diagnoses.
Discussion

Our study utilized similarity measurements that do not take individual preference scores, therefore, other methods provided by the Mahout collaborative filtering engine that either consider preference values or preference rankings were not suitable for our preprocessed clinical notes (e.g., Euclidean distance similarity, Pearson correlation similarity, Uncentered cosine similarity, and Spearman correlation similarity). TANI is similar to LLRS, with the only difference that the latter gives more weight to dissimilar patients if they have common phenotypes and assigns less weight to similar patients even they share exactly the same phenotypes. This weighting difference slightly depressed LLRS’s performance relative to TANI. Similar to LLRS, FMG gives weight to similarity, but not as much as LLRS. In addition, OL gives too much weight to patients’ similarities even with few shared phenotypes, which lacks the ability to stratify patients well. What is more, FMG is the only one that is sensitive to the selection of KNN or TPN, and significantly outperformed TPN. The reason is that setting threshold as 0.17 is more suitable than selecting 10 neighbors according to the neighborhood density formed by FMG in our clinical notes. Therefore, making a good balance between KNN and TPN has a potential ability to optimize the overall performance with idealized neighbors and similarity at the same time.

</table>
For overall performance across all recommendations, considering physicians have different descriptions of specific
diagnosis, string matching may overlook some associations, so we enriched disease matching with semantic
similarity. There exist some ontologies that describe diseases, such as Disease Ontology (DO)\textsuperscript{32} and Orphanet Rare Disease Ontology (ORDO)\textsuperscript{33}. However, for the detected rare diseases from clinical notes, only 56% and 52% are
covered by DO and ORDO, respectively. Therefore, we used SNOMED-CT, a more comprehensive ontology that
comprises 60% of our extracted rare diseases and maintains a more complicated hierarchical semantic relationship
for discovering disease associations. Nevertheless, due to the limited coverage, semantic disease checking didn’t
significantly improve the performance. To address this, some associations among rare diseases can be mined from
literature for evaluation.

For rare disease prediction with string matching, some phenotypes cannot uniquely characterize a certain type of
rare disease in our clinical notes. For example, hypopituitarism has 51 affected patients and prediction F measure is
0. Top frequent phenotypes for hypopituitarism are hypothyroidism, neoplasm, hypertension, apnea and
hyperlipidemia, which are very common symptoms shared with other rare diseases and are not useful to make
correct diagnose. Therefore, common comorbidities may create noises for decision making. In this preliminary
study, we only focused on patients with rare diseases and filtered out phenotypes that didn’t happen within 12
months of their rare disease diagnosis encounter time. To better characterize rare diseases and comorbidities, in the
future, we will pass all patients’ data to our system and target on giving recommendations for misdiagnosed and
undiagnosed cases. In addition, it would be interesting to investigate cross-institutional rare diseases to acquire
diagnosis experiences and intelligence from different hospitals and healthcare systems to build a more generic rare
disease diagnosis system.

Conclusion and Future Work

In this study, we have investigated patient based collaborative filtering with NLP and semantic techniques on large
patient cohort to assist rare disease diagnosis. We demonstrated its potential in facilitating rare disease prediction.

In the future, we plan to incorporate HPO phenotypic information content\textsuperscript{14}, topic modeling\textsuperscript{34}, word embedding\textsuperscript{35}
and deep learning temporal sequence analysis\textsuperscript{36} to give more degrees of similarity measurement for improving
prediction performance. In addition to phenotype based analysis, we plan to involve rare disease genotype from
PheWAS\textsuperscript{7} and literature to assist rare disease diagnose as well.

Utilizing Smartphone-Based Machine Learning in Medical Monitor Data Collection: Seven Segment Digit Recognition

Varun N. Shenoy¹, Oliver O. Aalami, M.D.²
¹Cupertino High School, Cupertino, California, ²Stanford University, Palo Alto, California

Abstract

Biometric measurements captured from medical devices, such as blood pressure gauges, glucose monitors, and weighing scales, are essential to tracking a patient's health. Trends in these measurements can accurately track diabetes, cardiovascular issues, and assist medication management for patients. Currently, patients record their results and date of measurement in a physical notebook. It may be weeks before a doctor sees a patient's records and can assess the health of the patient. With a predicted 6.8 billion smartphones in the world by 2022¹, health monitoring platforms, such as Apple's HealthKit², can be leveraged to provide the right care at the right time. This research presents a mobile application that enables users to capture medical monitor data and send it to their doctor swiftly. A key contribution of this paper is a robust engine that can recognize digits from medical monitors with an accuracy of 98.2%.

Introduction

The goal of this research is to develop and evaluate the accuracy of a smartphone based system to automatically recognize and record biometric monitor results to Apple's HealthKit (Apple Inc., Cupertino, Ca). As the internet becomes more embedded into medical monitors through Wi-Fi and Bluetooth technologies, people who cannot afford to upgrade to these expensive machines will fail to receive the benefits of rapid medical attention. Our solution relies on a common smartphone to do the data capture, processing and communication. We use computer vision based feature extraction alongside machine learning to decipher a reading of a medical monitor captured by a smartphone. The medical monitors generally use seven-segment displays (where each digit is made up of a combination of segments). The model proposed in this paper can accurately read the monitor 98.2% of the time.

Prior Work

Whilst seven-segment digit recognition technology has been created in the past, prior work has not accounted for conditions affected by variable lighting and positioning. One proposed solution was ssocr³, an acronym for Seven Segment Optical Character Recognition. Such an approach was unsuitable to actively adapt to dynamic orientations and lighting of a smartphone image. Tesseract⁴, Google's popular optical character recognition model, was also another choice. However, we learned that while Tesseract is strong at reading regular text on a page, it had a difficult time accurately reading seven segment displays. Prior work in the field of medical informatics focussed on the recognition of hand written characters⁵.

Implementation

We delineate implementation into three phases. The first part will cover the use model of the app, the second part will cover the front end implementation and user interface. Finally, we will discuss the backend digit recognition approach.

Application Use Model

The use model is described as follows. Consider the case of measuring a biomarker such as blood glucose. After the glucose monitor displays a reading, the patient opens the smartphone application and selects the “Glucose” option. Next, the patient scales a bounding rectangle to fit the digits on the display. These bounds are saved for the next time a measurement of glucose will be taken. After taking a picture, the image within the bounds is sent to a backend server using wireless communications via the internet. A trained machine learning Random Forest⁶ classifier with image processing based feature extraction divides the image into individual digits and classifies each of them. These
numbers are sent back to the user’s device. The user is presented with the server’s prediction for the digits in the image. The user can easily correct the predicted numbers by using a scroll picker for each of the digits. This data is then saved into Apple HealthKit and is readily available for the physician.

**Front-end Implementation and User Interface**

The front end implementation of the application is focused on an easy and intuitive use model. The target audience is mainly the elderly who lack the dexterity required to accurately use mobile keyboards. As such, it is imperative that the font sizes throughout the mobile application are large and bold to aid the user’s eyes in reading. We also implemented a voice assistant to guide the user through the steps and in reading the result. Ultimately, the goal was to make the final user flow (Figure 1) of the app succinct and user-friendly. Figure 1 shows the steps involved in measuring systolic blood pressure through our application.

![Figure 1. The User Interface Flow for the Mobile Application](image)

On the front end side of the application, the Swift 3.0.x programming language was used for developing the iOS app and interfacing with HealthKit in the Xcode 8.3.x integrated development environment. Alamofire, a networking framework, was used to simplify the process of sending the image from the phone to the server via Hyper Text Transfer Protocol (HTTP) in a multipart form. Since our model was not embedded into the device, and lives on a server, computational requirements for the client are minimal. Our application will work as long as the device can make HTTP calls and access the internet. Apple’s AVSpeechSynthesizer class was used in the app to provide an active voice assistant in the app. The voice tells the patient exactly how to take a picture and reads out the resulting digits when it is saved to HealthKit. All components of the app were optimized to work on any Apple iPhone running iOS 8 and above.

**Backend Digit Recognition Approach**

A basic block diagram (Figure 2) shows the backend methodology for the server side digit recognition algorithm. The model is first trained on a training set of images and then tested on a new set of images it has never seen before.

We chose to implement our algorithmic model in Python 2.7.x, since there exist a diverse set of libraries for machine learning and computer vision. We used the scikit-learn package to implement a Random Forest classifier and model persistence. OpenCV for Python was used for feature extraction and image normalization due to its versatility and high computation with a simple programming interface. The Matplotlib graphics library was used to create data visualizations for this research.
Figure 2. Image Processing and Machine Learning Methodology.

A shared aspect of the training and testing steps is the ability to separate an image into disparate digit components. This is called feature extraction. The input image is divided into individual digits so the classifier only has to work with ten possible classes (0-9). Image processing is used to reduce the complexity of input data and normalize the images for the machine learning model. OpenCV’s built-in Otsu’s thresholding algorithm is used to reduce the given image to just black and white pixels. Otsu’s method dynamically separates the foreground and background of the input image and maximizes the variance between the two. After thresholding, we segment the image into individual digits using a vertical projection algorithm. A graph for the average pixel color in each column of the image is created (Figure 3). Peaks on the graph where the average pixel value is white (255) should be disregarded and gives us a location for digit segmentation. Each column is scanned and a splice is created wherever the average color is close to white. All sections of pure white are deleted and each individual digit is separated to be classified in the machine learning model. All of the digits are scaled to 15x45 pixels to minimize variance between images with the same digit in them.

Figure 3. Feature Extraction Process on an Example Image.

A Random Forest is a machine learning classifier that is composed of an ensemble of decision tree estimators. Each decision tree is a tree-like model of decisions and their possible consequences, ultimately leading to a final conclusion (leaf node). While decision trees on their own are weak classifiers, Random Forests are fast, accurate, and not prone to overfitting. In this research, 100 trees were used in the forest for rapid training and testing. Trees in the forest are grown using bootstrap aggregating, or bagging. Each tree is constructed on a random subset of the input data, so they produce different models that can be averaged. This ensures that the model cannot be overfitted by the training data. When a new, unlabeled, piece of data is shown to the random forest, each tree assesses it individually. The forest makes a decision through majority voting by the trees. The Random Forest classifier machine learning model was chosen over others, since it is very fast and accurate. The fully trained Random Forest ensemble for this research only takes up 847 kB of space and takes under 3 seconds to train on a 2.9GHz processor for laptops. Calls to the server take 2-3 seconds to process and report data back to the client device.
Experimental Results

The past records of a patient’s heart pressure monitor and a weighing scale were used to cultivate training and testing data (Figure 4). We sampled the historical data stored within these devices to recover 108 images for the testing set. These images had 1-3 seven segment digits, which our algorithm had to segment and classify. The software was trained on a small additional subset of representative seven segment displays (25 images). Screenshots of digits typed using a seven-segment font were used as training data as well. Images in the training set were not used in the testing set.

![Example Images Used to Train and Test the Model.](image)

Furthermore, we observed a non-uniform distribution of digits in the collected samples (Figure 5). E.g. there were 85 images of “1”'s, significantly more than the rest. This was expected as systolic blood pressure values in healthy adults have a leading “1”. The same can be said for weight measurements as leading “1”’s and “2”’s are the most common.

![The Distribution of Digits throughout the Entire Dataset.](image)

The machine learning model successfully recognized all of the digits except in two cases, achieving an accuracy of 98.2%. We examined three dominant features using Principal Component Analysis (PCA) on the testing and training set. This helps us observe the strength of our algorithm by visualizing clustering patterns determined by the 3-component PCA (Figure 6). In these three-dimensional plots, digits of the same class are observed to be well clustered. However, certain digits are clumped closer together than others. For example, the digits “0” and “8” are clustered together. This means that visually, digits that are “8”’s and “0”’s are similar, and therefore, we require more data so the model can learn concrete differences between the two. Also, since we reduced every vector to three dimensions from 675, certain information that can be crucial to differentiating “8”’s and “0”’s may have been lost.

![Distribution of Digits in Dataset](image)
Figure 6. Different Orientations of PCA-Reduced Data in Three-Dimensions.
We analyzed the output of our model on our testing data and we found that it performed well across all 10 classes (Figure 7). Across the 262 individual digits in the testing set (post image segmentation), we achieved an overall accuracy of 98.2% and an F1-score of 0.978 with our Random Forest model. An F1-score is a metric for classification which is best at 1 and worst at 0. It is the harmonic mean of precision and recall.

![Confusion Matrix of Our Model on All 10 Classes.](image)

Figure 7. Confusion Matrix of Our Model on All 10 Classes.

Other machine learning approaches from the scikit-learn library were used as well to verify the strength of our proposed model (Table 1). Ultimately, the Random Forest model achieved the highest accuracy of 98.2% while the General Purpose Multi-layer Perceptron was only accurate 61.1% of the time. Furthermore, a single decision tree (a voting member of a random forest model trained on the entire training set) attained an accuracy of 64.8%. Random Forests did the best since it is very difficult to overfit on the testing data. Other models are more prone to overfitting on the training data and as such, fail to recognize testing data correctly.

Conclusion

In this research, we presented the design and implementation of a smartphone application that can capture medical data and communicate it to physicians. Using our tool, physicians can now catch early trends and diagnose critical issues before the onset of the medical vulnerability. We described a versatile seven segment digit recognition algorithm that can be used to rapidly read any digital display via computer vision and machine learning. Special attention was given to the user interface to serve the ill and elderly.

Since the submission of the paper for review, we have extended our backend infrastructure by uploading it to a cloud server (Amazon Web Services Lambda).

Further Work

There are many ways to further improve our algorithm. For one, sharp images guarantee better results. We would like to consider blur detection prior to analyzing our image. If the image is too blurry, we can send a message back to the user, requesting a clearer picture. There are many well known techniques to accurately measure blur within an image.

On a larger scale, it is necessary to gather more images for both training and testing. Creating a robust corpus of images will enable us to improve the accuracy of our method. We plan to test the software with real patients to validate the user interface in a medical environment.

We would also like to look into embedding our model into mobile devices directly without the need for a server. This will drastically increase speed for users and enable them to use the app in locations without access to the internet. State-of-the-art research is currently focussed on mobile embedded machine learning16.

Leveraging Clinical Time-Series Data for Prediction: A Cautionary Tale

Eli Sherman¹, Hitinder Gurm, MD², Ulysses Balis, MD³, Scott Owens, MD³, Jenna Wiens¹

Abstract In healthcare, patient risk stratification models are often learned using time-series data extracted from electronic health records. When extracting data for a clinical prediction task, several formulations exist, depending on how one chooses the time of prediction and the prediction horizon. In this paper, we show how the formulation can greatly impact both model performance and clinical utility. Leveraging a publicly available ICU dataset, we consider two clinical prediction tasks: in-hospital mortality, and hypokalemia. Through these case studies, we demonstrate the necessity of evaluating models using an outcome-independent reference point, since choosing the time of prediction relative to the event can result in unrealistic performance. Further, an outcome-independent scheme outperforms an outcome-dependent scheme on both tasks (In-Hospital Mortality AUROC .882 vs. .831; Serum Potassium: AUROC .829 vs. .740) when evaluated on test sets that mimic real-world use.

1 Introduction

The widespread adoption of electronic health records (EHR) for collecting and analyzing patient data presents a promising avenue for improving patient care¹. These retrospective data have been used in traditional statistical analyses to identify relationships between patient data and patient outcomes. For example, extensive work has been done to identify risk factors for sepsis², hospital readmission³, and heart failure-induced mortality⁴, among other conditions. In such analyses, the primary goal is to increase our understanding of the relationship between covariates and the outcome of interest. In contrast, the increasing accessibility of machine learning (ML) approaches has triggered a shift in focus to the development (and deployment) of predictive models, where the primary goal is good predictive performance⁵, ⁶.

This shift in focus necessitates a similar shift in methodology. For example, traditional analyses are often limited to a small number of variables, based on expert-driven clinical hypotheses or observations. Because the risk of over-fitting is low, researchers in this setting rarely consider a held-out test set. In a high-dimensional setting a held-out test set is imperative. More clinical researchers are recognizing this need and adapting their analysis appropriately, but this alone is not enough. The precise problem statement also requires an important, but often overlooked, reformulation. When the goal is prediction, the choice of method by which one chooses to extract one’s data is critical, for both training and testing purposes.

In particular, one must be careful to evaluate candidate models in a way that accurately estimates how they will perform when applied in clinical practice. This stands in contrast to previous analyses, in which the models may not have been intended for predictions. In a predictive setting, when a model will be applied, i.e., when a prediction will be made, is important. Two common methods for defining the time of prediction include: 1) indexing relative to a clinical event of interest e.g., onset of infection, and 2) indexing relative to an outcome-independent fiducial marker e.g., time of admission. The first approach is most common in a traditional retrospective analysis. In such settings, examples are typically derived by considering the event of interest and looking backwards to extract data collected prior to the event⁷,⁸. The second approach must be used a predictive analysis setting. Here, examples are derived based on a fiducial marker that precedes the clinical event of interest but is temporally independent of that event e.g., a particular operation/procedure.

In this paper, through two case studies, we illustrate some of the subtleties that surround prediction tasks and demonstrate how using an evaluation method that does not reflect clinical practice can result in misleading results. Leveraging a large publicly available dataset of ICU admissions, we apply several indexing techniques to two prediction tasks. In one prediction task, we aim to predict in-hospital mortality. In the other prediction task, we aim to predict hypokalemia, low serum potassium. We consider these two tasks since they are both important from a clinical perspective, but also because they present a contrast in terms of the number of events per admission. I.e., for the first task we may observe several test results, but in the second task there is only a single endpoint - in-hospital mortality. Through these
experiments we illustrate the importance of carefully defining one’s problem setup and demonstrate how evaluation performance can vary across settings.

In the following sections, we will: 1) discuss previous work in the development of predictive tools including examples of several indexing techniques, 2) formalize different indexing techniques/problem setups and outline how we will apply them to our case studies, 3) present results on the two real-world prediction tasks, and finally 4) reflect on the implications our experiments have on choosing an indexing method for extracting training and evaluation sets for a prediction model.

2 Related Work

Traditional low-dimensional statistical analyses are common in the clinical literature. Such studies typically focus on modeling relationships between covariates and outcomes\(^7\)–\(^\text{11}\). While the focus of these statistical analyses is often on testing hypotheses about relationships among variables, such approaches have been applied to prediction tasks. The popular mortality prediction scoring systems APACHE III\(^\text{12}\) and SAPS II\(^\text{13}\) serve as illustrative examples of this approach. In both models, a relatively small number of candidate covariates are hand-selected by experts and a mapping between covariates and outcomes is learned using standard statistical methods (e.g., logistic regression). This approach is limited in that data are collected at a specific point in the admission (24 hours after the time of admission, and at the time of ICU transfer for APACHE and SAPS respectively) and thus the models are only designed to make a single prediction.

In recent years, the focus has shifted to developing prediction models with high-dimensional feature spaces using machine learning techniques. These models are applied throughout the admission, providing updated predictions. As such, the question of how to index and extract time-series data from the EHR is now critically important. Numerous examples of indexing from the time of admission (or a related fiducial point) exist in both the healthcare and machine learning literature, including applications to patient status estimation\(^\text{14}\), diagnosis\(^\text{15}\), and sepsis\(^\text{16}\).

Despite the number of examples in which data are indexed based on an outcome-independent fiducial marker, the approach of indexing based on the event of interest still creeps into analyses today (perhaps since it was so common in a traditional, non-prediction centric, setting). Oftentimes, identifying the use of the event-based method is subtle and it is necessary to carefully consider the features included in the proposed model to confirm its use. For example, in work on learning a model for Clostridium difficile infection (CDI) risk prediction, it is not explicitly stated how examples are extracted\(^\text{17}\). However, in previous CDI work event-based indexing is clearly used\(^\text{18}\). Another paper developed a risk stratification tool for predicting sepsis risk in ICU patients in which the model used length of stay as a feature\(^\text{19}\). These types of features serve as a clear indication of backward-looking example selection. In another example, a paper proposing a heart failure prediction system generated covariates by looking backwards, testing different prediction intervals, from the diagnosis\(^\text{20}\). Collectively, these examples present an issue of data leakage, allowing extra information into the training process through problematic indexing schemes.

Others have published work on the potential pitfalls of working with EHR data\(^\text{6}\), and developed tutorial-style overviews of the process of developing and validating a clinical prediction tool\(^\text{21}\). These papers provide a fairly comprehensive discussion of how to undertake careful data analysis to create useful prediction tools. In contrast to previous work, we focus entirely on how training and test data are indexed when developing clinical prediction models.

3 Methods

In this section, we present and contrast common approaches for extracting and indexing EHR data. We begin by describing the general framework for data extraction, highlighting key choices one must make when extracting data. Then, we present the two case studies in which we aim to predict laboratory test results (specifically hypokalemia, i.e., low serum potassium) and in-hospital mortality.

3.1 Problem Setup and Notation

We limit our discussion to clinical prediction tasks during a hospital admission. For an admission, we have a set of \(d\) irregularly sampled, timestamped features. Additionally, we have a set of irregularly sampled, timestamped outcomes
\((y_j, t_j)_{j=1}^k\) where \(y_j\) is recorded at time point \(t_j\). Here, we restrict \(y \in \{0, 1\}\). Note that it may be possible for an outcome to occur multiple times, only a single time (e.g., death) or never at all within a given admission (i.e., \(k = 0\)). In the following sections, we will describe procedures for mapping these features and outcomes for an admission \(i\) into feature vector-outcome pairs of the form \((x, y)\) where feature vector \(x \in \mathbb{R}^d\) represents the covariates used to predict the outcome variable \(y\). Since our focus is prediction, \(x\) represents data recorded prior to observing outcome \(y\).

### 3.2 Indexing Longitudinal Data for Prediction

Considering the raw data for each admission as a collection of clinical data, we now outline careful considerations for extracting \((x, y)\) pairs. Figure 1 serves as a guide for the following descriptions.

- **Time of Prediction** The time of prediction, \(t_p\), is the time point corresponding to when a predictive model is applied to the data. The time of prediction affects covariate extraction and outcome/label extraction (more on this below), and is determined relative to some reference point \(t_0\). Given a model that predicts a particular outcome, one may choose to apply it at a single time point (as in the first time series in Figure 1), resulting in a single prediction per admission. If such a setup is desired then one test example should be extracted for each admission based on an outcome-independent fiducial marker (e.g., time of admission). Alternatively, one may choose to apply the model multiple times throughout the admission, updating predictions as new data become available (as in the second and third time series’ in Figure 1). To mimic this setup, examples can be extracted on a rolling basis, again starting from an outcome-independent reference point \(t_0\). More formally, starting from \(t_0\), one may extract either a single example \(x_p\) representing the admission from the time of admission to the time of prediction \(t_p\), or multiple examples \((x_1, t_1), (x_2, t_2), \ldots, (x_m, t_m)\) (at perhaps regularly spaced intervals). In the latter, each feature vector is updated based on data available at the time of prediction. The corresponding outcome variable \(y_p\) depends on the prediction horizon and the availability of ground truth, discussed next.

- **Prediction Horizon** The prediction horizon \(h\) (or window) is defined as the period for which a prediction applies and aids in defining \(y_p\). It begins at the time of prediction \(t_p\). In some settings, the prediction horizon is fixed and remains constant across examples, (e.g., when predicting 30-day mortality, or the value of a laboratory test in the next 12 hours; see the third time series in Figure 1). In many cases, the event of interest occurs at most once during the prediction horizon (e.g., 24-hr mortality), but is observed continuously (i.e., at every time point we know whether or not the patient is alive). In such settings ground truth is readily available and the corresponding \(y_p\) can simply be set to the observed value. In other settings, however, ground truth is only available at specific time points (e.g., when a laboratory test was ordered and returned). Here, it may be necessary to impute the corresponding outcome value or label. In the case study described below, we use a “copy-and-hold” approach: if there is no ground truth at the target time, we use the most recently observed \(y\) value that precedes the target time. Another way around this issue is to simply adjust the prediction horizon to be near zero and the prediction time to be driven the laboratory test order. In many settings, the time of the laboratory test order is still an outcome independent reference point, but depending on the task this may have limited clinical utility. Finally, in some settings, the prediction horizon may vary across admissions. E.g., many researchers aim to predict in-hospital mortality. Here, the prediction horizon varies with the length of stay, but \(y_p\) can be extracted similarly as if it were fixed.

Once the time of prediction and prediction horizon are defined, one can extract a feature vector \(x_p\) based on data available at the time of prediction, and \(y_p\) based on observations made during the prediction horizon. This results in either a single \((x, y)\) pair per admission in the test set, or \(m_i\) pairs for each admission \(i\).

To ensure evaluation accurately reflects how a model will perform in a practice, test data must be extracted in a way that mimics the clinical use case. In particular, when extracting test data it is necessary to use an outcome-independent reference point since outcomes are not available at test time. However, when training, we may want to make use of this additional information. In particular, one may choose to define the time of prediction based on the time of the event (e.g., work backwards from time of death) when extracting examples. When making multiple predictions for each admission, one extracts test examples regularly throughout each admission. But, applied to the training set, this procedure could introduce bias, since patients with longer stays will appear more often. To mitigate this issue, one
3.3 Dataset & Prediction Tasks

To measure the effects of the different data extraction approaches on the predictive performance of a model, we considered two prediction tasks applied to the same ICU dataset. In particular, we leverage the MIMIC-III Database\textsuperscript{22}. This dataset consists of 58,976 ICU admissions collected at a Beth Israel-Deaconess Medical Center in Boston, MA over the course of 12 years. The median length of stay is 6.9 days. We consider variables related to patient demographics, medications, laboratory tests, vital signs, and fluid inputs and outputs that are present in at least 5% of admissions. We encode each patient’s demographics as binary features. For the other variables, we generate summary statistics (e.g., min. value, max. value, mean value based on the several hours preceding prediction time) to encode the features for a given example. Using these data, we consider two clinical prediction tasks:

Predicting In-hospital Mortality In-hospital mortality prediction is a well studied problem in the healthcare-related literature. It is frequently used to benchmark new methods. For this task, we include all adult hospital admissions, resulting in 49,909 admissions. Here, we aim to predict whether or not the patient will expire over the course of the remainder of the admission (i.e., a variable prediction horizon).

Predicting Hypokalemia Accurate predictions of whether or not a particular laboratory test will return a hypokalemic result could help clinicians make better informed decisions regarding whether or not to order that test. This could in turn lead to a reduction in the number of unnecessary laboratory test orders. Here, we aim to predict hypokalemia. We focus on serum potassium (as opposed to other laboratory tests), since it is one of the most high volume tests in U.S. healthcare\textsuperscript{23,24}. From the MIMIC database, we include all adult patients with at least one serum potassium test. This results in a final study population of 49,354 admissions.

Using these data, we aim to predict whether or not the serum potassium laboratory test will return a hypokalemic
result, defined as serum potassium < 3.5, within the next 12 hours (i.e., our prediction horizon is 12 hrs.). This threshold was derived from a standard reference range. The prediction horizon was chosen based on the fact that many laboratory tests are ordered on a standard 24-hour schedule and discretionary testing occurs outside of this cycle. A 12-hour prediction window provides information that would ordinarily correspond to a discretionary test and therefore has the potential for eliminating the need for an extra discretionary test. Later, we consider another setup in which we generate a prediction of the current hypokalemia risk every time a potassium test is ordered. We describe this setup in more detail in Section 4.3.

3.4 Experimental Setup

Across all experiments, we build our training and test sets by repeatedly (100 times) randomly assigning 25% of admissions to the test set, and the remaining 75% to the training set. We are careful to not allow any admission to be represented in both the training set and test set since this would allow our learning algorithm to “memorize” the admission in question and subsequently perform better on the examples it had already seen. We use 5-fold cross validation on the training set to select hyper-parameters and retrain on the entire training set using the optimized parameters.

We extract examples according to the particulars of each experiment. Each example is a feature vector with 1, 222 features that encode summary information about the patient’s status over the 12 hours preceding prediction time. For instance, the patient’s glucose measurements over the 12 hours preceding the prediction time are encoded into variables describing the minimum, mean, and maximum values over the 12 hours. This summarization step allows us to account for the fact that different patients might have a different number of tests over the course of those 12 hours. We pick 12 hours so as to focus on the most recent clinical data while capturing temporal trends.

Using the training data, we train a classification model. Since the focus is on the problem setup, rather than the overall classification performance, we use a simple linear approach, specifically the liblinear implementation of Linear SVMs. For each experiment, we report mean and standard deviation statistics for area under the receiver operating curve (AUROC) scores across all 100 train-test splits. For models in which we make multiple predictions, each with a variable horizon as in the in-hospital mortality prediction task, we include each patient only once in the AUROC calculation. For each patient, we have a series of predictions, each in the form of a real valued number, the output of our classifier’s decision function. We sweep the decision threshold and if any of a patient’s predictions exceed that threshold we classify that patient as positive, and negative otherwise. This procedure is necessary since we are making predictions with a variable prediction horizon.

4 Experiments & Results

In this section, we describe and present results for several experiments using various problem setups. We analyze how different reference points and different numbers of predictions per admission impact model performance.

4.1 Event-dependent Training and Testing Yields Misleadingly Good Performance

We first illustrate the importance of selecting an appropriate outcome-independent reference point when extracting test data. For each task, we consider two different reference points: 1) time of admission and 2) the event of interest.

We first consider a single prediction setup for each task. For the in-hospital task, we use two different reference points to extract data. We 1) use the time of admission as our reference point, making a prediction 12 hours after admission, and 2) use the time of death (or time of discharge in the case of negative examples) as our reference point, making a prediction 24 hours prior to the end of the admission. When extracting examples for the laboratory testing task we 1) use time of admission as our reference, making predictions every 12 hours and 2) use the time of each potassium test as our reference, with a time of prediction 12 hours prior to each serum potassium test.

For these and all experiments in this paper, when we use the time of admission as our reference point, our first prediction is made 12 hours after the time of admission.

In order to isolate the impact that using an admission-based reference point has on this problem (rather than the number...
of predictions), we also consider a multiple prediction formulation. We create multiple-prediction training sets for the in-hospital mortality task using both event-independent and event-dependent indexing. For the event-independent training set we make predictions regularly – every 24 hours – throughout the admission. For the event-dependent training set, we make predictions in 24 hour increments, looking backwards from the end of the admission all the way to the beginning of the admission. The AUROC is calculated as described previously, where each patient contributes equally.

</tr>
</tbody>
</table>

Table 2: Number of examples extracted and the number of positive examples for each multiple prediction mortality set.

The resulting number of examples for each task and reference point are given in Tables 1 (single prediction tasks) and 2 (multiple prediction tasks). Admission-based reference points typically result in more examples compared to event-based reference points. The effects of these differences are explored later in this section.

The results for these experiments are presented in Figure 2. The three sections of this figure give results for the single mortality (a), potassium (b), and multiple mortality (c) tasks respectively. The red bars correspond to admission-based training sets applied to admission-based test sets; the blue bars correspond to event-based training sets applied to event-based test sets; and the green bars correspond to event-based training sets applied to admission-based test sets.
The first thing to note is the extremely good performance apparent in (a) and (b) when both training and test data are extracted in an outcome-dependent manner (AUROC .963 and .897 for in-hospital mortality and serum potassium respectively). However, when such a model is applied to outcome-independent test data (green), performance is significantly worse. Using time of event as a reference point for evaluation is not reflective of a realistic clinical use case. This conclusion is critically important and motivates our use of outcome-independent evaluation sets for the experiments that follow.

For the multiple prediction model (c), the event-dependent model performs relatively poorly when applied to both the event-dependent test set and to the event-independent training set. We suspect that this model does not perform as well as the single prediction model (applied to the event-dependent test sets) because the single prediction model is tested on only the easiest cases, those immediately preceding the end of the admission. The multiple prediction model, on the other hand, has a wider variety of examples (for both training and testing). While the point-wise performance of this model on the event-dependent test set is lower than the performance on the event-independent test, this difference is not statistically significant.

These results demonstrate the importance of admission-based indexing. When testing, admission-based indexing more accurately reflects the desired clinical use case. Moreover, in this more realistic test setting, a model trained using admission-based indexing outperforms a model developed using event-based indexing.

4.2 Training Data Must Be Chosen Carefully to Avoid Biased Models

When we used time of admission as the reference point for in-hospital mortality prediction above, we made daily predictions of in-hospital mortality. This approach is potentially problematic since there are patients who are represented in the training set several times more than average due to longer hospital stays. Here, we consider how sub-sampling the training data can affect performance.

We explore this issue by comparing the performance of the multiple predictions admission-based training set to a sub-sampled training set derived from the admission-based set. We randomly sample 6 times (with replacement) from each patient’s full set of training examples. This number was chosen because it corresponds to the median number of days in an admission and we are building a daily prediction model. We round down from 6.9 because our first prediction is not generated until after 12 hours have passed in the admission, as described above. This ensures that each patient is equally represented in the training set.

<tr>
<td>All Samples</td>
<td>.882 (.005)</td>
</tr>
</tbody>
</table>

Table 3: AUROC scores for the admission-based sub-sampling experiment. All Samples corresponds to a multiple prediction admission-based model. Median sample is a sub-sampling (based on the median number of days in an admission) of All Samples. Both are evaluated on a test set that uses time of admission as the reference point.

The results for this experiment are presented in Table 3. From these results we can see that sub-sampling helps performance, improving AUROC from .882 using the original training set, to .900 using the re-sampled set. Sub-sampling reduces the impact of outliers (i.e., patients with extended hospital admissions) on the model, and thus, we are able to learn a more generally applicable model.

4.3 The Use Case Can Significantly Affect Performance

As discussed above, evaluation should mimic the intended clinical use case. Different clinical use cases can result in different models and performance can vary greatly. To highlight this point we consider two additional experiments described below.

Many of the most widely used ICU risk scoring systems, including APACHE and SAPS, are defined based on a single time of prediction. While useful for making care decisions in the early stages of the admission, it is not clear how these scores generalize to multiple predictions (updated based on newly available data). To explore this issue, we
compare a model for predicting in-hospital mortality that makes only a single prediction at 12 hours to one that makes a prediction every 12 hours. While the model that makes multiple predictions has the advantage of additional data, it also has more opportunity to get the prediction incorrect. To compare these two approaches, we test both models identically in a multiple prediction setting (variable prediction horizon).

<tr>
<td>Multiple Prediction</td>
<td>Rolling</td>
<td>.882 (.005)</td>
</tr>
</tbody>
</table>

Table 4: Single and multiple mortality prediction AUROC scores. Single prediction is trained using data available 12 hours into the admission. Multiple Prediction is the previously described multiple prediction admission-based mortality model. Both models are tested on an admission-based test set with predictions made on a rolling basis throughout the admission.

We observe that a training set that makes predictions throughout the admission outperforms a training set that only makes a single prediction at the beginning of the admission (Table 4). A model trained on a single prediction made near the time of admission cannot necessarily be applied to the remainder of the admission. The model benefits from additional examples collected throughout the admission.

For the problem of serum potassium testing, we considered a use case in which one aims to predict future laboratory values every 12 hours. One could imagine a different use case in which one aims to predict the “current” laboratory test value. In this setting, a prediction is made every time a serum potassium test is ordered and the prediction horizon is immediate or essentially zero. To measure performance in this setting, we extract the training and test sets identically: we use each observed serum potassium result in a patient’s admission as the time of prediction and make a prediction using the covariates available prior to this order. The observed result serves as ground truth. In total we extract 649,949 examples, 69,723 of which are positive.

This extraction scheme is not the same as using an outcome-dependent reference point since the clinical use case is one of “on-demand” estimation rather than advance prediction. Note that this model is not directly comparable to an outcome-independent approach. Nevertheless, we can still draw some conclusions about the performance of such an on-demand model (Table 5).

<table>
<thead>
<tr>

<tr>
<td>On-Demand</td>
<td>.738 (.003)</td>
</tr>
<tr>
<td>Time of Admission</td>
<td>.829 (.002)</td>
</tr>
</tbody>
</table>

Table 5: AUROC scores for the on-demand and time of admission reference point models on the serum potassium task. Note that these problems are very different and their performance isn’t necessarily directly comparable. From the results, we note that the on-demand task is more difficult, despite the shorter prediction horizon. This is somewhat expected since we only make predictions when a laboratory test is ordered, versus every 12 hours. The fact that a test was ordered suggests the clinician suspects the value to differ from that of previous values. Again, while the tasks are similar (“predict potassium values”) the resulting performance is not comparable since test data are extracted in different ways.

While, the on-demand setting does not require imputation (since ground truth is always available), it could fail to mimic a real clinical use case. Once made available, clinicians may query the model more often (e.g., every 12 hours). This would shift the underlying distributions, resulting in a difference in performance.

5 Summary & Conclusion

In this work, we described methods for extracting examples from longitudinal clinical data for prediction tasks. These methods vary in terms of when predictions are made (e.g., in reference to what, and how often), and for how long each prediction applies (e.g., for the remainder of the admission or for the next 24 hours). These decisions should be largely dictated by the clinical use case. We illustrate how these decisions affect extracted data and in turn model performance using two different prediction tasks: hypokalemia prediction and in-hospital mortality prediction.
In both cases, we showed that using an outcome-dependent point of reference yields misleadingly good performance. Creating a test set from such a point of reference amounts to picking the easier examples and does not accurately reflect how the model would perform in practice. For example, a patient about to be discharged from the hospital will almost certainly be characterized by a healthier set of covariates just prior to discharge than a patient who is about to expire. For evaluation purposes, it is imperative that test examples be extracted independently from the label/outcome. Still, while predictions generated by models trained on outcome-dependent examples are biased, they can help uncover relationships between covariates and outcomes and shed light on our understanding of disease processes.

This work serves as a cautionary tale of the importance of carefully extracting examples from clinical data for the purposes of building a predictive model or clinical decision support tool. When training and testing prediction models using retrospective data, careful attention to the problem setup such that it accurately reflects the intended real-world use is critical. Neglecting to do so could result in a dangerous misinterpretation of the model’s clinical value.

Abstract

Academic medical centers commonly approach secondary use of electronic health record (EHR) data by implementing centralized clinical data warehouses (CDWs). However, CDWs require extensive resources to model data dimensions and harmonize clinical terminology, which can hinder effective support of the specific and varied data needs of investigators. We hypothesized that an approach that aggregates raw data from source systems, ignores initial modeling typical of CDWs, and transforms raw data for specific research purposes would meet investigator needs. The approach has successfully enabled multiple tools that provide utility to the institutional research enterprise. To our knowledge, this is the first complete description of a methodology for electronic patient data acquisition and provisioning that ignores data harmonization at the time of initial storage in favor of downstream transformation to address specific research questions and applications.

Introduction

Secondary use of electronic health record (EHR) data to support biomedical research is challenging. A common approach to secondary use of EHR data is a centralized clinical data warehouse (CDW)¹-⁵ involving dimensional modeling and terminological harmonization of source system data as a precondition for storage and use. To provide CDWs, institutions require extensive resources and may experience slow delivery of solutions for investigators due to maintenance of centralized data curation methods⁶. Additionally, the centralized modeling of data may limit the ability to meet researchers’ specific needs¹,⁶. Optimal approaches to secondary use of EHR data for meeting investigator needs are unknown.

Lacking a centralized clinical data warehouse, our institution needed to meet investigator needs for secondary use of EHR data. We hypothesized that an approach that aggregates raw data from source systems, ignores initial modeling typical of clinical data warehouses, and transforms raw data for specific research purposes would meet investigator needs. To our knowledge, literature describing such an approach to secondary use of EHR data is limited. The objective of this case report is to describe our approach to inform efforts at other institutions.

Methods

Setting

Weill Cornell Medicine (WCM), located on the Upper East Side of Manhattan in New York City, is the clinical research facility and medical college of Cornell University. WCM supports an academic staff of 1,049 physicians and educators and trains over 950 resident physicians and 450 medical students yearly. Faculty clinicians see patients through the Weill Cornell Physician Organization, a multispecialty group practice with more than 900 physicians and more than 20 sites across New York City. WCM faculty physicians have admitting privileges to NewYork-Presbyterian Hospital (NYP), a 2,478-bed hospital with multiple facilities. As long-time clinical affiliates yet separate legal entities, WCM and NYPH frequently collaborate in regards to clinical and translational research. In order to strengthen this collaboration, WCM and NYPH established the Joint Clinical Trials Office (JCTO) in 2013 to grow research activities between the two institutions. The JCTO regularly collaborates with the Clinical and Translational...
Science Center (CTSC) and the information technology (IT) departments at WCM and NYPH for research integrity and resource access purposes.

WCM and NYPH make use of multiple EHR systems from different vendors. In the outpatient setting, WCM Physician Organization Information Services (POIS) provides Epic Ambulatory. In the inpatient and emergency setting, NYPH uses Allscripts Sunrise Clinical Manager (SCM). Additional ancillary EHR systems cover various specialty areas, including perioperative documentation and imaging. Across WCM and NYPH, patients have a shared medical record number (MRN). Multiple interfaces between WCM and NYPH enable sharing of data.

The Information Technology and Services (ITS) department at WCM provides IT infrastructure, management, and service for the WCM community. Included within ITS is the Research Informatics division (RI), which, with financial support from the JCTO and CTSC, administers the Architecture for Research Computing in Healthcare (ARCH) program, a suite of tools and services for investigators to obtain electronic patient data.

System Description

To support the research enterprise with patient electronic data, RI has implemented a methodology and technical infrastructure termed Secondary Use of Patient Electronic Records (SUPER). SUPER undergirds all of RI’s efforts to provide investigators with patient data processes, and comprises multiple components, from data acquisition and manipulation, to feeding other clinical and research tools, to the underlying technical infrastructure. Figure 1 illustrates the workflow that powers SUPER activities.

![Figure 1. Model of flow from source systems to SUPER infrastructure](image)

Data sources

SUPER stores data from multiple clinical and research information systems, comprising the entirety of data gathered to support clinical, billing, and research activities across WCM and NYP. Data enter SUPER and are maintained in the same format in which they exist in their source systems.

For outpatient clinical and billing data, SUPER receives copies of Epic Clarity database tables which is a relational subset of the original transactional data from the EpicCare EHR. These relational data enter the SUPER infrastructure directly without any additional transformation. From the inpatient EHR, SUPER obtains a regular data feed from
NYP’s Clinical Data Warehouse (CDW), which similarly aggregates inpatient billing data in the form of HL7 messages from NYP’s Eagle patient accounting system, and the Jupiter analytics database. Jupiter contains tables copied directly from the Allscripts SCM inpatient EHR, as well as data from ancillary systems, including CompuRecord, the inpatient perioperative EHR for anesthesiology administration, OR Manager provides operative data, and Provation provides documentation from endoscopic procedures. SUPER imports all data from NYP’s CDW and Jupiter database without any form of transformation or harmonization; tables are replicated exactly as they exist in the source systems.

For biospecimen data, SUPER obtains data from Profiler, a locally developed system used by one of the larger tissue banks, and RURO FreezerPro, a commercial specimen management system used to track inventory for other research programs. For tumor registry data, SUPER receives registry data from a third-party vendor responsible for abstracting charts according to North American Association of Central Cancer Registries (NAACCR) standards. WCM’s clinical trials management system feeds directly to SUPER, providing records of patient enrollment in research protocols. For next generation sequence (NGS) data, SUPER receives data from the Standard Molecular genomic information system (GIS) for molecular tests, including the EXaCT whole exome test performed at WCM, and from Genoptix, a third-party laboratory. For case report form data, SUPER obtains data from WCM’s instance of REDCap.

Data acquisition process
As described above, the SUPER infrastructure and methodology depends on multiple partner organizations and teams, all of whom maintain their own clinical and research data systems. Obtaining data from these sources systems requires careful coordination with the teams responsible for their maintenance and care – the data systems feeding SUPER also send data to other systems and, in some cases, support user-facing activities. Given the significant demands imposed by regular data transfers, flexibility is crucial in order to avoid interference with clinical operations and other activities. To facilitate a flexible and modular approach, a series of extract, transform, load (ETL) database operations, application program interface (API) calls, and flat file imports provide data to SUPER. While SUPER pulls data from most source systems, some external systems push data to SUPER. Most source-to-SUPER data transmissions occur monthly while some occur weekly and daily to support specific projects.

The primary intake of data from the outpatient EHR occurs monthly over a one-week period, with each night of the seven-day period handling one section of a large ETL. Generally, each night’s job covers some of the significantly larger tables, along with related smaller lookup and metadata tables. The modular nature of this process allows for one night’s worth of data to be available immediately for use: in the event that a subsequent transfer fails, not all data is useless. Due to the size of the data set and underlying infrastructure limitations, the refresh is limited to 5 to 7 nights a week per source system. To ensure each night’s job proceeds as quickly as possible and ensure the capture of any retroactively imposed changes, WCM POIS will wipe any relevant data from the servers before initiating the transfer of the data set. A delta load approach, while appealing, would render the process overly time-consuming.

For data intake from the inpatient EHR via NYP’s CDW and Jupiter, the acquisition process differs. To allow for fine-grained control, we automate the process through the combination of Microsoft SQL Server Integration Services (SSIS) and SQL Server Agent. Using the proper driver – i.e., a DB2 driver to power the transfer from a DB2 server – we configure an encrypted SSIS package to make a connection to the relevant source tables, run a SQL query pulling out that data, and transfer the data to the SUPER landing server. The SSIS package is configured to ensure the preservation of the source schema. Overall these ETLs span a seven-day period, with each day encompassing several table transfers.

Other sources require different processes. To obtain NGS data from Genoptix, we rely on a cron job run from a virtual machine to pull data from a CSV file located on an FTP server into the SUPER infrastructure. To integrate data from FreezerPro, a Python script polls FreezerPro’s API and pulls data into SUPER. Intake of data from NAACCR’s tumor registry requires a SAS dictionary invoked from the command line, in conjunction with a Python script to transform the data and load it into SUPER. SUPER obtains data from small-scale systems, including the clinical trials management system and REDCap, more frequently, as the load is significantly smaller than other incoming data sources.

ETL code management
All ETL scripts are crucial to SUPER workflows. To ensure their security, currency, and homogeneity, SUPER relies on Subversion (SVN), a version control system that allows developers to save and compare their ETL scripts across
multiple domains and develop the versions of the process over time. With SVN, one change to an ETL script will propagate across multiple systems at once, ensuring that all iterations of a data model are identical.

To ensure that no individual ETL usurps all available resources, thereby affecting other jobs, the RI schedule places refreshes of the larger data sources at the last and first week of the month, and the smaller sources over a weekend. Individual data mart requests and ad hoc reporting take place during the two to three weeks in between each larger refresh, with bigger jobs occurring over a weekend. To avoid interference with day-to-day operations, weeknights and weekends are dedicated for resource-intensive ETL jobs.

ETLs are inherently ambiguous: while they inform the what and where for the transfer of data, they do not inform the how. Paver, a task manager developed in Python, manages priority levels and the order of task execution. With the use of SVN and a collaborative development process, ETL scripts are automatable and reusable. Paver renders them modular, affording the ability to configure the order of a set of scripts and have them run piecewise, thereby automating those reusable scripts in different contexts.

Indexing

SUPER stores several terabytes of source data, with some tables holding billions of rows of data. Without an indexing process, it is impossible to expect any ETL, or even query, to finish within a practical timeframe. However, indexing is time-consuming and must take place after every refresh cycle. To optimize the indexing process and ensure it takes place as quickly as possible, a cron job powered by Paver syncs index generation code with the latest revision and runs the index refresh script every six hours unless an ETL is currently running, signaled by a system flag created as part of the ETL script. The indexing script uses dynamic SQL to drop and recreate stored procedures. These stored procedures reduce active indexing time through the use of a procedural log, rather than a transactional log, and through previewing and optimization of the index processing time. Indexing scripts first check for presence of the index, with its presence signaling the job to move on to the next index. Since indexes are recreated with every refresh, there is no possibility of long term index usage and bug appearances - therefore, the method of ignoring an already created index should be sufficient.

Terminology management

SUPER does not conduct terminology management or data harmonization on sources accessioned to the landing server, instead relying on efforts already put in place by POIS and NYP IS to harmonize data. While not detailed here, a great deal of effort goes into standardizing data as it enters the EHR using an internally developed terminology server, TruData©, that normalizes data against reference and interface terminologies.

RI pulls data from a variety of sources, each of which is organized according to its own internal schema. Some data sources have already been subject to a data harmonization process, leveraging proprietary data models or other schemas and consistently using reference terminologies. Examples include Epic Clarity, which transforms Epic Chronicles data, and the NYP CDW, which has rules for data representation. Others consist of relatively raw transactional data. While internal data dictionaries for individual source systems afford developers and analysts the ability to understand the relations between tables within source systems, exploration of data is necessary to understand table relationships within and across source systems. Therefore, rather than maintain a common data dictionary for the various systems, SUPER relies on source system use of reference terminologies and engineering expertise to query data within and across applications.

Documentation and workflow management

To ensure a streamlined process for maintaining SUPER, analysts and engineers use multiple off-the-shelf work management tools, including ServiceNow, Jira, Subversion, Sharepoint, Box, Outlook, and Slack. RI has implemented a system of workflow management that leverages these tools to ensure all team members know what to do, when to do it, and how to ask for help. ServiceNow, WCM ITS’s internal ticketing system, allows for the triage of data requests and inquiries from investigators and research personnel, as well as infrastructure change requests and access control issues. To track work, including acquisition and integration of new data sources, data quality efforts, and the development of user-facing informatics tools, Jira allows for ticket-level tracking of tasks, priorities, and day-to-day work logging. As previously discussed, SVN allows developers to maintain and share code.

The use of SharePoint and Box allows team members to collaborate on external-facing reports and presentations to the research community, as well to aggregate and track documents gathered from and produced for investigators. A shared Outlook calendar makes all team members aware of ongoing ETL jobs or other pertinent events. Confluence stores wiki documentation written for the reusable code available to all team members, as well as ongoing issues
relating to individual tables, data sources, or user-facing tools. After a researcher submits a request via ServiceNow and engineers use Jira to work toward a solution, team members use Confluence to represent the knowledge distilled through the development process.

A weekly code review session allows software engineers to circulate and present code to their colleagues, exposing problems or issues, requesting help, or working together to develop and implement novel solutions. WCM ITS’s departmental Slack instance allows all team members to stay in constant contact, notifying each other of pertinent issues, as well as facilitating contact with other ITS business units to address issues relating to infrastructure, identity management, or project management.

Hardware and software infrastructure

SUPER consists of four Microsoft SQL Server 2014 database servers and five Linux virtual machines. WCM ITS provides clusters of virtual servers, which allow a more robust and flexible system of maintenance and deployment. The primary server is the landing server\textsuperscript{11}, which uses 40 gigabytes of random access memory (RAM), 21 terabytes of hard disk drive storage, and 20 virtual CPU cores. The landing server requires extensive system resources to ensure that data flows unhindered from source systems. In addition to enabling queries for the most recent data, the landing server provides data to development and production servers.

The SUPER development server is populated with data a week behind the regular refresh schedule of the landing server so as not to perturb data pulls; it also provides a backup should the landing server fail. Configured with 16 gigabytes random access memory, approximately 12 terabytes of hard disk drive storage, and 13 virtual CPU cores, the development server is not as powerful as the landing server, but allows for the development and trials of small ETLs, data mining queries, and relational data exploring. RI endeavors to keep the server as closely in line as possible with the landing server to ensure backup capabilities as well as utility for query transferring.

For production purposes, SUPER has two separate servers. For identified data available to researchers who access RI services, the production servers use 16 gigabytes of RAM, approximately 5 terabytes of solid state drive space, and 9 virtual CPU cores. Production servers are intended to handle multiple concurrent users.

Results

As shown in Figure 2, SUPER has enabled ARCH to support WCM researchers with multiple tools for using electronic patient data. For cohort discovery, i2b2 enables WCM investigators to query de-identified data from EHR and research systems\textsuperscript{12}. For EHR analytics, the Observational Medical Outcomes Partnership common data model (OMOP CDM)\textsuperscript{13} allows researchers to perform robust queries using standardized vocabularies. Alternately, for investigators with specific needs, developers and analysts work together to generate custom data marts from SUPER tables. Using REDCap in conjunction with the REDCap dynamic data pull (DDP) plugin and generalizable middleware to support REDCap DDP, investigators can populate REDCap fields with EHR data stored in SUPER\textsuperscript{14}. For multi-institutional data sharing, the New York City Clinical Data Research Network (NYC-CDRN), which receives funding from the Patient-Centered Outcomes Research Initiative (PCORI), enables queries of citywide EHR data; the SUPER infrastructure enables WCM to contribute data to the effort. Use of SUPER to support additional multi-institutional data sharing initiatives for clinical trial recruitment, including TriNetX\textsuperscript{15} and the National Center for the Advancement
of Translational Science’s Accrual for Clinical Trials program (NCATS ACT)\textsuperscript{16}, is underway. SUPER also previously enabled use of RexDB from Prometheus Research\textsuperscript{17}.

**Figure 2.** Model of data flow from sources to WCM SUPER staging environment.

**Discussion**

To our knowledge, this is the first complete description of a methodology for electronic patient data acquisition and provisioning that ignores data harmonization at the time of initial storage in favor of downstream transformation to address specific research questions and applications. While other institutions have outlined approaches that integrate data from different sources in their raw format and transform them on an ad hoc basis\textsuperscript{18}, the SUPER approach expands previous domain-specific work into the complex realm of health informatics. SUPER has successfully enabled multiple tools that provide utility to the WCM research enterprise, including cohort discovery, electronic data capture, and robust querying. In contrast to centralized data warehouses, the SUPER approach can enable institutions to tailor solutions that meet investigator needs rather than focus on dimensional modeling and other technology-oriented activities.

In characterizing SUPER’s methodology and infrastructure, the question naturally emerged: what is SUPER? Popular terms include data warehouse, data mart, and data lake. A data warehouse aims to render organizational data easily accessible in a credible and consistent fashion, adapt to shifting methodologies and use cases, secure sensitive data elements, drive enhancements in decision making, and serve as a usable and accessible resource to end-users\textsuperscript{19}. The Mayo Clinic’s Enterprise Data Trust (EDT), a “top-down, subject-oriented, integrated, time-variant, and non-volatile collection of data in support of Mayo Clinic’s analytic and decision-making processes,” serves as an example of the application of the data warehouse model within the healthcare setting. The EDT seeks to normalize data from disparate sources, implementing “consistent information models” and shared vocabulary to enable queries that touch data elements enterprise-wide\textsuperscript{1}. Other institutions have also pursued centralized data warehouses with controlled terminology and modeling rules\textsuperscript{3,4,6,7}. While the clinical data warehouse is defined by efforts to conduct semantic harmonization and data structuring during the ETL process from source systems, SUPER does not conduct any data harmonization, instead relying on efforts already put in place by teams maintaining source data.

An alternate approach to the data warehouse is the data mart – a specifically tailored data set specific to one research question, scientific workflow, or operational/quality improvement requirement\textsuperscript{20}. Often extracted from enterprise-wide data repositories, data marts offer an agile approach that is tailored directly to a specific use case. Purpose-built, they offer greater potential utility at the cost of flexibility and effort – each data mart often requires iterative definitional work with a business analyst to determine the specific requirements and often cannot be reused to support research questions outside of its bailiwick. Data marts also come with a particular suite of risks, including redundancy of effort of aggregation, inconsistency between marts, and difficulty connecting results with larger data sets\textsuperscript{20}. Although SUPER enables the creation of data marts, it also constitutes a more holistic effort to aggregate data across the entire institution and is not confined to individual research questions.

A third and relatively novel dimension for considering approaches to enterprise data aggregation and integration is that of the data lake. Coined by James Dixon, the data lake refers to an approach by which institutions aggregate
enterprise data in their native formats and store them unaltered. Analysts and developers then configure analytical components and export data to respond to individual queries and use cases as they emerge, working with users on an ad hoc basis. The data lake is not mutually exclusive with the data mart—indeed, they are intrinsically related, as the data lake relies on the data mart for the analysis and dissemination of the data that feeds its “aquifer.” SUPER seems to most closely fit the definition of a data lake, as it is characterized by its avoidance of data harmonization efforts during the intake process. However, its reliance on terminology management and semantic restructuring by groups maintaining source data feeds distinguishes it from a data lake in the strictest sense of the word. SUPER is, perhaps, comparable to a “data kitchen,” which regularly receives shipments of ingredients from vendors—some processed and some in their raw state—and uses these ingredients to “cook” an array of meals, some simple and designed to satisfy large numbers of people, and some complex, prepared for a specialized audience with particular tastes.

Our implementation of SUPER has yielded a number of pertinent lessons both technical and organizational. From a technical standpoint, SUPER’s ETL jobs are notable for their exhaustive resource use and lengthy duration. Our experience shows the value of developing large ETL jobs in a modular fashion and running them piecewise. While a large transaction log can have substantial utility, this approach offers greater benefit to the overall workflows the system facilitates and enables rapid recovery in the event of an individual component’s failure. Maximizing preprocessing is also crucial, with indexes configured to help as much of the process as possible. Additionally, retaining previous iterations of data sets on a development server creates a constant backup for operational use, obviating the need to ensure that the landing server is constantly available. While teams responsible for maintaining clinical and billing source systems may be initially reluctant to establish a workflow for transferring raw clinical tables, the SUPER approach offloads much of the iterative workflow in determining data flow and conducting tailored exports from source system teams onto RI. Investigators desirous of using clinical data for research may also be unprepared for the ramifications of its nature—underlining that data are accessioned from multiple sources and may not always be in agreement is crucial in setting expectations for the utility and quality of data delivered, especially for research use cases where data cleanliness is paramount.

Some limitations apply to this analysis. The study was conducted at a single site and may not generalize to other institutions. However, it may be potentially useful to sites with existing clinical data warehouses or sites considering their adaptation. Furthermore, the lack of terminology management may limit our approach: however, in a post-meaningful use healthcare setting, this may not be as applicable.

To our knowledge, this is the first comprehensive description of a methodology and infrastructure for secondary use of patient electronic data for clinical research that stores data from source systems in their raw format to serve specific investigator needs. We feel that this methodology possesses unique advantages and that it may be of use to comparable organizations considering potential approaches for secondary use of patient electronic data for research.

Disease-Specific Integration of Omics Data to Guide Functional Validation of Genetic Associations

Maya Shumyatcher, BA1, Rui Hong, BS1, Jessica Levin, MS1, Blanca E. Himes, PhD1
1Department of Biostatistics, Epidemiology and Informatics, University of Pennsylvania, Philadelphia, PA, USA

Abstract

Unbiased genetic association studies, including genome-wide association and whole-genome sequencing studies, have uncovered many novel disease-associated variants. Relatively few of these associated regions, however, have led to insights that are biologically mechanistic or clinically actionable due in part to the difficulty in designing appropriate functional validation studies to understand how variants contribute to disease. Asthma is a complex inflammatory lung disease for which many genetic associations have been identified. Using asthma as a disease model, we designed Reducing Associations by Linking Genes And transcriptomic Results (REALGAR), an app that facilitates the design of functional validation studies by integrating cell- and tissue-specific results of disease-relevant gene expression and other omics studies. Via specific examples, we demonstrate how integrated gene-centric and disease-specific information leads to asthma insights, and more broadly, can help understand complex diseases.

Introduction

The results of genome-wide association studies (GWAS) for various complex diseases have contributed to the growing credibility of using unbiased genetic association approaches for uncovering novel disease variants. In most cases, however, findings from GWAS have not yet led to significant progress toward understanding how identified genomic variants are functionally and clinically relevant. Recent exome sequencing and whole-genome sequencing (WGS) studies are finding an even greater number of variants associated with complex diseases, most of which have not yet been related functionally to outcomes. Among the factors that contribute to the slow translation of genetic association results into functional insights are: (1) functional studies are time-consuming, as each follow-up experiment has to be tailored to a particular complex disease phenotype and type of polymorphism in a genomic region, (2) in order to test genes and variants for function, complex diseases have to be simplified into assays that may not capture the cell-specific, developmental or environmental context necessary for functional elucidation of the gene, and (3) unlike older candidate gene studies, GWAS and WGS studies have identified loci in gene deserts and in genes with no annotated function, making the design of functional experiments even more difficult. In silico approaches that screen genes and variants for potential function are needed to guide the efficient experimental validation of top hits.

Functional validation studies of gene associations often begin with searches for what is known about a specific locus, including what genes are nearby and whether associated variants are expression quantitative trait loci (eQTL) and/or regulators of transcription of these genes. Although this information serves as a starting point, it does not offer phenotype-specific mechanistic clues about how the genes in question modify relevant biological pathways. To obtain such information, researchers often search public databases to find out the tissue(s) where identified genes are expressed and under what disease and treatment conditions they are differentially expressed. Public gene expression data from sources such as the Gene Expression Omnibus (GEO) are a primary resource for answering these questions, but many wet-lab and clinical researchers do not have the proper expertise or dedicated computational resources necessary to obtain and integrate gene expression microarray, RNA-Seq, and other omics results. Even researchers who do have such resources often repeat similar analytical tasks every time a new association locus is found. Having an integrated resource of tissue-specific results from expression and other omics studies that is guided by disease-specific knowledge would facilitate prioritization and rational design of experiments that can provide clinically actionable insights.

Asthma is an episodic inflammatory lung disease characterized by variable airflow limitation and airway hyperreactiveness that affects over 25 million Americans. One of the most common pharmacologic treatments of asthma consists of glucocorticoid medications, given in inhaler form as maintenance therapy or oral form to alleviate exacerbations or severe disease. Glucocorticoids, which are also used to treat various inflammatory diseases, act by modulating transcription of genes in a tissue-dependent fashion. The genetics of asthma has been studied for over 20 years, and consortium GWAS carried out in Europeans and diverse North American populations have
identified robust associations at loci such as the **GSDMB-ORMDL3-ZPBP2 17q21 locus, HLA-DQ, IL1RL1, IL18RL1, IL33, TSLP, SLC22A5, SMAD3, and RORA**. Most strikingly, the 17q21 locus association has been replicated in over 15 independent diverse populations and has been linked to childhood-onset asthma. How associations in this region are functionally related to asthma remains unclear. Because asthma features are heterogeneous and genetic variation also contributes to asthma-related phenotypes such as glucocorticoid response, there is difficulty in determining what specific traits are modulated by measured statistical associations with asthma.

Here, we present REducing Associations by Linking Genes And transcriptomic Results (REALGAR), an app that integrates results from gene expression, RNA-Seq and other omics studies to help guide validation experiments for gene associations. We use asthma as a disease model to show how gene-centric information that is gathered in a disease-specific fashion can be useful to better understand associations.

**Methods**

**Data Sources**

**Gene Expression.** A search for all human gene expression microarray datasets matching search terms related to “asthma” and “glucocorticoid” was performed in GEO. Raw signal intensity and phenotype files from relevant datasets were downloaded. The R package arrayQualityMetrics was used to perform quality control analysis on each dataset. Samples that did not pass quality control measures within datasets were excluded from subsequent analyses, and any provided covariates that were deemed to influence outcomes and/or produce batch effects via cluster analyses were noted. Pre-processing of raw signal intensities was performed with Robust Multi-Array Average (RMA). Three asthma-related RNA-Seq datasets were obtained from GEO.

**Gene Association.** Publicly available single nucleotide polymorphism (SNP) association results from asthma GWAS were obtained from three sources: (1) the Genome-Wide Repository of Associations Between SNPs and Phenotypes (GRASP), a catalog hosted by the National Heart, Lung and Blood Institute that contains all publicly available SNPs with reported p-values <0.05, (2) the GABRIEL Consortium, and (3) the EVE Consortium. GABRIEL results were filtered to select SNPs with p-values <0.05, and the EVE results, which contain distinct p-values for different racial/ethnic groups, were filtered to select SNPs that had p-value <0.05 in at least one group. The UCSC liftOver executable and chain files were used to convert the GABRIEL genome coordinates from the hg17 genome build into the hg19 genome build, which is the version used by GRASP and EVE. SNP locations were mapped to genes (within 10kb on either end) using BEDTools. ChIP-Seq results from this dataset were obtained via the UCSC genome browser, where they are reported according to the hg19 genome build, and mapped to genes (within 10kb on either end) using BEDTools.

**Glucocorticoid Receptor DNA Binding Sites.** ChIP-Seq results for a variety of tissues and transcription factors have identified protein-DNA binding events that may modulate transcription. Of relevance to asthma, one study identified regions of the genome where glucocorticoid receptors bind after 1 hour of treatment with a glucocorticoid (100nM dexamethasone) in A549 cells, an adenocarcinomic human alveolar basal epithelial cell line. ChIP-Seq results from this dataset were obtained via the UCSC genome browser, where they are reported according to the hg19 genome build, and mapped to genes (within 10kb on either end) using BEDTools.

**Gene Expression Analysis**

For microarray data, differential expression was quantified using the R package limma. For datasets with noticeable batch effects, the R package SVA was used to perform differential expression analyses while adjusting for batch effect. Fold changes were computed from the log2 fold changes output by limma or SVA, and standard deviations were computed as log2 fold change divided by the moderated t-statistic output by limma or SVA. Results from 27 asthma and glucocorticoid response datasets were saved for inclusion in the app.

RNA-Seq data was analyzed with Kallisto to quantify transcript abundance according to reads mapped to the hg38 reference genome and Sleuth to compute transcript-level differential expression results. Gene-level results displayed in REALGAR correspond to those of the transcript with the lowest differential expression p-value, in cases where genes had more than one transcript with reported results. The fold change and standard deviation reported in the app correspond to the beta and standard error of beta measures that are output by Sleuth.

For both microarray and RNA-Seq, differential expression results were computed for the test condition of interest relative to within-study controls (i.e. asthma vs. non-asthma samples, or glucocorticoid treatment vs. vehicle). Results of analyzed datasets were stored for use with the app.
To obtain an illustrative hypothesis related to our datasets, we conducted a meta-analysis of all available glucocorticoid response microarray datasets (Table 1) using the R package GeneMeta\textsuperscript{27}. Microarray probes were matched to official gene symbols using Bioconductor database packages for corresponding microarray platforms, and gene-level intensities were computed by obtaining the mean of probe intensities for all probes matching to an official gene symbol. Matrix files for overlapping genes of each study were used by GeneMeta to compute combined two-sided z-scores.

### REALGAR Design and Features

The RStudio package Shiny, which enables creation of web applications that users can easily engage without needing a background in programming\textsuperscript{28}, was used to create REALGAR, as its end users include wet-lab researchers with little computing experience. The app code, results of analyzed datasets and GENCODE hg19 reference genome files were saved on a DigitalOcean droplet containing a Shiny server that includes various R packages to retrieve and display results (i.e., forestplot, lattice, and Gviz). The app is displayed at [http://himeslab.org/realgar](http://himeslab.org/realgar), and the full code is available at [https://github.com/HimesGroup/realgar](https://github.com/HimesGroup/realgar).

To use the app, an official gene symbol or SNP ID is provided by a user (Figure 1). Users can select (1) tissue and (2) asthma types to be included by clicking on corresponding checkboxes, (3) what asthma-related drug treatment gene expression results to display (e.g., glucocorticoid, beta-agonist or vitamin D treatment), and (4) which of the GWAS results (GRASP, EVE and/or GABRIEL) to include. If EVE is selected, an additional option box allows the user to choose results from specific populations (i.e., African American, Latino, European American, or all subjects). As selections are made, the analyzed GEO datasets that match the selected criteria appear in a table in a separate “Datasets loaded” tab that provides: (1) GEO accession numbers that link directly to GEO entries, (2) PMIDs for papers, when available, that link directly to PubMed entries, and (3) a brief description of each dataset.

Study-specific results are visualized as a forest plot in which the selected gene’s fold changes for all selected tissue and asthma type comparisons are shown as computed relative to within-study controls (Figure 2A). If a SNP ID, rather than a gene symbol, is entered, results for the gene closest to that SNP are displayed. If one or more of the treatment options are selected, a second forest plot displays the fold changes of this gene under the treatment(s) selected, relative to within-study controls, for all selected tissue types with available data. Forest plot rows are colored according to the negative log10 of the corresponding false-discovery rate adjusted p-values (i.e., q-values), and an adjoining table displays study information, including tissue type and endotype or treatment, as applicable.

Below the expression results, an ideogram of the selected gene’s chromosome with its location indicated by a red line is shown, along with a genome track displaying the gene’s transcripts (Figure 2B). If there are SNPs with GRASP, EVE or GABRIEL asthma association results and/or glucocorticoid receptor (GR) binding sites within
10kb of the gene’s boundaries, then association and/or GR binding site tracks will also be present. GR binding sites are colored according to the ENCODE-provided binding scores, with higher scores corresponding to brighter colors. SNP association results are colored according to negative log10 of p-value, so that lower p-values correspond to brighter colors. Individual plots can be downloaded in .png format, and tables of expression results and SNPs can be downloaded in .csv format. GWAS results displayed can be downloaded, allowing users to obtain quantitative results of the associations across populations.

Figure 2. REALGAR output. A) Forest plots show gene fold-changes of differential expression, with colors corresponding to q-values. Example shown for SRC indicates that its mRNA is increased in CD8+ cells of severe asthma subjects and decreased with glucocorticoid treatment in macrophages. B) Genome tracks show gene transcripts, GR binding sites and SNPs with GWAS results. Example shown for SRC reveals that asthma-associated SNPs are within/near GR binding sites.
Results

Generating Hypotheses That Link Gene Associations to Function with REALGAR. The tissue-specific results available in REALGAR offer insights about the role of prominent asthma-associated genes. Looking up the 17q21 loci genes GSDMB, ORMDL3 and ZPBP2 in the app reveals that glucocorticoid treatment does not alter the expression of these genes, nor are they differentially expressed among subjects with asthma in any of the available tissue types. Thus, these genes are not involved in glucocorticoid or immune responses, nor are they useful as asthma biomarkers, according to the evidence provided. In contrast, REALGAR shows that IL1R1 is highly glucocorticoid responsive in macrophages, where dexamethasone treatment induces a 3.41 (95% CI: 2.65-4.39) increased fold-change vs. control (q-value 3.13x10^-6). Additionally, IL1R1 mRNA has decreased expression in nasal epithelium of asthma subjects with allergic rhinitis vs. non-asthma controls, exhibiting a fold-change of 0.60 (95% CI: 0.49-0.73; q-value 0.020). These tissue-specific results help suggest experiments that may clarify the role of IL1R1 in asthma.

Using REALGAR to Re-Prioritize Disease-Associated Genes for Functional Validation Studies. By combining GR-binding site results with SNP results from GRASP, EVE and GABRIEL, 511 unique asthma-associated SNPs that were within GR-binding sites were identified. Among these was rs6090585, within an intron of the SRC Proto-Oncogene, Non-Receptor Tyrosine Kinase (SRC) gene, which had a nominally significant association with asthma in the GABRIEL GWAS consortium study (p-value 0.010; OR 1.13 [1.03-1.24]). Although this SNP would not be a preferred candidate for further study based on the GWAS results alone, the integrated data in REALGAR provides further evidence that the locus may be relevant to asthma: (1) it is located in a putative GR binding site, (2) SRC mRNA expression is increased in CD8+ cells in severe asthma (fold change 1.33 [1.17-1.5] vs. non-asthma controls; q-value 0.012), and (3) SRC mRNA expression is decreased in macrophages treated with the glucocorticoid dexamethasone (fold change 0.47 [0.35, 0.64] vs. control; q-value 0.0038) (Figure 2). Another asthma-associated SNP within a GR-binding site was rs3759324, a SNP located within introns of two genes: Lymphotoxin Beta Receptor (LTBR) and Sodium Channel Epithelial 1 Alpha Subunit (SCNN1A). This SNP was nominally associated with asthma in the GRASP study (p-value 0.0044; OR 1.07 [1.02-1.12]), and thus would not be prioritized for further study based on GWAS data. Considering other data in REALGAR, however, increases support for the hypothesis that this locus is related to asthma: (1) rs3759324 is located in a putative GR binding site with the highest possible ENCODE binding score (1000), (2) the GR-binding site in question occurs fewer than 30kb upstream of several SCNN1A transcripts, suggesting mRNA levels of this gene are modulated directly by glucocorticoids, (3) SCNN1A mRNA expression is increased in CD8+ cells in severe asthma (fold change 1.53 [1.22-1.92] vs. non-asthma controls; q-value 0.027), and (4) SCNN1A mRNA expression is increased in lens epithelial cells treated with dexamethasone (fold change 14.98 [9.34, 24.01] vs. control; q-value 0.023). In contrast, no significant changes were observed for LTBR mRNA levels in any disease state or tissue type tested, although the GR-binding site containing the SNP of interest lies upstream of several LTBR transcripts. According to these results, SCNN1A should be prioritized for study as an asthma gene, and specifically as a modulator of glucocorticoid and/or immune response. These examples highlight how REALGAR’s integrated data can aid in re-prioritizing associations for functional validation studies.

Insights Provided By Meta-Analysis of Single-Modality Data in REALGAR. In addition to using REALGAR to understand genetic associations, integration of data types in the app provides novel insights about the role of genes in disease. For example, a meta-analysis of six of the glucocorticoid-response expression microarray datasets in REALGAR found that Suppressor of Cytokine Signaling 1 (SOCS1) gene ranked as the “top” gene according to magnitude of two-sided z-score (6.2; two-sided z-score false discovery rate <10^-5) (Figure 3). While SOCS1 was highly responsive to glucocorticoids in most tissues, structural cells were an exception: SOCS1 was not responsive in epithelium, and results in airway smooth muscle were mixed, with a nominally significant decrease observed in one study (fold change 0.74 [0.65, 0.85]; p-value 6.1x10^-3; q-value 0.089) and an increase in another (fold change 1.81 [1.30, 2.52]; p-value 3.58x10^-3; q-value 0.020). Previous studies have identified SOCS1 as a target via which glucocorticoids regulate inflammation and a mediator of rhinovirus-induced asthma exacerbations. REALGAR results provide complementary information: (1) a GR-binding site near the gene suggests that SOCS1 is directly activated by glucocorticoids, and (2) the results of 17 microarray studies and RNA-Seq show that SOCS1 mRNA levels are not significantly different between asthma and non-asthma subjects, except for in bronchial epithelial cells, where they were decreased in asthma subjects (fold change 0.83 [0.76, 0.91]; q-value 0.021). These observations suggest that glucocorticoids may not be able to rectify differences in SOCS1 levels that are present in bronchial epithelial cells of asthma subjects. Thus, aggregating single-modality data allows for detection of patterns
not apparent in single datasets, while complementary information available in REALGAR allows for quick insights into disease-specific gene function.

**Figure 3.** *SOCS1* was the most significant differentially expressed gene in response to glucocorticoids across all tissues. Its levels increased highly in immune cells and were not changed in structural cells, with the exception of airway smooth muscle, which had mixed results between datasets.

**Discussion**

Integration of omics data is challenging, as it requires a thorough understanding of heterogeneous data types, as well as computational resources and expertise to store and analyze large datasets\(^{31}\). Various public resources host omics data, but much work remains in maximizing this data’s ability to inform human pathobiology by presenting results derived from omics data integration to wet-lab researchers, who can validate hypotheses. The development of novel computational tools that integrate and visualize omics datasets is vital in bridging the gap between streams of raw data and clinically relevant findings. Several publicly available apps that are helpful in understanding GWAS data exist. For example, HaploReg is a widely used tool that allows users to look up information about a SNP, including others in linkage disequilibrium to it, chromatin state and protein binding annotation from ENCODE, sequence conservation, its effect on regulatory motifs, and associated eQTLs\(^{32}\). A visualization-centered app that provides similar information is LocusExplorer, which is built using the shiny R framework to provide high resolution graphics of omics data for a genomic region\(^ {33}\). Despite their utility, these tools’ insights are largely not tissue-specific and hence are limited in their ability to provide insights into disease and treatment mechanisms, which are tissue specific. Apps that focus on tissue-specific analysis include NetWAS, an efficient and visually appealing app that integrates GWAS results with tissue-specific networks derived from gene expression data to re-prioritize disease-gene associations\(^ {34}\). While NetWAS includes many tissue-specific results, it does not use disease-specific knowledge to guide integration and presentation of results to wet-lab researchers, who answer specific, hypothesis-driven questions. We built REALGAR as a tissue-specific and disease-focused app to ensure its results are immediately helpful to wet-lab biologists, as well as to researchers who seek to carry out unbiased data analyses.

A well-known challenge in understanding complex diseases such as asthma is that disease-associated polymorphisms vary by race and ethnicity. This factor will be important to address in bridging the gap from omics results to clinically relevant insights. REALGAR allows users to view GWAS results at a population-specific level, and functional validation studies that harness the granular nature of these population-level results can lead to improved understanding of the clinical significance of disease-specific loci. A detailed understanding of the
correspondence between genetic variants and clinical outcomes will be an important stepping stone towards more personalized medical care.

In ongoing work, we are improving REALGAR by including datasets for more phenotypes, and while we continue to be focused on pulmonary disease phenotypes, future versions will include other complex diseases. In addition to incorporating a broader set of phenotypes, we are adding additional data types, namely eQTL and additional RNA-Seq results. To complement the population-level GWAS results currently included in the app, we will integrate population-specific information for the gene expression results, as this information is available for some of the datasets. Rather than duplicate the compilation of SNP data that exists in other tools, we seek to focus on providing novel integration of disease-focused omics datasets. While scoring metrics across integrated datasets remain highly biased and arbitrary from a biological perspective, future versions of REALGAR will include a scoring metric that weights user-selected datasets to provide an overall ranking that is based on ranks within datasets. As with all \textit{in silico} tools, the goal of such scores will be to provide evidence-based hypotheses for experimental studies.

Conclusion

We created REALGAR, an app that integrates gene- and disease-specific data to present insights that are helpful for designing functional validation studies in support of genetic associations. REALGAR has an intuitive, user-friendly interface and, while it harnesses the computational power of R, requires no programming background for its use. We provide several specific hypotheses about asthma-related genes based on REALGAR results that may lead to biological insights about asthma and its treatment.

Abstract

The hospital to home care admission process is when nurses make important decisions about the post-transition episode, including medication reconciliation, plan of care, future visit patterns, and the inclusion of other disciplines. It is not clear how nurses get and use information to support decision-making. We conducted a focus group case study with six admitting home health nurses at a rural agency in Pennsylvania. We analyzed the data using thematic analysis and using our enhanced custom high level node-link diagram that highlights the relationships between decisions, tasks and information themes and sub-themes. The visualizations will be evaluated via review with home care subject matter experts.

Introduction

Home health agencies admit 11 million patients per year to home care1 with demand growing due to an aging population living longer with multiple chronic diseases and patient preferences for home care over facility-based care.2,3 Home care patients tend to be vulnerable older adults; 30% experience a readmission to the hospital within 60 days and many are readmitted to the hospital within the first two weeks of discharge.1 The hospital to home care admission process, when nurses make critical care planning decisions about the post transition episode, is therefore critical to quality healthcare and to reducing hospital readmissions.3,4 However, nurses’ information needs and how nurses obtain and use information for decision making during home care admission are currently poorly understood. What is known is that information relevant to a safe transition and developing the plan of care is often lacking at the start of home care. In fact, home care nurses receive only half of the recommended data.5 Missing, incomplete, or incorrect information is likely to impact the quality of the care plan which in turn may effect quality of care and patient outcomes.

This paper presents focus group findings of home care nurses’ tasks, information needs and decisions during the admission process. These findings will be integrated with those from observational studies and case reviews that are in progress in order to develop recommendations to enhance the home care admission process and to inform health information technology standards for home health agency electronic health record (EHR) systems. In addition to leading to home care domain related EHR requirements, this work introduces methods to support the analysts who seek to understand how nurses make decisions in relation to the information and tasks, and to facilitate the communication of findings to stakeholders including the home health agency nurses and other subject matter experts. Time with subject matter experts is precious and thus having supporting methods such as data visualization to represent the key issues for discussion is helpful.

A focus group was conducted at a rural Pennsylvania home care agency that uses a point of care EHR system. With respect to the home care domain, the focus group was designed to explore four main clinical decisions at the home care admission:

1. Medication reconciliation (process of creating an accurate list of medications that the patient should take and comparing that list against the physician's discharge orders and the medications in the home);
2. Plan of care (orders for assessment, education, and performance for the problems that the nurse has decided need to be addressed in the care episode);
3. Visit timing and frequency (the next skilled nursing visits following the admission and the total number of follow-up visits); and
4. Inclusion of other disciplines (“Services”) in addition to skilled nursing (additional agency services needed, e.g., physical therapy, social work) in the care plan.

To understand the associated tasks and information needed to make the four clinical decisions, we developed a custom node-link diagram visualization. The short term goal was to support the review of focus group findings with subject matter experts. The longer term goal was to inform health information technology standards. A node-link diagram, sometimes called a network diagram, is a visual representation that shows relationships using links (also
called edges) between nodes (also called vertices). Nodes are generally represented as shapes with or without text labels. Links are represented as lines between the nodes. According to Knuth, versions of node-link diagrams have been used since the 1200s. These diagrams have proliferated in use across many domains and with many types of representations, including health informatics. The links can be undirected showing association, or they can be directed showing the direction of the relationship. Arrows are typically displayed on the links to indicate direction.

This manuscript presents a focus group case study executed to identify the relationships between admission nurses’ decisions, tasks, and information gathering and use. It presents our enhanced node-link diagram concept developed to represent the qualitative findings from the focus group. The concept was informed by collaboration between experts in the clinical decision making process and human factors professionals. This manuscript introduces the features in the enhanced node-link diagram and presents visualization guidelines for how to instantiate each feature in order to highlight findings considered significant by clinical experts. The focus group data are presented with prototype visualizations that meet the guidelines. The manuscript presents a discussion of the use of the designed representations and highlights future work.

Methods

The Drexel University Institutional Review Board approved this study.

Participants

All participants provided informed consent. The study took place with six admitting registered nurses working in a free-standing, small, rural agency that serves a majority white population with lower socio-economic status. When conducting admissions, the clinicians at this agency at the time of the focus group used a laptop-based commercial EHR from Allegheny Software Publisher that is widely used in rural agencies in the region.

Focus Group Data Collection Procedure

The participating agency limited the focus group data collection period to 75 minutes. The researchers designed the focus protocol with this limitation in mind.

The researchers developed a demographic data collection instrument and a set of open-ended focus group questions. The demographic instrument was modeled based on the demographic data collection section of the EHR Nurse Satisfaction Survey which assessed clinician satisfaction with EHR impact on clinical process. Respondents documented their age, gender, ethnicity, race, job title, prior experience with EHRs, years of experience in health care, and self-assessment of computer knowledge.

The open-ended questions were developed based on the team’s experience. The questions focused on the admission decision making process and how nurses use the EHR and other information to document the care plan and medication reconciliation. The care plan defined the problem list or priorities that the agency will address, the timing of the next visit and the total number of visits, and inclusion of the other disciplines in addition to skilled nursing. Nurses were specifically asked about the start of care visit:

1. What tasks they needed to complete for each of the clinical decisions (i.e., medication reconciliation, visit pattern and frequency, care planning, services needed); and
2. Whether the task generated information they needed for the related clinical decision.

KB, an experienced focus group moderator and home care researcher, led the focus group. She elicited detailed responses from participants following the initial responses. All responses were recorded, including responses not related to the questions posed. As participants responded to the moderator-posed questions, responses were written on flip charts that were adhered to the meeting room walls for ease of reference. Using the participant input, researchers used colored circles to code tasks and decisions by topic (see an example in Figure 1). Visual display of the documented responses provided opportunity for member-checking and respondent feedback. Researchers also documented in field notes. In addition, the focus group was recorded using digital voice recorders.

A 30 minute follow-up phone call with two focus group members addressed member-checking and elicited responses for questions that were not addressed during the 75-minute focus group. For the follow-up call, the team selected focus group members who had contributed the most responses during the focus group and who were demographically representative of the agency’s nurses.
Figure 1. Example flip chart page for the “Start of Care tasks” with activities and color-coded circles representing the associated four clinical decisions (e.g., blue represents plan of care decision, green represents visit timing and frequency decision).

</table>

The main nodes are decisions, tasks, and information gathered and/or used. In the diagram, nodes are grouped by category (decisions, tasks, and information) and listed in vertical columns. Each category is color-coded. This organization supports the analyst to see the list of decisions, tasks, and information elements. The redundant coding (use of columns and color coding of the node shape) help to differentiate one category from the other.

Links are used to represent associations between nodes. The vertical edge of the node is proportional to the number of links adjacent to that edge. Directed links indicate whether information is generated or used. For example, if the directed link is from a task to information, then the task generates the information.

In qualitative analysis, a concept may be decomposed into lower level concepts. For example, an information node
theme such as “Patient” may have many sub-themes. Representing all of the sub-themes can be useful in some cases but in other cases, it can make a visualization very cluttered. In order to leverage the design concept of overview plus detail,² node themes that have sub-themes have indicators. Optionally, the number of sub-themes as well as the sub-themes themselves can be displayed.

Nodes and links were identified based on the thematic analysis data. To produce the diagrams, the nodes defined from the qualitative analysis were entered into an Excel Spreadsheet (Microsoft Inc.). Each node was associated with a text description for display purposes and related identifiers. Columns identified the links between nodes.

To generate the data visualization, we used Lucidchart (Lucid Software) to represent the nodes (i.e., decisions, tasks, information) and links (relationships). After the nodes and links were displayed, annotations related to the sub-themes were added. Some changes (e.g., spacing of nodes, path of links) were made to the images to improved readability.

Data Analysis

We analyzed the focus group products (i.e., transcripts, visually recorded documentation) with thematic content analysis and presented the analysis using the developed data visualization. All data in response to the open-ended focus group questions was included in the analysis. We presented data from different perspectives to yield synergistic insights.

Thematic analysis is used to inductively analyze data to identify descriptive or topical categories. It involves familiarization of the data to identify themes that emerge, grouping of similar concepts, and consistent coding of all such occurrences. Using principles of thematic content analysis, AH, a nurse and experienced qualitative coder, analyzed inductively the transcribed audio recordings of the focus group sessions to identify descriptive or topical categories. Each theme was labeled as per the framework: as a decision, task, or information. AH created a codebook detailing the rules and definitions of the nodes that emerged. Three authors (SP, AH, PS) participated in the coding process of the focus group transcript. SP used the codebook to assign themes to 50% of the transcript. Two authors (SP, AH) discussed differences in individual coding and updated the codebook and coding until 80% inter-rater reliability was established. AH then updated the second half of the transcript according to the updated codebook. PS joined the coders to oversee the updated theme assignment of the second half of the transcript and codebook.

NVivo (QSR International), a qualitative data analysis software, was used to organize themes that emerged from the focus group transcript. AH and PS identified similar concepts in the transcript, and combined them under assigned aliases under the related theme. Using NVivo, concepts were categorized under the appropriate sub-node (child theme) of the associated larger concepts(s) (parent theme). Parent themes categorized under a clinical decision or a task were to be represented in the node-link diagram as linked concepts.

The team met to review the qualitative analyses and results. The team discussed all themes that emerged and the diagram showing all themes related to all of the clinical decisions and also the start of care process. The team grouped similar themes within each category (tasks, information) based on the underlying concept (e.g., patient characteristics, caregiver characteristics, home characteristics). Team members (AH, YY, PS) grouped information themes into aggregated themes which reflected the underlying concept. To improve presentation and readability, additional diagrams were generated showing the themes related to each separate clinical decision. Information sub-themes were listed in versions of diagrams for the clinical decisions. KB led the team in review of the clinical relevance and validity of the node-link diagram analysis findings.

Results

Participants

The focus group nurses were RNs and care managers, white, young (median age of 32 years) and majority female. They had some experience with EHRs (median of 3 years) and in health care (median of 6 years).

Thematic analysis

The thematic analysis was clustered around the four clinical decisions as well as the start of care process. The focus group identified 28 tasks (Figure 2). For the clinical decisions, the Visit Timing and Frequency decision was associated with 11 related tasks, the Plan of Care decision with 14 tasks, Medication Reconciliation with four, and the Other Services with six. The Start of Care was associated with 22 tasks.

The focus group identified seven themes of information generated from tasks to make clinical decisions:
1. Patient (e.g., vital signs);
2. Resources external to the home (e.g., insurance coverage);
3. Home environment (e.g., clutter);
4. Medication reconciliation;
5. Medication self-administration;
6. Caregiver; and
7. Home care agency resources (e.g., services, policies and procedures).

These information themes were distributed among clinical decisions, with some information types occurring in more than one clinical decision. The seven information themes contained 51 sub-themes. Of these sub-themes, 38 were distributed in the seven information themes as follows (details appear in Figure 2): 22 in Patient Information, 3 Medication Reconciliation, 5 Medication Self-Management, 2 Home Care Agency Resources, 4 External Resources, 1 Home Environment, and 1 Caregiver. The remaining 13 sub-themes were not related to a task and were not shown in the visualizations. Almost all these sub-themes were patient sub-themes (e.g., allergies, baseline function, admission indication), with one external resource theme (i.e., community resources needed). With respect to Medication Reconciliation, the focus group participants clarified that this clinical decision has two main aspects: 1) comparison of the patient’s medications to the discharge documentation medication list (drug name, dosage, frequency, and route) and 2) medication self-management (e.g., the patient understanding and ability to self-manage the medication (e.g., self-administration)).

**Node-link analysis**

The node-link diagram shown in Figure 2 with the abbreviations in Table 2 characterizes the relationships between tasks, information, and clinical decisions. Figure 2 was designed to show the high level findings from the focus group. Figures 3 and 4 were designed to highlight specific design features related to the decomposition of information into sub-themes. Each diagram has three columns: nodes in the same category are organized by vertical position. The left column shows the clinical decisions of interest in the study. The middle column contains the tasks. The right column shows the nodes of information grouped into the aggregated themes. The color of the node indicates node type taxonomy (e.g., clinical decision nodes are blue). The horizontal links between nodes indicate associations between tasks, information, and decisions. The vertical edge of the node is proportional to the number of links adjacent to that edge and can indicate prominent tasks and information. Directed links were included when relevant. For example, if the flow is from task to information, then the task generates the information. An example of the opposite direction is a cluttered home (information) which is a reason for the nurse to document in the EHR outside the home (task).

Figure 2, as a high level summary, illustrates a number of design features. Regarding the clinical decisions, the Start of Care, Plan of Care, and Visit nodes have longer vertical sides (indicating more links) than the Medication Reconciliation and Services nodes. Among the 28 tasks, the majority have nodes with sides of shorter height (nodes with few links) meaning that there is a small set of information types associated with the tasks. The few task nodes with sides having larger height are: Medication Reconciliation; Disease Management Teaching; Obtain Health History; Conduct Review of Services; the Physical Assessment; and Document in the EHR. These tasks thus are associated with many different types of information. Eleven task nodes do not link to an information node and this lack of associations is apparent in the figure. During the focus group no associated information was mentioned for these tasks: participants did not mention generating or using information types.
Figure 2. Enhanced node-link diagram of four clinical decisions and start of care. Nodes are organized by type (decision, task, and information). Node side height indicates the number of links. Direction links indicate information.
Among the seven information themes, the Patient theme dominates with respect to the number of tasks that generate information. This is as expected as the purpose of the admission is to assess the patient’s situation and needs in order to develop the plan of care.

To support analysis for each clinical decision, we created a separate node-link diagram. Plan of Care (Figure 3) includes 13 tasks and 5 information themes (27 sub-themes). The Conduct Medication Reconciliation task node has the most links to information types and thus its longer left side is salient in the figure. Five tasks did not connect to an information theme and thus come to point on the left side. These pointed sides are also salient and may indicate where further discussion with subject matter experts is warranted. The information group with the most associations was Patient, as expected.

**Figure 3.** Enhanced node-link diagram of plan of care clinical decision information. The total number of information sub-themes of an information theme is indicated with the number next to the triangle in the information theme node rectangle. For a task-information theme pair, the number of shared information sub-themes is indicated by the line style thickness of the associated link.

Links between task and information nodes have different line thickness to indicate the number of associated sub-themes. For example, the task, Establish the Goal of Care, was associated with 5 information sub-themes (Diagnosis, Other Therapy Needed, Patient’s Desired Outcomes, Pre-Hospitalization Baseline, OASIS, and Start Of Care Assessment). Having an ability to be able to drill down into the sub-themes is the focus of the visualization in Figure 4.

Visit Frequency and Timing had 11 tasks, six of which linked to an information theme (Figure 4). This clinical decision had five information themes and 21 information sub-themes. The information theme, Caregiver, appeared in only this diagram. This situation is clear in Figure 2 as there is only one link to this node. However, in Figure 2 it is not clear which decision is relevant. Of special interest were task nodes with fewer links (and thus shorter sides) than expected. In addition, there were task nodes with no links to information nodes. Team members knowledgeable of home care admissions (KB, PS, EB) identified cases where the visualization results did not match their observa-
tions of admissions or their knowledge of the admission process. One would expect, for example, that the Assess Home Safety task would link to the information theme Home Environment. The team was cognizant that sparse or absent links may have been due to data collection limitations (75-minute period).

Figure 4. Visualization of visit timing and frequency decision showing information sub-themes

As in Figure 3, Figure 4 includes the number of links between tasks and sub-themes, as indicated by line width. Figure 4 also includes the specific information sub-themes associated with the tasks in the information nodes. While somewhat cluttered, this representation showed, for example, that information sub-themes such as Health History and Diagnosis can be generated from multiple tasks. This type of analysis would be more difficult to conduct without the sub-theme data.

The diagram for Services (not included as a separate figure herein for space reasons) includes very few nodes, having only six tasks and no information themes. This finding related to Services was unexpected, as in our admission nurse observations, we documented the nurse receiving an intake form with specific information pertaining to the services ordered by the physician. For example, we expected to see the Services decision linked to the task, Review the Home Care Chart, which was linked to the information item, Home Care Agency Resources.

The medication reconciliation diagram (not included as a separate figure for space) included four tasks and three information themes. Two tasks (Educate the Use of IV and Medication Reconciliation) did not link to information. However, we would have expected the task of Educate the Use of IV to link to the Patient information node, to ascertain the patient’s medication self-management capability.

Start of Care (SOC) (not included for space) contained the most tasks, which was expected as the SOC is the main purpose of the nurse’s visit. However, 11 tasks linked exclusively to SOC did not link to an information group. The diagram indicated that the SOC involved many tasks to gather a plethora of information.
Discussion

We investigated home care nurses’ information needs during the admission with qualitative data derived from a focus group. We developed a custom node-link diagram visualization of the themes that emerged related to admission nurses’ tasks and information related to four clinical decisions. The node-link analysis revealed the relationships between tasks, information, and decisions as well as highlighted cases where more data may need to be collected.

From an analyst’s perspective, the visualizations help to answer a number of types of questions. The first are exploratory questions. Information emerges from the node-link diagrams which the analyst may not have noticed otherwise. For example, information about the home environment was sparse (Figure 2). In our observations of home care admissions, nurses often identified the need for occupational therapy. Those therapists would assess the safety of the home in a separate visit. This lack of a connection in the node-link diagram, for example, highlights the need to ensure that the nurse assumes that another clinician (e.g., occupational therapist) is responsible for surveying the home environment. This assumption is based on the nurse’s expectation that the therapist would contribute to an assessment of patient safety.

The second type of question is related to our interpretation of the data, and checking back with the subject matter experts to verify what the data suggest. As indicated in Figure 1, there are many ways links between categories of information can be represented. In Figure 1 relationships were identified using colored circles. During the focus group, the nurses were reminded what the colors represented. The data visualization graphics may be more informative to the nurses as compared to a flip chart, spreadsheet or table. Also it allows patterns to be identified using perceptual abilities. For example, the Visit Timing and Frequency diagram (Figure 4) indicates the Caregiver information theme is linked to Conduct Medication Reconciliation. However, there is no link from Conduct Physical Assessment to Caregiver, contrary to our observations during nurse assessment of patient functional status related to activities of daily living (e.g., ability to bath, toilet). Here, the nurse could be shown the gap (the lack of a link) and asked if the physical assessment task was conducted to garner information about the caregiver situation.

Another type of question is related to admission workflow: showing where the nurse was expending effort to do something that may better be achieved by another entity or process. For example, the nurse obtains eligibility criteria information (e.g., insurance coverage, homebound status) from the patient during the start of care (Figure 2). Obtaining this information does not require clinical expertise, nor does the task generate information used by the nurse. After member-checking, this finding might indicate a change in workflow or a need for interoperability which could be incorporated in a requirements document. Similarly, the diagrams indicate where the nurse conducted many tasks (e.g., start of care, plan of care) which did not produce information needed for the admission.

The fourth type of question is relevant to the methods used to collect information. In this case, did our focus group data collection method provide a consistent set of information? For example, the Medication Reconciliation task is associated with decisions and information, and occurs among all clinical decisions and Start of Care (see five links going into the node in Figure 2). Member checking would inform the team whether the occurrence of different information related to medication reconciliation distributed among the four clinical decisions was meaningful or was an artifact of how the question was asked. Another method question is whether the numerous tasks and the sparse Services diagram indicate that the 75-minute data collection may not have been enough time. The data visualization does suggest where the gaps in data are, so that during the next data collection the team can probe further.

Our custom visualization includes design features to support the production of unique node-link diagrams (Table 1). In this case study, we presented different combinations of the design features in Figures 3 and 4. In future work, we will evaluate the efficacy of the visualizations in check backs with the home care agency. Future work should investigate the implementation of the design guidelines in Table 1 with respect to usability as well as extending the set of features included. We can develop additional representation guidelines related to the links, such as line color or line style, and related to the nodes, such as symbol shape, to represent additional features.

Conclusion

We developed a custom information visualization to characterize the decision-making process of home care nurses during admission. This visualization has advantages, compared to other methods such as a flow chart, information flow diagram, or decision ladder\(^1\) that respectively show detailed process information for an individual activity, how information is communicated, and decompositions of decision sequences and short cuts that can be taken in the process. The node-link diagram can be synergistic with those techniques and be helpful in answering other types of questions. An advantage of the information visualization method was that it provided a high-level view of themes and relationships of clinical decisions, tasks, and information. This high-level representation enabled us to have a
systematic understanding of the decision-making process, i.e., how information is used (and not used) in multiple tasks and decisions. Detailed diagrams with information about sub-themes helped to highlight information used across tasks. We anticipate that the data visualization method will be useful outside of healthcare in domains that have limited numbers of decisions, tasks, and information elements, for those seeking to map information-related decision-making.

Acknowledgements

This research is supported by the Agency for Healthcare Research and Quality (AHRQ) Grant # R01 HS024537. The authors thank Wei Quan for encoding data visualizations that were used in an earlier version of this manuscript. They also thank the home care agency and the participants. And the authors thank the anonymous reviewers who encouraged the authors to improve upon the originally submitted data visualizations.

Abstract
An integral element of value-based care is care team access to both physical and behavioral health data. Data release processes in both environments are governed by federal and state statutes. The requirements for obtaining consent are complex and often confusing. Little is known about the consent processes and practices in the behavioral health setting, specifically how patients and surrogates engage in the process and their interactions with electronic consent tools. This study analyzes the consent processes from the patient perspective at two community behavioral health clinics. Outcomes include description of the processes using electronic consent, workflows and consenter-provider interactions. Conclusions include need to streamline and standardize consent technologies and improve consenter engagement. This study supports the development of an electronic consent tool, My Data Choices (MDC), funded by the National Institute of Mental Health, that offers individuals with behavioral health conditions more control over their medical records.

Introduction
Behavioral health conditions affect nearly 46 million American adults, a quarter of whom have a serious mental illness1. Substance Abuse and Mental Health Services Administration (SAMHSA) defines behavioral health as the mental/emotional well-being and/or actions that affect wellness. Behavioral health problems include substance use disorders; alcohol and drug addiction; and serious psychological distress, suicide, and mental disorders2. Caring for the total person is important. Patients with behavioral health conditions are more likely to have a chronic medical condition, with nearly 70% of adults with a behavioral health condition having at least one medical condition. Individuals suffering from a serious mental illness (SMI) have higher emergency room, primary care and specialist visit rates1. Patients receiving both behavioral health and physical health treatment often see multiple providers and thereby benefit from integrated care amongst a variety of providers and organizations1. Sharing health data between providers requires obtaining informed consent from the patient or legal guardian of the patient, when the patient is physically, mentally or legally not capable of providing consent3. Informed consent is the most widely recognized ethical safeguard in research and clinical care used to protect patient rights3,4. Patients use informed consent to decide what health information to share and with whom.

Patients with behavioral health conditions often suffer social stigma, fear of losing employment, insurance discrimination or legal concerns5. Such fears might influence their care and related data-sharing decisions5. Studies have shown that patients want more control over their data and the Office for the National Coordinator for Health Information Technology recommends that patients be given more choices at a granular level7,8. Granular control could afford patients more control over how personal health information is shared, with whom, and why. The consent decisions pertaining to sharing health data for care can affect treatment and care coordination, compelling the need for meaningful consent. Meaningful consent involves key components such as patient engagement, education and ensuring alignment with laws and regulations6. Understanding the quality of provider-consenter interaction and patient and legal guardian comprehension and involvement is vital. Studies rating the quality of informed consent and related tools exist to guide the design of
consent processes for clinical research. Our review of the state of the art indicates lack of studies about the quality and effectiveness of informed consents for treatment, and studies focusing on patients with behavioral health conditions and legal guardians.

The conventional means to obtain the informed consents has been paper based hard copy forms. Nevertheless, these forms could be long, verbose and monotonous and retrieving information could be time consuming and cumbersome. With advancements and increased adoption of electronic health records (EHR), over the last decade, studies documenting the introduction and development of electronic consent technologies to support the transition from paper-based to electronic consents have been published. Many universities and organizations have contributed to developing multiplatform open-source consent systems for research and treatment. Apple’s ResearchKit provides an open source framework to create visual consent templates. Similarly, in its early stages, ‘Consent2Share’ is an open source web-based consent tool developed by SAMHSA which supports a patient facing interface with granular and dynamic consent choices. Electronic consents could be more convenient, less time consuming, more informed and interoperable with EHR systems. Studies and pilots have noted improved comprehension, better patient awareness, reduced provider workload, improved patient and provider satisfaction and more effective consent management with the transition to electronic consent systems.

The main objective of this paper is to observe, capture and report on the current state of consent tools and processes for treatment and care at two community behavioral health clinics in Phoenix, Arizona to better understand behavioral health consent workflows and challenges and to identify improvement opportunities related to electronic consent technologies. The outcomes presented in this paper will contribute to the broader goal of deploying a patient-centered electronic consent tool, My Data Choices (MDC), that supports more granular data access for patients with behavioral health conditions and surrogates based on interoperability standards.

Methods

Study Participants

Following Institutional Review Board (IRB) approval, subjects were recruited from two outpatient behavioral health clinics in Phoenix, Arizona. Patients and legal guardians of patients diagnosed with general mental health illness or SMI and providers involved in the consent process, were enrolled. Patients and legal guardians were required to be 21 years old or older and English speakers. Participants were identified by facility staff during routine clinical visits and referred to recruiters. Participating providers at each facility were 21 or older, certified behavioral health professionals with experience as case managers and/or behavioral therapists. Patients, legal guardians and providers to be observed were consented by recruiters before the observation sessions. Participating patients and legal guardians were compensated for their participation with gift cards.

Study Sites

Our study sites include one clinic (Site 1) which offers general behavioral health and social services to children, families and adults of all ages. Licensed clinicians are responsible for treating and consenting the patients at Site 1. Study site 2 offers a range of recovery-focused services to adult patients with SMI. Providers consenting the patients at Site 2 are case managers. Both the study sites use a similar proprietary EHR system with embedded consent management and e-signature systems. The EHR system used in both facilities is widely used in the US, including customizable behavioral health modules. Use of the same EHR system in these two different care environments aided in the capture of comparable and contrastable workflow processes at both sites.

The Network: Arizona’s statewide physical and behavioral health information exchange, also known as ‘The Network’, follows an opt-out consent model where patient data is automatically shared unless explicitly declined to share. About 6.7 million Arizona patients receiving care from 246 participating providers are enrolled in the state. Physical and behavioral health information is shared automatically, except the alcohol and drug abuse records protected under 42 CFR Part 2 regulations, accessible only if the explicit opt-in consent is obtained which requires a patient consent to share personal health information.

Consent Observations

For this non-participatory qualitative study, seven graduate students and one undergraduate student, all from the Department of Biomedical Informatics at Arizona State University (ASU) completed IRB and facility requirements, including Human Subject Protection and HIPAA training, completion of required documents from the study sites and compliance with Level 1 fingerprint security clearance.
Prior to observations, students reviewed hard copies of electronic consent forms used at each site. A semi-structured Observation Outline (Table 1) was developed by ASU researchers to guide observers and was piloted during the consent sessions. The goal of the outline was to capture qualitative and quantitative information such as demographics of the process, formats of consent, quality of patient/legal guardian-provider interactions, and patient consent choices. The Observation Outline was divided into five sections:

1. **Header**: captured information about the observer, study site, date of observation and length of the observation in terms of start and end times.
2. **Demographics of the process**: six questions (Questions 1-6) related to consenter (patient or legal guardian) observed, accompanying individuals, purpose of the visit, types of consent reviewed and discussed, and format of consent (paper, electronic or both).
3. **Quality of provider-patient/legal guardian interaction**: eleven questions divided in four sections (Questions 7-10) assessed the quality of the provider’s consent explanation, questions or clarifications asked by the consenter and provider’s responses, and moods of patient/guardian and providers.
4. **Patient choices**: five questions in one section (Question 11) to record consent choices of patient/guardian, and related discussions.
5. **Additional notes**: allowed observers to document comments that they deemed important during the observation.

The sessions were carried out in providers’ personal offices or facility meeting rooms. Each session was observed by only one student observer. Observers documented processes using the Observation Outline form, but were not permitted to ask questions or otherwise participate in or interfere with the session. Though the providers and patients/legal guardians signed a consent to be observed, they were unaware of the objectives of the observation or the content of Observation Outline.

We assessed the readability of the facility consent forms per Flesch-Kincaid Grade Level (FKGL) test in Microsoft Word software. FKGL scores range from a minimum of grade level 1 but do not have a maximum grade level calculation bound\(^2\). Even though FKGL scale was designed to measure readability of school texts, it is widely used to measure readability of informed consents, patient education materials and medical literature\(^1\). It is anticipated for scores beyond grade level 12 to bear less practical validity.

**Workflow Analysis**

After completing the observations, ASU students created mental models of the consent workflows at Sites 1 and 2. Discrepancies were resolved through consensus. The purpose of this process was to identify similarities and
differences of consent processes between the facilities. A generalized workflow was created using a free, web-based workflow modeling tool, LucidChart23.

Results
Consent Observations
Of the 20 observed consenters, 19 (95%) were patients and one (5%) was a legal guardian. Participants at Site 1 included 10 patients with general mental health conditions and 7 providers. At Site 2, participants included 9 patients with SMI, 1 legal guardian of a patient with SMI, and 7 providers. In one case, other individuals (such as family, caretakers, etc.) who were not legal guardians accompanied patients during the session.

The average length of sessions at Site 1 was 10 minutes (range 5 - 20). An average of 3 forms (range 1-5), were discussed during the process. At Site 1, the readability of the forms ranged between grade level 10.6 to 12.1. At Site 2, the average length of session was 23.1 (range 3-36) minutes. An average of 6.1 (range 1-11) forms, were discussed. Readability of the consent forms at Site 2 ranged between grade level 7.0 and 15.0.

At both sites, observers identified a variety of consent forms covered during respective processes. Site 1 used electronic consents exclusively, while Site 2 providers used both paper and electronic consents based on patient preference. In all sessions, providers referenced their computer (desktops or laptops) screens to explain electronic consents. In 20% of sessions, providers referred also to paper-based materials to explain consents. Observers rated the explanations provided by the providers at both sites while categorizing the explanations into three categories: ‘Excellent’ (40%), ‘Good’ (40%) and ‘Poor’ (20%).

The number and type of consent forms discussed per session were based on the purpose of the appointment. Of the 10 appointments at Site 1, 9 (90%) appointments were for new patients, followed by 1 (10%) appointment for yearly reassessment. On average, new patients completed 2.6 (range 1-5) forms and the reassessment patient completed 3 forms. At Site 2, 5 (50%) appointments were for new patients and 5 (50%) for transfer patients. The new patients at Site 2 completed an average of 6.4 (range 2-10) forms, whereas the transfer patients completed 5.8 (range 1-11) forms.

Each site had unique consent forms. Table 2 provides a summary of the types of consent forms observed at both sites. Most of the forms, except forms 3a-3e, supported broad consent models. Forms 3a-3e provided consenters with granular consent opportunities to share or restrict specific health information (such as medications, assessments, diagnosis, substance abuse and HIV related information, treatment and discharge records and psychotherapy notes) and to direct the information to and from specific entities such as patients’ primary care provider (PCP) or other specialty providers, family members, living facilities (such as group homes) and any federal or state government agencies (e.g. Department of Child Safety or data protected under 42 CFR Part 2 regulations), as necessary.

In most sessions (75%), providers asked consenters if they had any questions. Overall, among all the sessions, only two (10%) of the consenters had any questions. One of the two consenters asked questions pertaining to what type of personal health information to share and with whom. No consenters had any questions about how consents would
affect their care. Further, observers noted the quality of provider responses to questions by the consenters. One response was rated ‘Excellent’ and one was rated ‘Good’. Only one of the two consenters who asked questions was found receptive to the provided explanations.

Observers rated the mood of the consenters and providers during the process. The response options for this section were: a) Angry/Frustrated, b) Sad, c) Uninterested/bored, d) Overwhelmed, e) Other. The researchers subjectively categorized the responses in category ‘Other’ as: ‘Interested’, ‘Happy’, ‘Depressed’, ‘Confused’, ‘Annoyed’, ‘Optimistic’, ‘Nervous’ and ‘Neutral’. The most common response for the mood of the consenters between both facilities was ‘Interested’ (40%), followed by ‘Neutral’ (20%) and ‘Happy’ (20%). Some of the less common responses were: ‘Uninterested’ (5%), ‘Depressed’ (5%), ‘Confused’ (5%) and ‘Annoyed’ (5%). When it comes to the providers’ overall mood, the common response was ‘Interested’ (45%) followed by ‘Happy’ (30%) and ‘Neutral’ (20%). One (5%) provider each was rated as ‘Annoyed’, ‘Optimistic’ or ‘Nervous’.

Lastly, observers noted the consent choices of the consenters. Most participants (90%) chose to consent and share all personal health information with one or more entities (for e.g. PCP, family, care facility, etc.). Two (10%) participants chose to provide consent to share some information (such as restrict medications from PCP and treatment records from family) and restrict certain information. No explanations or information were provided by the providers to the consenter regarding decision to restrict the health information and any consequences.

Issues with the consent processes were reported as free text. We identified seventeen free text notes related to five themes: a) education methods, b) consenter-provider interaction, c) consent interruptions, d) use of electronic consent technology, and e) use of paper-based consents. In 6 (35.3%) sessions, no visual guide was provided for consenters during explanation referencing screen. In 4 (23.5%) sessions, observers recorded lack of interaction such as eye contact between consenters and providers. There were also interruptions due to location-based noise and distractions by persons accompanying the patients (17.6%). In 3 (17.6%) sessions, problems with the function of the electronic consent technology were noted. Lastly, in 1 (5.9%) session, a provider left the meeting space to print consent documents requested by the patient.

**Discovered Workflow:**

![Generalized Consent Process Workflow](image)

**Fig. 1** Generalized Consent Process Workflow, from observations at behavioral health Sites 1 and 2. In color Yellow, workflow step sometimes observed at Site 1, in color Blue workflow step (printing the filled consent forms when patient/legal guardian prefers signing paper-based consents) only observed at Site 2.

The students observed ten consent processes at each site and created a generalized workflow to describe the steps involved in the observed consent process (Figure 1). Any observed differences in consent workflows between Sites were noted in the workflow. Below we provide a step-by-step description of the observed consent workflows:
Step 1: The consent process starts with provider meeting the patient/guardian and accompanying members, if any, in ‘Patient Waiting Areas’ and escorting them to the meeting space.

Step 2: In the meeting space, the provider chooses one consent form from a potential set of forms and verbally explains it with the aid of their computer systems, based on the type of appointment and requirements.

Step 3: The consenter is asked if s/he has questions about the specific consent form.

Step 3a: If the consenter has questions, the providers clarifies consenter’s concerns.

Step 4: The consenter makes consent choices. In the case of release of information forms (Forms 3a-3e from Table 2), the consenter can choose whether to provide consent to share ‘all, some or none’ of their information and with whom.

Step 5: The provider either requests the consenter to provide an electronic signature or requests to sign the paper copies of the consent form (only observed at Site 2).

The described process (steps 2-5) is repeated for each consent form, based on the set of consent forms to be discussed.

Step 6 and 6a: Consenter is offered and provided a printed copy of the signed consent form/s, as per their preference (sometimes at Site 1).

Site 1 consenting sessions were performed before the therapeutic treatment sessions, instead of after the session, to better accommodate student observations. This modification could have introduced changes in the workflow and consent session length.

Discussion

Literature describing the use of electronic consent technologies is increasing. Much of the research has focused on consent for clinical research and patient recruitment. These have identified increased flexibility and interest, greater comprehension and patient engagement, reduced provider workload and higher satisfaction among patients and providers as potential benefits of electronic consent. As well, the transition from paper consent forms to tablet or web-based consent tools is noted to be feasible, effective and preferred by users. However, we identified no studies that analyzed the consent process in the routine ambulatory environment using electronic consent tools.

Informed consent for patients with behavioral health conditions is complicated by comprehension and decision-making issues. Disorders and treatments that impair cognitive and intellectual functioning interfere with the comprehension and retention needed to make informed decisions. Similarly, certain conditions may produce declines in intellectual processes, compromised judgement and insight impairment. These factors can contribute to increased cognitive load and result in confusion for some individuals, especially those with behavioral health conditions.

The lack of preexisting studies on consent processes and the effect of electronic consent tools on behavioral health patient and surrogate engagement convinced us of the importance of this research. It is particularly important for behavioral health patients that the consent process is understandable and low burden, but our study findings suggest that current processes differ from these expectations. Below we summarize our observations during the consent process at two outpatient behavioral health clinics, Site 1 and Site 2:

The consent forms offer granular choice: Both study sites currently offer patients a certain level of granular choices to share/restrict health information (Table 1, forms 3a-3e), specifically medications, assessments, diagnosis, substance abuse and HIV related information, treatment and discharge records and psychotherapy notes. This is consistent with the recommendation from the Office for the National Coordinator for Health Information Technology and with patients’ desires for more control over data sharing and in compliance with regulations.

The consent process is burdensome and time consuming: The consent process duration ranged from 3 to 36 minutes between both sites. Consenters completed multiple forms electronically (desktop or laptop) or paper-based forms during the process, with average of 5 forms and 2.25 pages of written information. In the worst case, one consenter was asked to complete 11 forms; this process consumed 34 minutes during which 15 pages were discussed. The length of the consent process and number of forms covered, in part reflect the distinct patient populations (general mental health vs. SMI) they serve. However, within each site we observed variation in the process based primarily on the type of visit, i.e. new or established and the nature of the presenting problem. Such variation reflects the necessity of personalizing the consent process for each patient within the structure of a standardized protocol and process.

The reading level of consent documents is high: An average American reads at an eighth-grade level. This was affirmed by Doak and Doak who studied the average reading level of patients in a public hospital and found that despite reporting high school education, most patients read at a seventh-grade level. A 2007 review of 154 informed consent forms from mental health studies in Massachusetts that found the consents were written at an average of 12-14.5 grade level. This is consistent with our study where the mean reading level of consent documents ranged from
grade 7.0 to 15.0. To accommodate patients with low reading levels or low health literacy, Paasche-Orlow and Taylor suggest the target reading levels of grade 4 to 6\(^2\).

The terminology and layout of consent forms are variable: Study Sites 1 and 2 use consent forms which serve similar purpose but are titled differently. For example, the Release of Information form is known as ‘Consent for Disclosure of Confidential Information’ at Site 1 and ‘Consent to Release Protected Health Information (PHI)’ at Site 2. There also appears to be an effort towards consolidation of some related forms, as exhibited in Site 2 (Table 2, forms 3a-3e and 4). An additional issue results from different titles for a similar process. Site 1 refers to the consent process as ‘Intake’ while Site 2, calls this segment the ‘Welcome Packet’. Such variations may cause confusion for the patient, especially as they visit other medical facilities and execute similar documents.

The physical space was not organized optimally: Effective patient-provider communication and shared decision making can improve the efficacy of the informed consent process\(^29\). However, we observed that the seating arrangement and the location of the consent technologies (i.e., desktop computers and signature pads) could be improved. Observers noted lack of eye contact and the absence of visual aids. Combined, these issues in setup can interfere with the consent interaction, affect consentor comprehension and may lead to a lack of shared decision-making between patient and provider.

Though the sample size was small and the observations limited to two clinics, we offer these corresponding consent process areas for improvement:

**Standardize the consent processes, forms and terminology, where possible:** With the involvement of the behavioral health facilities, attempts could be made to understand if some of the observed processes, forms and terminology could be standardized to reduce variability. We do acknowledge that the differences in patients’ demographics (general behavioral health vs. SMI), providers’ roles and relationships with patients, and types of services could impose constraints in the standardization process.

**Combine consent forms:** As feasible, multiple consent forms should be combined (as it was observed at Site 2, when ‘Release of Information’ and ‘Consent for Email/Voicemail Communication’ forms were consolidated), to streamline the consent process.

**Reduce reading levels and length of consent forms:** Embedded consent forms that are written for sixth-grade level and content divided into easily digestible thematic sections might help to increase patient focus, understanding and reduce cognitive load.

**Address challenges in provider-consenter interaction related to physical space and technology arrangements:** As consents are embedded in the EHR, providers take an active role while consenters are generally passive during the consent process. Electronic consent tools supporting multiplatform interfaces could allow providers and consenters to interact with the tool on any stationary (such as desktop) or mobile (such as tablets or smartphones) device. Potential use of handheld mobile devices can provide mobility to the providers in the meeting space, foster improved provider-consenter interaction and allow consenters to take an active role in the process.

**Incorporate multimedia educational material:** Multimedia education use has shown promise among physical and behavioral health patients with increased understanding, comprehension and interest towards treatment and care\(^29\). Embedding on-demand educational material relevant to consents, health data sharing and related consequences into the electronic consent forms would enhance direct patient engagement and involvement in the process.

**Personalize consenter experience:** Consent tools could be personalized based on the type of patient (general behavioral health diagnosis vs. SMI), patient appointment type (such as new, referral.transfer, reassessment), preferred language (English or Spanish) and past user experience (such as providing instructions when using the tool for first time). Personalized experiences and flexibility to access the tool virtually (inside or outside care facilities) could encourage patient engagement and help reduce the complexity and time to complete the consent process.

In terms of methodological improvements, the free text notes from observers helped to identify a need to amend the Observation Outline (Table 1) to reflect some consistent observations, including the lack of visual guides for patients, lack of eye contact between patient and provider and interruptions during the process. Revisions to the Observation Outline would include questions related to quality of the interaction, such as eye contact, conversation, etc., number and nature of interruptions such as environmental noise, disturbances by accompanying member or other staff, etc., technology arrangement and physical space, such as sitting arrangements, direction of computer screens, etc. Furthermore, observers noted challenges related to the use and absence of electronic technologies, such as issues with signature pads or absence of printers in provider meeting space. Observers often subjectively noted consenter or provider moods as ‘Interested’ or ‘Happy’. Certain positive moods can be accommodated in the revised outline. Such revisions could enhance future data acquisition using the proposed Observation Outline instrument.
An important limitation of our study is the number of observations. We observed ten consent processes for each site and included only one legal guardian. Also, each site has multiple providers responsible for the consent execution, but we observed only a limited number of providers. Another limitation is the lack of diversity within the observed population. Only English-speaking consenters and providers were included in the study. Differences in culture, lack of familiarity with the U.S. health care system or the use of translators could greatly affect the dynamics of the consent process. Similar studies should be conducted on a larger and more diverse sample of patients with behavioral health conditions, surrogates, and providers. Companion studies in the physical health environment will also be useful as technology permits greater data granularity.

Conclusions and Future Work
Informed consent establishes ethical safeguards for care and research and protects patient rights. Such protections are particularly important for individuals being treated for behavioral health conditions. Based on our observations of consent processes at two community behavioral health clinics, we identified several challenges and highlighted areas for improvement. These include standardizing the consent protocol and process; applying quality improvement techniques to minimize variation; redesigning consent artifacts to a reading level of grade six; re-imagining the physical space to include technology hardware; and upgrading the electronic consent software. More research is needed to better understand how electronic consent technologies and educational support will impact the informed consent practices and preferences of patients with behavioral health conditions, their surrogates and providers.

The outcomes from this observational study will be supplemented with semi-structured provider interviews and a survey of patients with behavioral health conditions and legal guardians to guide the development of electronic consent tools, such as My Data Choices.

Abstract

In theory, the logic of decision rules should be atomic. In practice, this is not always possible; initially simple logic statements tend to be overloaded with additional conditions restricting the scope of such rules. By doing so, the original logic soon becomes encumbered with contextual knowledge. Contextual knowledge is re-usable on its own and could be modeled separately from the logic of a rule without losing the intended functionality. We model constraints to explicitly define the context where knowledge of decision rules is actionable. We borrowed concepts from Semantic Web, Complex Adaptive Systems, and Contextual Reasoning. The proposed approach provides the means for identifying and modeling contextual knowledge in a simple, sound manner. The methodology presented herein facilitates rule authoring, fosters consistency in rules implementation and maintenance; facilitates developing authoritative knowledge repositories to promote quality, safety and efficacy of healthcare; and paves the road for future work in knowledge discovery.

Introduction

One well established best practice for designing rules for decision support systems (DSS) is that “decision rules should be atomic”.1 Although in theory this is widely agreed upon, in practice this is not always possible. What normally starts as a simple logic statement in the antecedent of a decision rule can develop into what looks as a procedural piece of code when additional conditions are added to the logic in order to restrict the overall rule to a specific context. These additional constraints may very well contain relevant information and are perfectly valid, yet from a knowledge representation perspective, they could be considered contextual knowledge that should be independent from the logic of the rule. For example, a decision rule that alerts for an abnormal laboratory test result should specify the laboratory test result in question, a comparison operator and a threshold value. However, the logic of such rule also tends to include conditions for age and gender, among other patient characteristics. This results in having a single rule with a long conditional expression, or multiple variations for the same rule to account for different age groups and genders. This approach creates rules that are less reusable, with large numbers of pre-coordinated logic expressions that are difficult to maintain.

Consistent with previous work2 we believe that decision rules could be modeled as adaptive agents capable of exhibiting specific behavior in response to their environment,3 where such environment is defined by contextual constraints. This approach allows us to identify and separate contextual knowledge from clinical knowledge and still preserve the intended functionality of decision rules. Furthermore, by clearly separating context from the logic of the rule, we not only facilitate rule implementation and maintenance, but also potentially promote knowledge discovery. The proposed approach to modeling contextual knowledge for decision rules is based on Ontologies, with some basic concepts borrowed from Complex Adaptive Systems and Contextual Reasoning. The work reported herein is part of ongoing efforts to further an authoritative knowledge repository to promote quality, safety and efficacy of healthcare.

Ontologies

An ontology is a conceptualized and agreed upon collection of entities, relations and instances in a domain of interest where all elements are unambiguously described by means of a declarative language and a shared vocabulary.4 From a modeling perspective, ontologies are of particular interest for this project as they align with ongoing efforts for extraction, modeling and curation of expert knowledge currently embedded in a variety of systems across Partners Healthcare.4 A large amount of this expert knowledge is in the form of decision rules, and collecting this knowledge from within a variety of disparate systems into a single platform optimized for curation is a crucial strategic initiative at Partners.10
Complex Adaptive Systems

Holland describes Complex Adaptive Systems (cas) as a large number of simple agents, each exhibiting their own behavior in response to external stimuli. There are seven basics (four properties and three mechanisms) central to all cas. Our previous work incorporated the four basics (aggregation, tagging, building blocks, and internal models) that we believed best contributed to modeling rule interactions. From those four basics, we further explore two mechanisms: a) Tagging mechanism facilitates the formation of aggregates and delimitation of boundaries, the latter being a key feature for describing behavior within a context. b) Building Blocks mechanism allows reusability and building complex things from repetitions and combinations of simple ones. Our modeling efforts align with both mechanisms in that by tagging a decision rule we successfully remove contextual information from the antecedent of the rule, and explicitly set the boundaries of the environment where such a rule applies. As a result, simplifying the logic of the rule makes it more atomic and more reusable.

Contextual Reasoning

Reasoning about context mainly arises from the problem of locality, namely, knowledge that only applies in a restricted world. Such a restricted application might be represented by a set of values that explicitly delimits the boundaries of a world where knowledge is valid. For example, the statement “It’s raining” is true only in the context of a given location and time. This is the contextual information we need to explicitly define a more concise representation of the world. There is no need to define all possible aspects of the world that may determine a particular context, only those relevant to a given circumstance. Using the above example, we do not need to state whether we are wearing a raincoat or not, or the color of the raincoat for that matter, unless, for some reason such information is relevant. As a result, a partial representation — that only includes location and time — suffices for the purposes of setting a context that allows us to determine the validity of the statement “It’s raining.”

For our modeling purposes we aim at characterizing such a world by borrowing concepts from knowledge representation and reasoning for Ontologies and Semantic Web technologies. We specifically base our approach on the metaphor of context as a box. This metaphor defines contextual metadata in terms of three basic elements: a set of parameters $P_i$; a collection of expressions representing the domain at hand; and three abstract forms of reasoning: expand/contract, push/pop, and shifting, each corresponding to an operation on one of the basic elements of the representation, i.e. parameter, value, and expression. Each parameter is seen as a dimension of a box (context), which in combination with a value indicate the position of the specific context within a multi-dimensional space. Hence delimiting what is “inside and outside the box.” The remaining of this section describes in more detail these contextual reasoning operations.

**Expand/Contract:** operations are based on the intuition that an explicit representation associated with a given context only contains a partial subset of facts — information inside the box. As a result, such subset could be expanded as more pertinent information is available, or contracted if information no longer relevant is removed.

**Push/Pop:** $Push$ operation removes information from inside the box and adds it as a parameter value outside the box; conversely, $pop$ removes a parameter value and adds it as information inside the box. For example, if our original statement about the weather were “It’s raining in Boston” then we would only have time as a context parameter (the location information is inside the box). However, we may choose to remove “Boston” from our statement and push it outside the box as location information. These operations have a direct effect on both the number of parameters and their values, while delimiting the box and the information inside it.

**Shifting:** operator allows us to move from one representation to another by changing the value of one or more contextual parameters, as long as the relationship between the parameter’s values and the statements inside the box is known. A simple example would be to state “Today is raining” in the context where the date/time parameter is set to today’s date, and then having the statement “Yesterday it was raining” and shifting the value of the date/time parameter to tomorrow’s date. We can see that both statements refer to the same fact, though the context was shifted.

These operations provide the mechanisms for handling the fundamental aspects of the proposed contextual representation: a) partiality, namely the portion of the world being represented; b) approximation or level of detail by which the portion of the world is being depicted and; c) the point of view or perspective from which the world is being observed. Authors showed that “at a suitable level of abstraction, a logic of contextual reasoning is precisely a logic of the relationships between partial, approximate and perspectival theories of the world.” In other words, from all possible representations of the world, we may choose a (partial) (approximation) of what we consider relevant to our purposes, and needs (perspective).
We believe that the context as a box metaphor is consistent with the Tagging mechanism for cas in that both approaches specify a context and delimit the scope of decision rules. Our only departure from the context as a box metaphor is that we do not allow any overlapping boxes (contexts); all boxes must be mutually exclusive, since any overlap may lead to ambiguity, and its inherent difficulties (e.g. limitations of existing rule engines to deal with ambiguity). In the following sections we will further expand on this notion of decision rules as “agents interacting inside a box.”

Furthermore, by applying these concepts to if...then decision rules we are able to explicitly circumscribe the context where actions specified in the consequent of a rule are executed when the conditions in the antecedent are satisfied.

Modeling Contextual Knowledge as Constraints

Capturing context is critical for understanding and handling knowledge. This is particularly true in a clinical setting where knowledge embedded in decision rules often times is tailored to specific settings and scenarios. However, it is also most desirable to preserve the generality of rules, ensuring a high degree of reusability and maintainability.

![Figure 1. Simplified Schema for Decision Rules.](image)

The schema for decision rules in Figure 1 consists of a) Generic Properties: Provenance, and Constraints for the overall content of the rule, e.g. a decision rule may apply to patients of all ages, and the constraint for AgeGroup would be set to “ANY”, or to both genders, and so the Gender constraint will be set to “ANY”; and b) Type Specific Properties, which model the rule expression (described in Sordo et al.) and represent the rule itself and its behavior. In other words, the “hasConstraint” generic property defines the full context where a rule applies (e.g. “big box”), whereas the type-specific “hasConstraint” defines more restrictive contexts (e.g. “small boxes”) and behavior of the rule. It is worth noting that all restrictive contexts (“small boxes”) must be contained in the full context (“big box”). For example, we could define the generic “hasConstraint” AgeGroup to “Adults”, and then define more specific ones as “Young Adult”, “Mature Adult” to restrict the scope. We currently focus on the type-specific property hasConstraint, and we will further describe it in the following section.

Type Specific Property “hasConstraint”

Rule execution can be constrained to narrower scopes by restricting it to more specific contexts. As long as we keep this in mind, we can define as many “sub contexts”, or boxes as needed for a single rule. For example, an alert for an abnormal laboratory test result may be relevant to all patients regardless of gender and age, and so the constraints in the generic properties of the rule should be set to Gender=“ANY”, AgeGroup=“ANY”. The “ANY” value means that such dimension is unrestricted. However, threshold value(s) for the rule may depend on the age of the patient. Therefore, by specifying such threshold values constrained by age groups in the data definition of the rule expression (type specific property), we can still model an alerting rule as simply as if LabResult <operator> threshold then alert; where the values assigned to threshold are constrained by the context (AgeGroup) where such values apply. Hence, the logic is the same, but the content (operator and threshold values) is defined by the context; in other words, the content – what is inside the box - is dependent on the parameters and values outside the box. This is consistent with the context as a box metaphor. Such metaphor and the operations presented in a previous section lay the foundation for our work and allow us to extend/restrict the scope of such rules.

Clinically-Relevant Constraints

In previous research authors identified clinically-relevant constraints that should be considered when modeling clinical scenarios. Such constraints are represented by three main context dimensions: a) Patient, further subdivided into age, gender, clinical condition, clinical protocol/trial, and health insurance plan; b) Provider-related including: group, role, and clinical specialty; and c) Care Setting consisting of care setting (inpatient/outpatient), geographic region, facility, department, unit, unit type, room, and bed. From these dimensions, we defined a partial approximation by choosing the following four: Patient Gender and Age Group, Care Setting Site, and Venue; and
abstracted away those dimensions that currently do not advance our purposes. However, as our clinical content evolves, we may choose to further expand such partial representation and include additional dimensions. We modeled the AgeGroup dimension as non-overlapping three subcategories: “Prenatal,” “Pediatric,” and “Adult,” with each subcategory potentially containing sub-sub categories. For example, “Adult” may contain “Young Adult,” “Middle Age Adult,” “Mature Adult,” etc. Patient Gender is modeled as “Male” and “Female.” Care Setting Site currently includes a limited number of Partners Healthcare hospitals: “Brigham and Women’s Hospital” (BWH), “Massachusetts General Hospital” (MGH) and, “Newton-Wellesley Hospital” (NW). Venue includes “Inpatient,” “Outpatient,” “Intensive Care Unit” (ICU), and “Emergency Department” (ED). All dimensions support a value of “ANY” to denote that a dimension is explicitly included, but it is left unrestricted. In other words, the scope of a dimension with a value of “ANY” includes all possible values available in such dimension. For example, an AgeGroup dimension with a value of “ANY” would include all three age groups, and be satisfied by any of these values.

These four dimensions define a box into which we place our decision rules. Values of “ANY” to specify the scope of a dimension allow us to always include all four dimensions, even if not restricted. This has the advantage of providing a fully explicit depiction of the dimensions of our box. As shown in Figure 2a, an unrestricted decision rule is placed in a box with all four dimensions set to a value of “ANY”. This means that this hypothetical rule inside the box will apply to any patient regardless of age or gender, at any site or venue. For example, if such rule were to measure potassium levels, Figure 2a would be specifying that such rule would apply at any Site, any Venue, and to any patient regardless of Gender or Age.

![Figure 2](image)

**Figure. 2.** (a) A generic decision rule inside an unrestricted box with dimensions unrestricted with an assigned value of ANY. (b) Rule with context-specific threshold value for adult inpatient females at BWH. (c) Rule with threshold value for adult inpatient males at BWH.

![Figure 3](image)

**Figure. 3.** Mutually exclusive “boxes” stacked to delimit multiple scopes of a single decision rule with context-specific threshold values.

However, if we chose to define a specific threshold value, e.g. 40 mg for adult inpatient women at the BWH, then instead of adding such constraints to the logic of the rule and changing the threshold value to 40 mg, we push the constraint values into the parameters (dimensions) outside the box and expand (add) the context-specific threshold value inside the box (Figure. 2b). This is equivalent to having both the rule and the threshold value dependent on the context. Additional context-dependent threshold values may exist for a given rule. This would be equivalent to “stacking” boxes. For example, we may define an additional threshold value of 30 mg for adult males for the same site and venue for the above rule. We shift the value for the Gender dimension and change the threshold value accordingly (Figure. 2c). This will result in two boxes for the same rule, each having its own context-delimited threshold.
For the sake of graphically representing this notion of “stacking boxes”, let us momentarily abstract away (remove) the Venue dimension, and draw a 3D representation (Figure 3). These two “boxes” are stacked side-by-side to cover the Gender dimension of the context box. Such (broader) Gender “box” is divided into two, more restrictive, non-overlapping boxes, each box describing a partial representation (portion) of the world, with its own threshold value.

We believe that by having fully circumscribed, mutually exclusive boxes representing partial views of the world we can build a robust contextual representation (consistent with cas internal models) of clinical decision rules that can be aggregated and reasoned upon. Similar to the building blocks mechanism of cas, the rationale behind the context as a box approach is to model simple, well-circumscribed behaviors for rules and, then, aggregate them to model more complex behaviors. In the remaining of this paper, we present some exploratory examples and discuss findings and limitations.

Results

We focused our initial analysis on the decision rules used by the Results Manager (RM) computerized application at Partners Healthcare. RM is an application in the outpatient setting consisting of 84 rules that enable clinicians to review, acknowledge, and act upon abnormal/critical results of chemistry, hematology, toxicology, radiology, and cytology tests in a timely manner.

The generic representation of RM alerting rules is as follows: If LabResult <Operator> <threshold> then Alert; where LabResult is the value of a given laboratory test result, e.g. “Potassium” (chemistry), “Acetaminophen” (toxicology), “INR” (hematology); Operator is a comparison operator to determine whether the laboratory test result is normal/abnormal when compared to a threshold value. Threshold value is a reference value for the laboratory test based on values found in a particular population cohort. Rules were enhanced to include variations on reference threshold values based on gender, age, and health status of the patient, resulting in a repository of 166 rules. For example, a patient in the ICU or with a chronic condition most likely has some abnormal laboratory test results. This is why, besides age and gender, venue is important to determine the threshold value of a test. We propose the following approach: starting with the general representation of the rule, with all dimensions set to “ANY”, we push the constraint on the venue dimension outside the box, and expand (add) the context-specific threshold value inside the box. Therefore, in this scenario, the venue would be set to “ICU”, and the threshold value for patients in critical condition would be added inside the box, with the desired effect of having a decision rule with a threshold value targeted to a specific context, that will only trigger an alert under these more delimited circumstances.

Some chemistry rules may need to be restricted to age ranges within an AgeGroup. For example, for patients with some suspected thyroid gland dysfunction, a thyrotropin (TSH) chemistry test might be ordered to check the endocrine function of the gland. TSH reference values are age-related, with specific reference values for Pediatric and Adult populations, with further subgroups in the Pediatric population with age ranges of [1 day, 4 days), [4 days, 8 days), and [8 days, 18 years). The initial generic representation of this rule is depicted in Figure 4a. In Figure 4b, we push the Adult AgeGroup outside the box and expand the operator and threshold value. In Figures 4c-4e, we shift the AgeGroup to Pediatric (PEDI) and include the additional age range, and replace (contract and expand) the facts inside the box for threshold and operator.
Figure 4. An example of pushing, expanding and shifting parameters for a single rule in multiple contexts.

Discussion

We have demonstrated the feasibility of the modeling strategy proposed above by implementing relevant test scenarios through our analysis of the clinical decision rules in the aforementioned application. Currently, our model supports non-overlapping, mutually exclusive contexts consistent with most our current decision rules. However, we anticipate the need for more flexible rules that could interact in environments where such clear boundaries do not apply. We have incorporated a “degree of membership” to our model to deal with potential overlapping “boxes”, though at the time of writing, we have not evaluated it.

We have shown that with a relatively simple approach we can model abstract contextual knowledge from a variety of rules while preserving the desired functionality. We found that by applying contextual reasoning operators we could expand/contract the context where decision rules apply, while keeping the rule representation as atomic as possible. Further, given that both contextual and clinical knowledge may lie on the same continuum with no fixed point separating them, having the flexibility to vary the degree of approximation of a given representation allows us to regulate the interplay between what goes inside (clinical knowledge) and outside the box (contextual knowledge). By doing so, decision rules can easily be adapted to new contexts, without encumbering the rule logic with extra conditions. We believe this approach is consistent with the internal models and building blocks concepts of complex adaptive systems, and it will allow us to model more complex behavior for rules while preserving a simple and sound representation. Likewise, from an ontology perspective, the same mechanisms can be applied to represent both contextual and clinical knowledge as “conceptual building blocks” that can be reasoned upon while preserving the correctness and expressiveness of the underlying ontology.

Conclusions

Sound and comprehensive approaches are key to accurately modeling knowledge content of any type. In the case of clinical decision rules, it is highly desirable to capture and model not only knowledge pertaining the logic and actions of such rules, but also the context where such knowledge becomes relevant and actionable. Currently, contextual knowledge is not identified as such at modeling time, and we strongly believe that it should be. Such contextual knowledge should be removed from the antecedent of a rule, so the logic remains as atomic as possible. The proposed approach provides the means for identifying and modeling contextual knowledge in a simple, yet sound manner. Furthermore, the methodology presented herein facilitates rule authoring, fosters consistency in rule implementation and maintenance; facilitates developing authoritative knowledge repositories to promote quality, safety and efficacy of healthcare; and paves the road for future work in knowledge discovery.

Reducing the Toxicity Risk in Antibiotic Prescriptions by Combining Ontologies with a Multiple Criteria Decision Model

Souhir Ben Souissi, MSc1,2,3, Mourad Abed, Prof1, Lahcen Elhiki, Dr2, Philippe Fortemps, Prof3, Marc Pirlot, Prof3

Abstract

We consider the risk of adverse drug events caused by antibiotic prescriptions. Antibiotics are the second most common cause of drug related adverse events and one of the most common classes of drugs associated with medical malpractice claims. To cope with this serious issue, physicians rely on guidelines, especially in the context of hospital prescriptions. Unfortunately such guidelines do not offer sufficient support to solve the problem of adverse events. To cope with these issues our work proposes a clinical decision support system based on expert medical knowledge, which combines semantic technologies with multiple criteria decision models. Our model links and assesses the adequacy of each treatment through the toxicity risk of side effects, in order to provide and explain to physicians a sorted list of possible antibiotics. We illustrate our approach through carefully selected case studies in collaboration with the EpiCURA Hospital Center in Belgium.

Introduction

Adverse drug events are one of the most important causes of mortality in the healthcare context. They claim each year between 700,000 and 1.5 million casualties in the United States1. From these, antibiotics are the second most common cause of drug related adverse events2,3,4 and one of the most common classes of drugs associated with medical malpractice claims5. Every antibiotic treatment is associated with a risk rate, i.e., an assessment of the degree of risk, which takes into account both the severity and the frequency of undesirable side effects. Determining the best treatments is highly dependent on the considered acceptance risk. The acceptance risk of a particular treatment varies according to the vulnerability of the patient. Therefore, physicians are in need of support that can give them both an overview of the situation, but also a detailed description of the risk and the vulnerability of each patient.

For many hospitals, guidelines constitute the solution to guide antibiotic prescriptions, by linking infection diagnosis to the relevant antibiotic therapies. As an example, our collaborators in the EpiCURA Hospital Center have been using a hundred-page guideline since 20116. Unfortunately, there is evidence showing that little or nothing has really changed regarding the malpractice issue in spite of the existence of guidelines. The main causes of this situation are that a) the physician cannot have a global view of the guidelines or complete explanations for the suggested treatment; b) in their current textual form these guidelines are completely static, making them hard to use and adapt to either the specific needs of the patient or the changing environment context (e.g. usage in emergency rooms).

Using decision support systems (DSS) in a clinical context is mainly about providing recommendations to physicians. Some of these Clinical DSS are using semantic technologies. From this perspective, Bright and coauthors7 have developed a formal ontology to structure the empiric antibiotic therapy guidelines of the New-York Presbyterian Hospital (NYP). The guidelines in this study have been explicitly entered in Protégé. This work was able to generate three kinds of prescribing alerts when the guidelines were not respected. Despite its advantages, this approach has serious limitations. Its main drawback is that both the basic data and the relationships between them should be explicitly entered in the system (i.e. the system cannot generalize to new data), making maintainability difficult, if not impossible. Other funded projects around semantic technologies for medical procedures such as REMINE8 and PSIP9 use data mining techniques to reduce drug adverse effects by taking into account the patient’s medical record.

Despite these efforts there is currently no widely accepted standardized framework that will help physicians in their day to day prescriptions needs, although some researchers have tried to move towards this direction10,11. The broadest approach has been taken by Doulaverakis and coauthors12,13 to cover drug to drug interactions and drug to diseases interaction but, apparently, with no consideration of patient vulnerability and the risk of the drug side effects. Other
Clinical DSS use Multiple Criteria Decision Aiding (MCDA). For example, the AHP (Analytic Hierarchy Process) method has been used to analyze and compare the treatment options for eradication of H. pylori infection in children. The main limit of this work is the lack of structured objective knowledge. The recommendation is highly sensitive to the stakeholders evaluations and weights.

Clinical DSS have another important task which is to provide physicians with explanations for recommendations. In a previous work, we combined semantic technologies with MCDA to sort alternatives (antibiotics) by their suitability to the subject (patient) but we did not consider the toxicity risk as is done by the physicians (assessing the risk level by combining severity and frequency).

Our objective in this work is to build a model for a clinical DSS that links knowledge structures for assessing the antibiotic prescription risk. The method we propose integrates MCDA with ontologies in order to provide to physicians sorted list of antibiotics assessed according to their toxicity risk for a given patient with an infection disease.

We use ontologically structured knowledge about the pharmacological characteristics of antibiotics and an ontology describing the critical criteria of patients. These ontologies are then linked through a set of rules structured in a Majority Rule Sorting model (MR Sort) with Veto. This model, which is a simplified version of ELECTRE TRI, assesses the alternatives by sorting them into ordered categories. This process results in antibiotic prescription recommendations categorized according to the risk of their side effect toxicity. We model the relations between concepts by simple interpretable rules, involving a small number parameters, to guarantee generality and maintainability of the knowledge model.

The main contributions of this paper are:

- A new model for integrating MCDA with ontologies for clinical Decision Support Systems
- An adapted version of the ELECTRE TRI – Majority Rule Sorting model (MR Sort) with Veto that is tailored to prescription recommendation with explanation.
- An experimental validation of the above model for categorization of antibiotics through risk assessment of side-effect toxicity

The rest of the paper is organized as follows: The next section (“The system”) describes our adaptation of the ELECTRE TRI – MR Sort rule, as well as our model for integrating the method with the systematic representation of patient profiles and antibiotic knowledge in ontological structures. Section “Illustration” details our validation of antibiotics categorization through the risk of side-effect toxicity. Finally in the “Conclusion” section, we present further research perspectives.

The system

The Semantic Model Our solution models a patient P that hosts pathogens which cause a bacterial infection. This patient goes to the hospital to seek medical care and requires a treatment by antibiotics. The first step of the decision support model for antibiotics prescription is to gather knowledge.

For this purpose we use an ontology O_P that models the patient and his/her relevant characteristics. These involve gender, age, comorbidities, allergies, and all the necessary patient information in order to assess the efficiency and the hazard of an antibiotic. All these characteristics influence the choice of an antibiotic in a way which is specified in reasoning rules. Indeed, a given antibiotic could suit a pregnant woman but not an old diabetic man, or conversely.

The variable \( SP_j \rightarrow \{0, 1, 2\} \) represents the sensitivity indication of patient to the side effect \( S_j \). A value 0 means “no sensitivity”, a value 1 means “minor sensitivity”, while 2 represents “major sensitivity”.

Our second ontology \( O_A \) provides us with the set of side effects \( S_j \) of a given antibiotic \( A_i \).

The variable \( RSA_{ij} \) is the risk of side effect \( S_j \) caused by antibiotic \( A_i \). It represents the relation between an antibiotic \( A_i \) and a side effect \( S_j \) with indication of harmfulness. \( RSA_{ij} \) combines the intrinsic (i.e., independent of the anti-
The values of the severity $GS_j$ are presented in Table 1. Value 0 indicates that side effect $S_j$ is not severe. Value 1 indicates that the side effect $S_j$ is severe. Similarly, value 3 corresponds to a harmful side effect. The frequency values $FSA_{ij}$ are presented in Table 2. Value 0 represents a less than $1/10,000$ chance that antibiotic $A_i$ has side effect $S_j$. Similarly, values 1 and 2 represent the chance being between $1/100$ and more than $1/100$, respectively.

Currently we deal with a total of 45 side effects organized in 8 categories for 60 antibiotics and 22 patient criteria.

**The MR Sort model with Veto for assigning objects to ordered categories** We use the MR Sort (Majority Rule Sorting) model with Veto (18,19,21) to classify the antibiotics for a given patient in ordered categories. MR Sort with Veto is a variant of ELECTRE TRI, which is a decision model belonging to the family of outranking methods (22, 23). The goal of MR Sort (and ELECTRE TRI) (24) is to sort alternatives in ordered categories based on their performance on several criteria. In our context, the alternatives are antibiotics $A_i$ and the criteria are the side effects $S_j$. The performance of an antibiotic w.r.t. a side effect for a given patient is determined by three elements: the severity $GS_j$, the frequency $FSA_{ij}$, and the sensitivity of the patient to the side effect $SP_j$.

Each category $C_k, k = 1, \ldots, K$, is associated a lower profile $t(C_k)$, which is a vector of levels on each criterion representing the minimal requirements to belong to category $C_k$. Actually, not all these requirements are to be fulfilled, but only a sufficiently large majority of them, in order for an alternative to be assigned to this category. The majority condition can be implemented by assigning weights to the criteria and selecting a majority threshold; the condition is fulfilled whenever the sum of the weights of the criteria on which the alternative is at least as good as the profile passes the majority threshold. A simpler version of this rule consists of counting the criteria on which the alternative is at least as good as the profile; the condition is fulfilled whenever this number passes a minimal fixed number of criteria (This is tantamount to assigning equal weights to all criteria). An additional condition for being assigned into category $C_k$ is that none of the alternative performances is “unacceptably bad”. Unacceptably bad performances are determined by veto thresholds on each criterion. Whenever the performance of an alternative on some criterion is worse than the corresponding profile performance by some specified quantity, a veto is activated which precludes assignment into the category.
To sum up, the principle implemented in MR-Sort with Veto in order to assign alternatives into categories is the following: An alternative is assigned to category $C_k$ or better (i.e. $C_{k+1}$ up to $C_K$) if the performances of the alternative are at least as good as those of the profile $t(C_k)$ on a majority of criteria and none of these performances falls below the veto threshold on each criterion.

In this work, we chose to use MR Sort with Veto for two reasons. On the one hand, it gives us structured rules to link the antibiotic knowledge structure to that of the patient. On the other hand, it provides us with an assessment of the suitability of the antibiotics to the patient. In addition, our method assigns the antibiotics (alternatives) in three categories ($K = 3$): $R$ (“recommended”), $P$ (“possible”) and $TBA$ (“to be avoided”), according to their toxicity risk.

The MR Sort with Veto assignment principles are applied to the context of antibiotic prescription, yielding the following rules:

- An antibiotic is assigned to category $R$ for a given patient if it has only a small number of side effects that the patient is sensitive to and if there is no unacceptable side effect (risk) for the same patient (no veto against $R$).
- A similar rule applies for an antibiotic being assigned to category $P$. The number of side effects tolerated is higher than those for category $R$ and the list of unacceptable side effects (risk) can possibly be smaller.
- If none of these conditions are fulfilled, the antibiotic is assigned to category $TBA$.

**Coupling ordered classification with the Semantic Model** MR Sort with Veto is combined with the Semantic models to assess one by one each antibiotic $A_i$ (as illustrated in Fig. 1).

These assignment principles are implemented using the following mathematical representation:

- $A_i, i \in 1, \ldots, n$ denotes the antibiotics that are potentially considered, i.e., antibiotics that cover the germs infecting the patient.
- $S_j, j \in 1, \ldots, m$ denotes the possible side effects of an antibiotic.
- $CSA_{ij}, i \in 1, \ldots, n, j \in 1, \ldots, m$ is a variable taking its values from $\{0, 1, 2\}$. It represents the level of risk of side effect $S_j$ of antibiotic $A_i$ for the patient (taking into account the sensitivity of the patient to side effect $S_j$.

$$CSA_{ij} = \begin{cases} 
0 & \text{if } SP_j = 0 \\
1 & \text{if } SP_j > 0 \text{ and } 1 \leq RSA_{ij} \leq 2 \\
2 & \text{if } SP_j > 0 \text{ and } RSA_{ij} = 3
\end{cases}$$

- $CSA_i$ is a number associated to antibiotic $A_i$. It counts the number of risky side effects $S_j$ such that $CSA_{ij} \neq 0$.
- Two tolerance levels $\lambda_R, \lambda_P$ with $\lambda_R < \lambda_P$ determine the maximal number of side effects (risk) that are compatible with an assignment in categories $R$ and $P$, respectively.
- An unacceptable risk ($CSA_{ij} > 1$) can prevent assignment of $A_i$ to category $R$ or $P$. The list of unacceptable risks for an assignment to category $R$ (resp. $P$) is a subset $Veto[R]$ (resp. $Veto[P]$) of the set of all side effects risks. The vetoes are presented in Table 3.

For a given Patient, the assignment of a suitable antibiotic $A_i$ to the class $R$, $P$ or $TBA$ is summarized in Table 4. $CSA_{ij}$ counts the number of side effects the patient is sensitive to. The first tolerance level, $\lambda_R$, is the maximum number of side effects the antibiotic could have to be in the $R$ (recommended) category. The second tolerance level, $\lambda_P$, is the maximum number of side effects the antibiotic could have to be in the $P$ (possible) category. In our application, $\lambda_R$ was empirically set to 6 and $\lambda_P$ to 12. Some side effects can induce a high risk on a patient, which
Figure 1: Using MR Sort method with Veto in the Semantic Model to link and to assess antibiotics for a patient by toxicity risk explains the usefulness of vetoes (Table 3). The first veto, Veto[P], is put when the antibiotic has an unbearable side effect for the patient. This antibiotic could not be prescribed, even though it only has this side effect. For example, this veto would be raised if the antibiotic contains penicillin (RSA_{ij} = 3) and if the patient has a major allergy to penicillin (SP_j = 2). With a Veto[P], the considered antibiotic is put in the TBA category. Similarly, a second veto, Veto[R], is put when the antibiotic has a very rare severe impact on the patient health (RSA_{ij} = 1), which, however, is not unbearable. For instance, an antibiotic which contains penicillin would get this Veto[R] if the patient has a minor allergy to penicillin (SP_j = 1). With the Veto[R], the considered antibiotic A_i is put either in the P (possible) or in the TBA (to be avoided) category, depending on the value of CSA_i.

Illustration

In order to illustrate the model, we built a scenario through several meetings with practitioners of the EpiCURA Hospital Center (infectious diseases specialist, microbiologist) through which we were able to tune the sensitivities and the thresholds of our model. For the purpose of illustration, we present the following case:

Bill is a 68 years old man, he is suffering of alcoholism problems and he is diabetic. He comes to the emergency room with an increased temperature of 40.1°C and he has an inflammation in his leg (see Fig.2). It is later revealed, that he got injured 2 days before when he was gardening. The diagnostic yielded is “Erysipelas”.

</tr>
</tbody>
</table>

Figure 2: Erysipelas around the ankle

Figure 3: Guidelines recommendation for Erysipelas

The guidelines (Fig.3) inform us about the pathogens which cause the infection. In our example, the pathogens in question are *Staphylococcus Aureus* (MSSA) and *Group A streptococci* (GAS), as indicated in the second line of Fig.3. To suggest an appropriate antibiotic, the guidelines distinguish three situations with respect to penicillin: (a) a patient who is not allergic to penicillin, (b) a patient with a minor allergy and (c) a patient with a major allergy. In the latter two cases, it suggests two different antibiotics.

Table 5 gives us the set of side effects (we did not present all the side effects that Bill is sensitive to, because for this use case the set of all antibiotics (Table 6) that can help Bill don’t have them; in terms of frequency, $FSA_{ij} = 0$), that Bill is sensitive to. $SP_j$ denotes the sensitivity of Bill to the side effect $S_j$, $j = a, ..., h$.

The list shown in Table 6 gives us: The set of antibiotics which are effective against or cover the germs causing Bill’s infection; the set of side effects $S_j$; the severity evaluation of the side effects $GS_j$; the frequency $FAS_{ij}$ and the risk $RSA_{ij}$, where $i = 1, ..., 8$ is the set of antibiotics and $j = a, ..., h$ is the set of side effects.

We sort this list by suitability to Bill. The output of our system for this case is the following:

**P**: Oxacillin, $CSA = 2$, Veto[$R$]

P: Amoxicillin-Clavulanic, $CSA = 1$, Veto[$R$]

P: Piperacillin-Tazobactam, $CSA = 2$, Veto[$R$]

TBA: Clindamycin, $CSA = 2$, Veto[$P$]

TBA: Cefazolin, $CSA = 2$, Veto[$P$]

TBA: Ceftriaxone, $CSA = 2$, Veto[$P$]

TBA: Vancomycin, $CSA = 2$, Veto[$P$]

TBA: Moxifloxacin, $CSA = 4$, Veto[$P$]

Note that, currently, in order to get these results (without using our system), the physician has to manually cross-check and combine several different sections of the guidelines.

More precisely, for a patient that is as much vulnerable as Bill, at least one of the vetoes [$R$] and [$P$] are activated and therefore, no antibiotic is assigned to category “R”. For this kind of situation, indeed, we rarely find antibiotics sorted in the “Recommended” category. The best alternatives are usually sorted in the “Possible” category. The advantage of this kind of output is that it provides the prescribing physician with a global view of the sorted treatments. In addition it gives him/her a detailed explanation of the toxicity risk assessment for each particular patient.

To describe in further details our model, we present here a second scenario. For this scenario we consider the case of "Abscess Perirectal" from the guidelines (as seen in Fig.4).

![Abscess Perirectal](image)

**Figure 4:** Guidelines recommendation for Abscess Perirectal

The guidelines inform us about the pathogens which cause the infection in the second line of Fig.4. For this example, the pathogens are Enterobacteria, Anaerobes, Enterococcus. To suggest an appropriate antibiotic, the guidelines distinguish three possible contexts with respect to penicillin: (a) a patient who is not allergic to penicillin, (b) a patient with a minor allergy and (c) a patient with a major allergy. In the last two cases, the guidelines suggest the same antibiotic.

The list presented in Table 7 gives the set of antibiotics which are effective against the germs causing the infection (Amoxicillin, Clavulanic, Piperacillin, Tazobocamt, Moxifloxacin). The set of side effects $S_j$, where $j = 1, \ldots, 22$ is presented underneath. These side effects can be given by the antibiotics: Amoxicillin, Clavulanic, Piperacillin, Tazobocamt and Moxifloxacin.

The severity evaluation of the side effects $GS_j$; the frequency $FAS_{ij}$ and the risk $RSA_{ij}$ (where $i = 1, \ldots, 3$ is the set of antibiotics and $j = 1, \ldots, 22$ is the set of side effects) are all presented in Table 7. The case description follows:

</table>

Alex is a 29 years old patient, who is suffering from “Abscess Perirectal”. He is otherwise in good health without any history of medical incidents. His laboratory tests reveal that he does not have allergies and his creatinine level is 80ml/min.
For this case of infection, a surgical drainage is essential with antibiotic prescribing. Table 8 indicates the sensitivities $SP_j$ of Alex to the side effects $S_{ij}, j = 1, \ldots, 22$.

We sort this list by suitability for Alex. The output of our system for this case is the following:

- **P**: Amoxicillin_Clavulanic, $CSA = 1$, Veto[R]
- **P**: Moxifloxacin, $CSA = 1$, Veto[R]
- **P**: Piperacillin_Tazobocamt, $CSA = 2$, Veto[R]

If Alex has a “Major allergy to penicillin”, the sensitivities $SP_{19}$ and $SP_{21}$ change: $SP_{19} = 2$ and $SP_{21} = 2$. The output of the system becomes:

- **P**: Moxifloxacin, $CSA = 1$, Veto[R]
- **TBA**: Piperacillin_Tazobocamt, $CSA = 4$, Veto[P]
- **TBA**: Amoxicillin_Clavulanic, $CSA = 3$, Veto[P]

The recommendations of our system match the ones in the guidelines (as seen in Fig.4). Even in the case of “Major allergy to penicillin”, Moxifloxacin remains the only option.

**Conclusion**

We have developed a novel approach to help physicians with antibiotic prescriptions. Our solution combines semantic technologies with our own adaptation of the MR Sort method with Veto.

Our method sorts antibiotics in three categories: **R** (“recommended”), **P** (“possible”) and **TBA** (“to be avoided”) based on a small number of general rules. It is able to take into account a patient’s specific clinical criteria as well as generalize to new cases when – for example – a new antibiotic is added to the knowledge base. Using input from practitioners in the EpiCURA Hospital Center we have tuned the sensitivities and thresholds of our model and were able to validate our approach through examples that score prescription recommendations according to the risk of side effect toxicity.

In terms of future work we would like to apply our model to other types of drugs to determine if our method is applicable beyond antibiotics. We plan to expand our model to other dimensions of the prescription problem including: costs, drug-drug interaction and drug-disease interaction among others.

**Acknowledgement**

We are grateful to Dr Jean Pierre Sabot – medical director of the EpiCURA Hospital Center – for his warm welcome and availability considering our research. We also want to thank Dr. Sammy Place (infectiologist), Dr. Lorenzo Filippin (microbiologist) as well as all the EpiCURA Hospital Center staff for numerous helpful meetings that allowed us to improve and validate our approach.

A Data-Driven Method for Generating Robust Symptom Onset Indicators in Huntington’s Disease Registry Data

Zhaonan Sun1, PhD, Ying Li1, PhD, Soumya Ghosh1, PhD, Yu Cheng1, PhD, Amrita Mohan2, PhD, Cristina Sampaio2, MD, PhD, Jianying Hu1, PhD

1 Introduction

A disease registry is an organized system that uses observational study methods to collect uniform data to evaluate specified outcomes for a population defined by a particular disease, condition, or exposure, and that serves one or more predetermined scientific, clinical, or policy purposes[1]. Different from Electronic Health Record (EHR), whereas the research of understanding a particular disease belongs to the secondary use of data, the disease registries serve as a primary source to study the target disease. As a primary source, the registry data usually involves data generated from known and comprehensive clinical assessments for the target disease, and therefore a disease registry can be a powerful tool to observe the course of disease, to understand variations in treatment and outcomes, to examine factors that influence prognosis and quality of life, and to assess the clinical cost and quality of care.

The natural course of a disease can be characterized by the onset and progression of symptoms. Measures from clinical assessments are collected in a disease registry for tracking various symptoms of a target disease. However, such measures can be biased since they not only can be affected by the progression of the target disease, but also can be influenced by non-disease-related factors, e.g. selection bias, clinical instrument sensitivity and participant compliance. Moreover, for a symptom of interest, its onset and progression indicator are decided by threshold values of recorded clinical measures. Such threshold values are currently determined based on evaluation of measures recorded in comparable historical studies or by domain expert, and are applied to all participants in a registry. Consequently, they do not take individual variations into account. In order to address the aforementioned issues, data-driven methods are needed to generate robust (less biased) and personalized symptom onset indicators, and as a result, in return for better understanding the natural course of a target disease.

A disease registry may include only people with disease of interest, or may also include one or more comparison groups for which data are collected using the same methods during the same period. Hereinafter, we refer to patients with disease of interest as case participants, while patients in the comparison group who are not at risk as control participants. Control participants may share some similar traits or are exposed to similar environmental factors as case participants. In this article, we propose a data-driven method to generate robust symptom onset indicators based on assessments collected in disease registry data with the requirement that this disease registry should have included control participants. According to our knowledge, the proposed method is the first of its kind that uses control participants in a disease registry to adjust the biases inherited in the raw clinical measurements among case participants. The biases are caused by non-disease-related factors such as natural aging process, education level and marital status. In the remainder of this paper, we will exemplify the application of this novel method to integrated data from observational Huntington's Disease studies.

Huntington’s Disease (HD) is an autosomal dominant fully-penetrant neurodegenerative disorder, which is caused by an abnormal expanded trinucleotide (CAG) repeat in the Huntingtin (HTT) gene[2]. Owing to its monogenic nature, predictive genetic testing is able to determine whether the disease will manifest in an individual. Among genetically confirmed HD patients, a clinical diagnosis of HD is typically made when an individual exhibits overt, otherwise unexplained extrapyramidal movement disorder. While motor impairment is currently the primary indicator of clinical onset, cognitive[3] and certain behavioral disorders[4] are also known to surface years before motor onset. As such, clinical measurements along these dimensions are also important for understanding the progression of the disease. Functional assessments in particular are important in measuring overall quality of life of individuals with HD and prove useful for a descriptive characterization of HD progression.

In recent years, several large-scale observational studies have been conducted in HD gene expansion carriers (HDGECs)
with the hope to understand the natural history and pathophysiology of the disease. A diverse range of clinical assessments have been designed in HD observational studies to record the triad of motor, cognitive/behavior, and functional symptoms of HD. While accessibility to a wide range of clinical assessments from these domains has helped gain insightful information about the natural history of HD, these clinical assessments are often influenced by factors other than HD disease status and progression. For instance, natural aging processes are especially known to affect participants cognitive and functional abilities. Therefore, absolute changes in most cognitive and functional assessment scores can be attributed to multiple factors including both HD disease progression and the natural aging process, rendering assessment scores less robust for tracking disease progression.

Onset of new symptoms is useful in characterizing the course of HD. Certain clinical measures collected have pre-defined thresholds to indicate reliability of clinical diagnosis. For example, a Diagnostic Confidence Level (DCL) of 4 is used to indicate motor symptom onset, thereby leading to a confirmed diagnosis of HD onset. However, other measures (e.g. the SDMT score, which is used to assess cognitive abilities) do not have clearly defined thresholds for disease onset. To address this inconsistency in a systematic manner, a data-driven method is needed for generating robust symptom onset indicators for better understanding of the progression of the disease.

In this article, we propose a data-driven procedure for adjusting the values of clinical assessments and generating robust symptom onset indicators. Its worth pointing out that although this article and methodology described here relies on HD observational data sets, the methodology can be generalized to other disease registry data if they have also recruited control participants.

For readers benefit, the contents of this paper are organized as follows. In Section 2, we describe the HD observational data used in this work. In Section 3, we describe a novel method for generating robust clinical assessments from the outcome measures recorded in the observational datasets. In Section 4, we use two cognitive assessments to demonstrate the properties of the generated assessment score. Lastly, Section 5 provides a summary and brief discussion of the new method.

2 Data Sources

In this study, we integrated data from four large prospective observational studies of HD, namely Enroll-HD[5], REGISTRY[6], TRACK-HD/TRACK-ON[7, 8], and PREDICT-HD[9], respectively.

Enroll-HD is a worldwide observational study of Huntington’s Disease families. The study aims at providing a platform to support the design and conduct of future clinical trials, improving the understanding of the phenotypic spectrum and the disease mechanisms of HD and improving health outcomes for the participant/family unit. The study monitors how HD appears and changes over time in different subjects. It recruits confirmed HD patients, HD at-risk patients, HD genotype negative participants as well as control participants from HD family. Study participants are required to visit study sites annually, and undergo a comprehensive battery of clinical assessments. In this work, we used the ENROLL-IDS-2015-10-R1 version of the Enroll-HD periodic data, which contains un-monitored data from 7614 subjects who made their baseline visits prior to October 2015. Among the participants, 5475 are Huntington’s disease gene expansion carriers (HDGECs) with CAG length greater than 35, 1613 participants are control subjects (i.e. CAG length ≤ 35), and the other 527 have unknown CAG length. Subjects have up to four annual visits, with an average number of visits being 1.44.

REGISTRY is a multi-center, multi-national observational study, managed by the European Huntington’s Disease Network (EHDN), with no experimental intervention. REGISTRY aims at obtaining natural history data on many HD mutation carriers and individuals who are part of an HD family, relating phenotypical characteristics of HD, expediting the identification and recruitment of participants for clinical trials, developing and validating sensitive and reliable outcome measure for detecting onset and change over the natural course of pre-manifest and manifest HD. The REGISTRY cohort used in this study consists of 12108 participants, among which 7988 are HDGECs (i.e. CAG > 35), 758 are control participants (i.e. CAG length ≤ 35), and the other 3894 participants do not have CAG length information. Participants have up to 15 annual visits, with the average number of visits equals to 2.9.

TRACK-HD is a multinational study of HD that examines clinical and biological findings of disease progression in individuals with pre-manifest HD and early-stage HD. Participants in the study underwent annual clinical assessments
for 36 months. At the baseline visit, 402 participants were enrolled. Among the participants, 127 participants were control subjects, 144 participants were pre-manifest subjects who had not reached HD clinical onset, and 130 were post-manifest subjects who had already reached HD clinical onset. 298 participants completed the 36-month follow-up, among which 97 were controls, 104 were pre-manifest subjects at their baseline visits, and 97 were post-manifest subjects at their baseline visits.

TRACK-ON is a follow-up study of TRACK-HD with the aim of testing for the compensatory brain networks after structural brain changes in TRACK-HD pre-manifest participants. Participants in the study underwent annual clinical assessment for 24 months. At the baseline visit, 245 participants were enrolled, among them 181 were participants of TRACK-HD who have not reached HD clinical onset at the end of TRACK-HD, and 64 participants were newly recruited in the study. 112 participants in TRACK-ON were control subjects, and others are HDGECs.

PREDICT-HD is another longitudinal observational study of subjects who chose to undergo predictive testing for the CAG expansion in the HD gene but did not meet criteria for a diagnosis of HD (Diagnostic Confidence Level = 4). Participants were recruited from 32 sites worldwide beginning in October 2002. The goal of PREDICT-HD is to define the neurobiology of Huntington’s disease (HD) and to develop tools to allow clinical trials of potential disease-modifying therapies before at-risk individuals have diagnosable symptoms of the disease. It collected a variety of biosamples including MRI, blood and urine samples, and comprehensive assessments of cognitive, motor, functional and psychiatric outcomes to characterize the pre-manifest syndrome in HD, to document the rate of change of these variables during the years leading up to and following a clinical diagnosis of HD, and to investigate the relationship among neurobiologic factors, clinical diagnosis and CAG repeat length. The PREDICT-HD data used in this study consists of 1481 participants. Among them 316 were control subjects. Participants have up to 14 annual study visits, with the average number of visits equals to 5.2.

3 Materials and Methods

3.1 Integration of Multiple HD Data Sets

The four studies introduced in Section 2 contain a diverse set of clinical assessments that span a spectrum of clinical symptoms expressed by HD patients. In this section, we briefly describe the process of integrating data from these four studies.

We began by matching subjects across studies using a unique Recoded HD participant ID. This unique identifier also allows us to recognize the subjects who participated in multiple studies. In the four HD observational studies, participants visited study sites approximately annually and were evaluated by a diverse range of clinical assessments. In the rest of this paper, we refer to the data generated from one visit of one participant as an observation. In each of the four studies, the date of a participant’s first study visit in the study, referred to as the baseline visit, was used as the reference date for the participant and was set to 0. The visit dates of all his follow-up visits in the same study were aligned with the reference date and measured in days. In addition, for a subject who participated in multiple studies, the time gaps between the multiple reference dates from different studies were also available. Therefore, subjects’ records from multiple studies could be stitched together when they were available.

The second step of combining the multiple data sets was matching and merging variables. Not all variables were named consistently across studies. We analyzed data dictionaries, study protocols and guidelines from the four studies and manually matched variables across studies. We also corrected coding inconsistencies across studies.

We categorized variables into two groups, namely, assessment score and demographical information. The assessment score group consists of measurements from clinical assessments performed at annual study visits to capture wide range of clinical symptoms among HDGECs, such as motor impairment, cognitive deficits, functional decline, and behavioral disorder. The demographic information group includes participants’ demographics (e.g. age, sex, education level, etc.), CAG length, medical history (e.g. drug abuse history, alcohol abuse history, etc.), and other information related to study designs (e.g. region, study site). The integrated data set contains 106 variables from the participants demographic information group and 2079 variables from the assessment scores group.

Finally, we performed cross-study distributional check to filter out obvious erroneous measurements in the integrated
After all these steps, we ended up with a data set containing 55782 observations from 16553 HDGECs and 2716 control participants. The average number of observations per participant of the integrated data is 2.9.

3.2 Flow of the proposed new method

The aim of this work is to develop a data-driven method to generate robust symptom onset indicators based on the clinical assessment scores collected in HD registry data. In the rest of this paper, we will refer to the original assessment scores as the ‘raw assessment scores’, and the newly generated scores as the ‘robust scores’. A robust score is generated from its raw assessment score. As proof of concept and application, we will showcase the proposed method using two cognitive assessments in the integrated data, which are Symbol Digit Modalities Test (SDMT) total correct score, and the Stroop Word Reading Test (SWRT) total score.

As discussed in Section 1, raw assessment scores can be influenced by both disease-related and non-disease-related factors. While influence of the disease-related factors on these assessment scores is desirable, influence of non-disease-related factors on these scores can result in misleading follow-up analysis and conclusions. Figure 1 illustrates an example from the raw SDMT total correct scores. The left panel (1a) depicts the distributions of raw SDMT scores vs. the levels from International Standard Classification of Education (ISCED). The right panel (1b) depicts the distributions of raw SDMT scores vs. HD stages of participants in the aggregated data. HD clinical stage has been discretized here into early pre-manifest, late pre-manifest, HD1, HD2, HD3 and HD4. It is used here as a surrogate for HD disease progression. From the figures, it is clear that SDMT scores not only depend on HD disease status and progression, but also depend on other factors such as education levels.

The integrated HD observational data includes control participants who do not carry HD gene expansions. Control participants by definition are not affected by HD disease progression. Therefore, raw assessment scores of control participants are expected to be influenced by non-disease-related factors. Throughout this study, we assume that the underlying effects of a non-disease-related factors on an assessment score are the same for both control participants and HDGECs. Any differences in the effects between the two groups can be attributed to the disease. The basic idea of the proposed procedure is to utilize the control cohort to evaluate the effects of non-disease-related factors on an assessment score of interest. Then for a case participant, the predicted control value of the assessment score can be produced from the control-based model. The predicted control value gives an estimate of what the expected assessment score look like for a hypothetical control participant with similar characteristics as the case participant. Subtracting the predicted control value from the observed value can remove the effects of non-disease-related factors. The remaining part of the assessment score is less subject to changes of non-disease-related factors, and is more robust in terms of reflecting the effects of HD related factors. The onset of a new symptom (e.g. cognitive impairment) is defined to be
the critical point at which a case participant exhibits significant difference from control participants. Comparing the observed assessment scores with the distributions of the predicted control values could lead to personalized symptom onset indicators.

Next we describe the work flow of generating the robust measure of a target assessment score. For each target assessment score, the framework consists of a sequence of steps: (1) check missing values. If there are missing values in the data, perform imputation to generate multiple sets of complete data sets. (2) For each imputed dataset, build a model for the target assessment with participants’ characteristics, using control subjects only. The model is referred to as the control model for the imputed dataset. (3) For each imputed dataset, get predicted control values and the prediction confidence interval for HDGEC based on the control model from step (2). (4) For each imputed dataset, generate robust assessment scores for target assessment scores. (5) Aggregate the robust assessment scores from multiple imputed datasets. If there is no missing values in the data, steps (2)-(4) will be performed on the observed data set, and step (5) will no longer be needed. We discuss each step in detail below.

**Step 1.** Check missing values and perform multiple imputation.

All four HD observational studies have missing values. Therefore, the aggregated data contain missing values. To cope with this problem, we performed Multiple Imputation (MI) with the Fully Conditional Specification method [10] and Predictive Mean Matching [11] to impute the missing values and generated multiple sets of complete data sets. Multiple Imputation [12] is a statistical technique for analyzing incomplete data sets. Instead of filling in a single value for each missing value, MI procedure replaces each missing value with a set of plausible values. Uncertainty about the value to impute can be represented by the multiple imputed values. These multiple imputed data sets are analyzed individually. Results from the multiple sets of complete data sets are then aggregated to generate the final results. In this paper, we applied the MI procedure using the MICE package in R [13] and generated ten sets of complete data sets.

**Step 2.** Build control models.

With each imputed data set, we build a model for the target assessment score using available patient characteristics as the predictors. The goal of this step is to build a model with high predictive power. For each target assessment score of interest on each imputed dataset, we compared multiple candidate predictive models, and choose the one with the highest predictive power (measured by R-squared) as the model of choice for the target assessment score on the imputed dataset. In this study, we used three types of models as candidate control models in the experiments: the generalized linear regression model, Support Vector Machines (SVM) with RBF kernel, and Multivariate Adaptive Regression Splines (MARS). The proposed method is not limited to the three types of models. Other types of predictive models can be included in this step.

**Step 3.** Get prediction confidence interval of a target assessment score on HDGECs from control models.

Once a candidate model is selected as the control model for a target assessment score on an imputed data set, we obtain predicted control values of the target assessment scores for HDGECs on the imputed data set. We also obtain the lower and upper bounds of the 95% confidence interval of the predicted control value (PCI) for each case observation. In this paper, we used bootstrap method to obtain the PCI for case observations on each imputed dataset.

**Step 4.** Generate robust assessment scores.

The PCI obtained from Step 3 gives an interval estimate of what an assessment score would be for a hypothetical control participant with similar characteristics as a case participant. We define the symptom onset as the event when a case participant can be distinguished from the control participants. The PCI obtained from the previous step can be used to mark the boundary to determine whether a case participant presents significant difference from the controls. Therefore, the time of symptom onset is defined to be the first time that an assessment score of a case participant...
Figure 2: Description of the method in Step 4

falls out of the PCI. Following the above definition, the robust assessment score is defined as the distance between the observed assessment score and the boundary of the PCI. Figure 2 summarizes the method. If the raw assessment score decreases with time (left panel of Figure 2), the difference between the observed value and the lower bound of the PCI is used as the robust assessment score. If the raw assessment score increases with time (right panel of Figure 2), the difference between the upper bound of PCI and the observed value is used as the robust assessment score. The sign of a robust assessment score from an observation can indicate whether the participant show significant difference from controls in the symptom assessed by the corresponding raw assessment score. A positive sign indicates that the participant cannot be distinguished from controls. A negative sign indicates that the participant can be distinguished from controls. The value 0 serves as a natural threshold for deciding the onset of a new symptom. Therefore, the robust assessment score can be used as a symptom onset indicator. Note that a robust assessment score can be generated from each raw assessment score. A robust assessment score assesses the same symptom as the symptom targeted by its corresponding raw assessment score. Multiple robust assessment scores together could be used to provide a comprehensive view of the progression pathway of the target disease.

Step 5. Aggregate results from multiple imputed data.

Up to Step 4, for each HDGEC observation, we generate ten robust assessment scores, each from one imputed data set. The final step is to aggregate the ten sets of robust assessment scores. In this study, we used the average across the ten sets as the final robust assessment scores. When there is no missing values in the observed data set, steps 2-4 will be performed on the observed data set and step 5 will be skipped.

4 Results

We applied the proposed procedure to the integrated HD observational data. In this section, we demonstrate the characteristics of the robust assessment scores using two cognitive assessments: the Stroop Word Reading Test (SWRT) score and the Symbol Digit Modalities Test (SDMT) total correct score.

Both the two assessments have missing values in the data. Step 1 of the proposed method generated multiple complete data sets using the Multiple Imputation method. We first check the quality of the imputed data. The imputed values should 1) have the same support as the observed data; 2) have similar distributions as the observed data. We adopted the Predictive Mean Matching method in the MI step, therefore the imputed values were guaranteed to have the same support as the observed data. In this section, we compare the distributions of the imputed values with the observed values by visual inspection. One example of the inspection is showed in Figure 3. The left panel of Figure 3 shows the distribution of observed SDMT scores in each age group, and the right panel shows the distribution of imputed SDMT scores in each age group. The plots demonstrate that the distributions of the imputed value are similar to that of the observed values. Similar inspections were performed for observed and imputed values versus other factors. Due to lack of space, we do not show the details in this paper.

After obtaining the ten sets of imputed data, we build control models for SDMT and SWRT separately on each
Figure 3: Boxplots of imputed and observed SDMT scores in each age group

Patient characteristics, such as study ID, age, gender, and education levels, were used as predictors in the control models. For each assessment score on each imputed dataset, three types of candidate models (Generalized Linear Regression (GLM), Support Vector Machine (SVM) and Multivariate adaptive regression splines (MARS)) were compared. The type of model with the highest R-squared value was selected to build the control model on the imputed data set. A summary of the R-squared values from the selected models are listed in Table 1. After building the control models, bootstrap method was used to obtain the 95% PCI for each case observation. The robust assessment scores for each complete dataset were calculated following the descriptions in Section 3. In the final step, we aggregated the robust scores from the ten sets of complete data sets by calculating the mean values across the ten sets of complete data sets.

Next we discuss the properties of the robust assessment scores. Values of raw assessment scores were not only influenced by HD disease status and progression, but also by other non-disease-related factors. The proposed method utilizes the control cohort to model and adjust the effect of non-disease-related factors. The robust assessment scores are expected to be less subject to the non-disease-related factors. Figure 4 and 5 show two examples comparing the distributions of raw and robust SDMT scores among the HDGECs versus two patient characteristics, which are age groups and ISCED education levels. The left panels show the distributions of the raw SDMT scores vs. age groups and ISCED education levels, respectively. The right panels show the distributions of the robust SDMT scores vs. age groups and ISCED education levels, respectively. The raw SDMT scores demonstrate strong correlation with age and education levels, while the robust SDMT scores demonstrate decreased correlation with the two factors.

Table 2 summarizes the influences of non-disease-related factors in raw and robust SDMT/ SWRT scores. For categorical factors, we calculate the average Cohen’s d effective sizes of the scores between pairs of levels of the factor. For continuous factors, we report the Spearman’s correlation coefficients. A smaller average effective size or smaller absolute value of Spearman’s correlation coefficient indicates decreased influence of the non-disease-related factor.
Most non-disease-related factors show decreased influence in the robust scores. The few exceptions can be attributed to the imbalance of factors’ effects in the control model. In general, the robust scores are less subject to changes in non-disease-related factors.

The values of raw SDMT scores range from 0 to 120. A few previous literature [14, 15] reported some threshold values to distinguish normal vs. impaired cognitive abilities. However, whether these threshold values can be applied to HDGECs has not been systematically tested. There is no clear threshold to decide when a HDGEC participant starts to show the symptom of cognitive impairment. A robust SDMT score comes with a natural threshold (i.e. 0) for deciding whether a HDGEC starts to show cognitive impairment. Since influences of the non-disease-related factors for the observation have been adjusted in the robust assessment score, the threshold is personalized and specific to HD. Similarly, a value of 0 serves as a natural personalized threshold for other robust assessment scores to determine the onset of other symptoms in HDGECs. It is worth mentioning here that ‘onset’, for a case participant, is being identified as a deviation from the model learned based on control participants. This data driven ‘onset’ is a hypothesis that needs further clinical validation.

5 Discussion

In this paper, we proposed a method for generating robust assessment scores and symptom onset indicators from patient registry data set which have recruited both case and control participants. The generated scores are more robust in the sense that they are less subject to changes due to non-disease-related factors. Therefore are more relevant when evaluating subjects’ disease status and tracking disease progression. The signs of the robust assessment scores indicate whether an observation can be distinguished from the control cohort. The value 0 serves as a natural indicator
to indicate the onset of the symptom assessed by the score.

We applied the proposed procedure to an integrated HD observational data set and discussed the properties of the robust assessment scores using two cognitive assessments. The proposed procedure is not limited to these two assessment scores. It could be applied to other assessment scores in HD observational data.

The proposed method may also be applied to other disease registry data that have recruited both case and control participants. However, the application of the proposed method to other disease registry data should be conducted with caution. Owing to the monogenic nature of HD, the identification of the control participants in HD observational data is relatively clearer compared to other types of diseases. Participants in the control cohort of HD data sets by definition are not expected be affected by any direct (or known) HD disease-related factors. The identification of a control cohort in other disease registry may require more efforts such as matching and stratification.

One limitation of the proposed method comes from the nature of observational studies. The proposed method can only adjust the effects of non-disease-related factors that are available among both case and control participants. If a factor is not collected in the patient registry data or is only available in one of the groups, its influences cannot be adjusted. In other words, the proposed procedure only mitigates the effects of non-disease-related factors, but does not guarantee elimination of their effects entirely.

Despite the aforementioned limitations, the proposed procedure is useful in improving the quality of assessments scores in patient registry data. The value of zero serves as an indicator for detecting symptom onsets. Better understanding of the course of the disease could be obtained by comparing the times and order of multiple symptoms. We will explore the clinical insights of the generated symptom onset indicators in future work.

Designing Decision-Support Technologies for Patient-Generated Data in Type 1 Diabetes

Si Sun, PhD1, Kaitlin L. Costello, PhD2
1IBM T.J. Watson Research Center, Yorktown Heights, NY
2Rutgers University, New Brunswick, NJ

Abstract

People living with type 1 diabetes generate data as a byproduct of diabetes management. The development of decision support technologies can be enabled by harnessing these patient-generated data, but a major challenge is for these technologies to provide meaningful and highly personalized guidance to support individual patients’ decision-making processes. In this paper, results from a year-long qualitative study were reported. Twenty-six people with type 1 diabetes were interviewed regarding the types of self-generated data they use for decision-making, their decision-making processes using self-generated data, and the difficulties they experience when attempting to use this data for decision-making. These patients’ behaviors and difficulties point to new approaches to designing decision support technologies for personal use, including patient-centered and automated data entry, automated and individualized data analysis, and humanized output.

Introduction

Patients with type 1 diabetes are forced into frequent decision-making processes related to their health on a daily basis. Data generated by type 1 diabetes patients (e.g., blood glucose levels, food consumption, mood, stress levels, and co-morbidity medication) can be a valuable resource for patient decision-making. This paper examines how patients with type 1 diabetes use various types of self-generated health data in their everyday decision-making processes. Understanding this issue will help improve consumer decision support technologies and enhance our capacity to use patient generated data in clinical decision support technologies.

In this paper, self-generated health data refers to health information that is collected by patients about their condition (e.g., blood glucose readings collected with a glucometer), their actions (e.g., exercise intensity), or their experiences (e.g., pain). Patients with type 1 diabetes can achieve better health outcomes by using their self-generated data to make decisions about their health, such as dietary choices spurred by frequent monitoring of their blood glucose levels.

However, maintaining and using self-generated health data can be challenging. An average diabetes patient spends about an hour every day on self-care. Collecting and maintaining health data adds to patients’ responsibilities and intensifies patients’ stress. Also, in many cases this patient work is invisible to health care providers, making it difficult or impossible to address in clinical environments.

Research on consumer-oriented technologies point to the potential value that they have in assisting patients’ efforts to collect and use self-generated health data for decision making. For example, technologies that support frequent monitoring (e.g., continuous glucose monitors) may help patients to maintain better glycemic control. Real-time feedback through mobile phones for diabetes patients based on their blood glucose levels, diabetes medications, and lifestyle choices may lead to improved glycated hemoglobin test results. The medical informatics community is also exerting increased effort in incorporating patient-generated data in clinical information technologies (e.g., patient portal systems and electronic health records), but more research is needed to investigate the impact of this data and potential approaches to facilitate the process.

This paper offers a patient’s perspective toward self-generated health data, including its value and use by patients with type 1 diabetes for decision-making. Our purpose is to improve the usefulness and adoption rates of decision support technologies for these patients by informing technology design through naturalistic research. The research questions include: (a) What types of self-generated health data do patients with type 1 diabetes consider useful for diabetes decision support? (b) How do patients use this data for decision-making? (c) What difficulties do patients encounter when using self-generated data for decision-making?

Related Studies

Studies reporting the types of diabetes patient-generated data used in decision support technologies usually focus on health indicators and health behavior. For example, a randomized controlled trial on a community-based decision
support system, COMPLETE II, tracks patients’ blood pressure, cholesterol, glycated hemoglobin, foot check results, kidney function, weight, physical activity frequency, and smoking frequency\textsuperscript{10}. Other decision support systems reported using similar data to generate personalized decision support, including health outcome (e.g., blood glucose levels\textsuperscript{7,11–16}, Hemoglobin A1c\textsuperscript{17}, blood pressure\textsuperscript{17}, lipid\textsuperscript{17}), diet (e.g., carbohydrate intake\textsuperscript{7,11}), medication\textsuperscript{7,11}, and exercises\textsuperscript{11}. One data type that is not currently well supported by these systems is the illness experience, an important aspect of decision-making processes for patients with diabetes\textsuperscript{1}.

The aforementioned decision support systems were mainly developed for shared decision-making between healthcare providers (HCP) and patients. The types of data entered are predefined, and data entry into these systems requires patient work with the help of sensor technologies. Decision support, however, is mostly directed toward HCPs, not patients. Some data that patients find useful is considered irrelevant by HCPs\textsuperscript{18}. In other words, when using these decision support systems, diabetes patients contribute to data entry but they do not play a major role in making decisions for themselves using the generated data. For a chronic disease that involves day-to-day self-care, type 1 diabetes calls for patients’ effort in daily decision-making\textsuperscript{1}. To date, not enough research has examined patients’ requirements for these technologies\textsuperscript{19}, particularly since they may use the data generated and stored in these technologies for daily self-care efforts.

Recently, the roles that patients and their self-generated data play in decision-making have been explored in several studies. This research suggests that personal preferences, values and context can shape patients’ decision-making processes\textsuperscript{1,20,21}. Disregarding these individualized requirements to pursue standardized goals may not necessarily lead to improved long-term health outcomes\textsuperscript{19,20}. Indeed, research on various diabetes patient decision aids (e.g., cards and apps) attempts to take personal preferences into consideration\textsuperscript{22}. Nevertheless, much remains unknown about how to design technologies that put patients at the center of the decision-making process to support their decision-making activities.

**Method**

**Participant Recruitment**

Participants were recruited through snowball sampling via the researcher’s personal network. The first author recruited the first group of participants among people she knows in person. Then, the first author asked the existing participants to introduce this study to people in their personal networks who were potential candidates. This process carries on through the researcher’s and existing participants’ networks. Snowball sampling is a recruiting method that can effectively and efficiently reach stigmatized populations, making recruitment for this study possible\textsuperscript{23}.

Twenty-six eligible participants with type 1 diabetes were recruited. Among them, 23 live in New York City and 3 are located in other cities in the East, North and Midwest regions of the United States. To protect participants’ privacy, the names of the 3 cities are not reported in this paper. Participants’ characteristics are presented in Table 1.

**Data Collection**

The data presented in this article were collected through one-on-one semi-structured interviews. The first author carried out all of the data collection using an interview guide, which was tested and revised iteratively through a pilot study with 30 diabetes patients; data from the pilot study is not reported in this paper. The major questions

asked in the interview include: (a) What health data about yourself and generated by yourself do you collect? (b) Is this data useful for your diabetes management? If yes, in what way(s)? (c) (If participant mentioned decision making) How do you use this data to make decisions about diabetes? (d) Did you encounter difficulties in this process? (e) What kind of technologies do you think can help you overcome these difficulties?

Data Analysis

All interviews were transcribed and inductive coding was performed for each of the 5 major interview questions. The analysis follows this iterative procedure: The first author (a) coded a sample, (b) discussed the coding with colleagues, (c) revised the codebook and the coding procedure, (d) coded the old sample(s) along with a new sample, (e) repeat the previous two steps until the codebook is no longer updated, which is 8 iterations, and (f) code the other 18 interviews. A second coder coded 5 interviews with high agreement (Krippendorff’s Alpha = 0.817; Cohen’s Kappa = 0.818). The number of participants who mentioned each theme is not reported, as is common in research that uses semi-structured interviews for data collection24. Specifying the number of participants mentioning each theme may not fully represent their exact behaviors.

Results

In this section, results for each of the three research questions are presented. First, the types of patient generated health data collected and used by participants for decision support are presented. Next, four decision-making patterns reported by participants are described. Finally, the difficulties that participants experience when engaging in each of the four decision-making patterns are discussed.

Types of Self-Generated Health Data that Patients Collect and Use in Decision Making

Participants in this study report collecting, maintaining, and using a wide range of self-generated health data for making health-related decisions. A list of the various types of self-generated health data that participants use to support decision-making processes is presented in Table 2. Note that not all participants report using all types of data. In other words, participants may use a subset of the types listed in Table 2. Also, participants’ preferences for different data used in decision-making processes may develop and change over time. For example, P19 was diagnosed with lupus shortly before the interview and her new procedure for diabetes decision-making takes into consideration the ways in which lupus treatments would impact her diabetes-related routine.

The types of self-generated health data used by participants for decision-making cover many aspects of their health condition, related treatments, regimens, and personal contexts. The scope of this data sometimes extends beyond that advised by participants’ HCPs. Some participants recall their HCPs asked them to collect blood sugar levels and test time and date. Others add that food diaries detailing the types of food and corresponding portion size are recommended by their HCPs. However, participants were not required to keep records on other types of data that they use for decision making or keep uninterrupted records of the types of data preferred by their HCPs.

Use of Self-Generated Health Data in Decision Making

Participants report four patterns of decision-making processes that rely on the use of self-generated data related to diabetes. These four patterns include: (a) connecting causes and effects – “What caused these health outcomes?”, (b) establishing priorities – “What should I do next?”, (c) negotiating outcomes – “What may I give up?”, and (d) setting visibilities – “What do I want to see?”. In the rest of this section, each of these four patterns will be introduced with detailed descriptions and examples.

Pattern 1: Connecting Causes and Effects

Participants make decisions about future actions by identifying specific factors, based on the data they collect, that positively or negatively impact their health outcomes. In Table 2, blood glucose and other health indicators are considered health outcomes by participants and the other types of self-generated health data (e.g., insulin, food and exercise) are considered causes that may affect health outcomes. Three approaches were taken by participants to connect cause and effect, including observation, statistic testing, and experimentation.

Observation. In all cases of observation, participants observe changes in their self-generated health data by using time-stamps, which allow them to solve problems related to diabetes management. Some of these observations occur over short periods of time. For example, all participants test their blood sugar levels before and after meals. When their test results are unexpected, they estimate or check the carbohydrate content in their meals to find out which items are responsible for causing specific test results. Likewise, for participants who perform a variety of exercises and experience various treatments, they tend to associate unexpected health outcomes with changes in their exercises and treatments occurring immediately before the observed changes in their health outcomes. Participants who observe immediate health outcome changes following activities they perform tend to adjust their activities to amplify positive outcomes and temper negative ones. For example, consuming food with high carbohydrate levels (e.g., orange and potato chips) lead to spikes in some participants’ blood glucose levels immediately afterwards, which makes them reconsider similar food options in the future.

However, not all cause and effect connections are easily observable in the short term. For example, participants complain that injecting insulin at the same site on the body can affect the effectiveness of the insulin, potentially because of the building up of scar tissues. This phenomenon cannot be observed in the short term, and participants often suspect other factors that can have a more direct impact on blood glucose levels (e.g., food consumption and exercise) before moving on to the less obvious factors (e.g., insulin injection site and temperature). In this circumstance, keeping long term records of self-generated health data is a necessity. For example, P2 keeps paper records of his blood sugar levels over the long term and he color-codes these records according to how high the blood sugar levels are when measured. He keeps a large board and pins his records on it so he can easily observe
patterns of codes and colors in his records. When he observes a cluster of certain color, he reads the annotations in these records on the contexts of these records (e.g., food intake, insulin injection location, and finger used for a blood sample) to find out what may have caused these clusters of certain blood sugar levels. Participants who observe cause and effect connections over the long term tend to approach behavior change decisions more cautiously. Some participants reported consulting other sources (e.g., HCPs, support groups, online communities, and medical and health articles) for reassurance before taking actions.

Statistical analysis. Participants who maintain electronic records of their self-generated health data sometimes conduct statistical analyses with their observations in order to locate potential problems. For example, P18 built annotated records of his blood sugar levels with Microsoft Excel spreadsheets. He describes how he uses statistical analysis to identify issues of importance in these records, “I noticed the clustering. I noticed the change on weekends, I noticed the changes on the seasons, because my overall requirements are a little higher in the summertime, and down a little bit in the winter time. Took me years of charts to try to work that out. ...In an effect, it speaks to me. Also in terms of time series. I go back, and then look at it month before, I look at it years before, around this time of year, and I know I’m having a seasonal change. ...This is why a data driven approach was for me.” P18 was confident with his findings because they were based on models using longitudinal data. These findings alleviated P18’s concerns about unexpected changes in his blood glucose levels during the winter and prompted him to monitor his condition more closely and make necessary adjustments to his insulin intake during the same period.

Other participants report benefitting from statistical analysis provided by applications for diabetes management, such as those that work with their continuous glucose monitors. Participants note that these applications usually help identify patterns of changes in health outcomes (e.g., blood glucose levels), but do not associate these outcomes with a wide variety of potential causes (e.g., exercises, stress and temperature), although some connect carbohydrate intake with blood glucose levels. Also, participants complain that these applications require manual entry of nearly all of their self-generated health data, except for blood glucose levels, which are automatically measured and documented by their continuous glucose monitors and related applications. Due to the lack of functionality and the efforts required for manual data entry, participants who report using such applications find their data entry incomplete (e.g., P7 had interim blood glucose records on her continuous glucose monitor) or that their usage declines and stops after a few months. These participants explain that these applications were not very useful for them, but their HCPs can help them with decision-making after reviewing the blood glucose levels they collected over 10 days to 2 weeks before their clinical visits, depending on their HCP’s requirements.

Experimentation. Some participants experiment on themselves to extract the causes of certain health outcomes. Experimentation is usually employed by participants who do not identify relationships between causes and their effects through observation and statistical analysis. An experimentation method reported by participants is to establish a routine of daily activities and test the effect of new behaviors (e.g., eating a new type of food, performing a new physical exercise, changing insulin injection schedule, mixing different types of insulin, using expired insulin, and switching medical devices) on specific health outcomes. Participants also voice that diabetes management is a “noisy system”, and they usually repeat the same experiment multiple times before making a conclusion if they do not consider the changes in their health outcomes large enough to justify the necessary behavior changes.

Pattern 2: Establishing Health Priorities

When cause and effect connections are established, participants plan the steps they will take for future behavior changes. While some changes may be perceived by participants as straightforward (e.g., reducing carbohydrate intake to an amount recommended by HCPs), others may involve multiple processes when the cause and effect relationships are intricate.

Take P16’s treatment of chronic fatigue as an example. P16 was living with cancer and type 1 diabetes, and one of the treatments for cancer made her suffer from chronic fatigue. The symptoms of the fatigue were so severe that she struggled to get out of bed every morning. Every time when she attempted to test her blood sugar, she falls asleep without realizing it. This fatigue, coupled with her unstable blood sugar levels, became dangerous because it increased the risk of her inability to react during a hypoglycemia episode.1 To treat the fatigue, P16 had three options, and could choose any of the options or a combination of the options: (a) change her cancer treatment, (b) change her diabetes treatment (e.g., adjust insulin dosages and dosing methods), (c) change her diabetes regimen (e.g., increase exercises

1 Hypoglycemia: Situations of blood glucose levels dropping below a certain threshold. Hypoglycemia may be more difficult to recover in patients with type 1 diabetes that use insulin. If left untreated, hypoglycemia can worsen and lead to severe health consequences, such as seizures, unconsciousness.
and reduce carbohydrate intake). P16’s health care team offered her a wide range of choices for potential treatments and regimens, but they did not have a clear sense of how effective these changes would be for P16 as an individual patient. She decided to immediately change her cancer treatment; then, she joined a physical training class in the same hospital where her health care team was located. Finally, she changed her diabetes treatments by acquiring a continuous glucose monitor. These changes took course over a 2-year period, and P16’s fatigue was largely reduced.

P16’s decision-making process involves considerations for cause, convenience and cost; she prioritizes different considerations for different reasons, at different times during her decision-making and her resultant behavioral changes. First, she removes the cause of negative health outcomes (e.g., fatigue-inducing cancer treatment). Then, she increases positive health outcomes by participating in convenient behaviors (e.g., exercising). Later, she aims for less convenient and costlier causes of positive health outcomes (e.g., a continuous glucose monitor).

Other participants also report considering cause, convenience and cost, but with different priorities. For example, P13 acquired a continuous glucose monitor shortly after her diagnosis because being able to monitor her blood glucose levels in real time helps her make decisions on micro-adjustments and maintain constantly in-range blood glucose readings. In this case, P13 prioritizes cause and convenience over cost.

**Pattern 3: Negotiating Outcomes**

Participants report that they have specific goals in mind when they make connections between causes and effects and they negotiate between these goals to decide what actions to take. Some of these goals are straightforward health outcomes, such as achieving stable blood glucose levels and not experiencing diabetes complications. While many health outcomes pursued by participants require similar actions (e.g., timely insulin injection around meal time can help type 1 diabetes patients avoid symptoms of hyperglycemia and also reduce the chances of complications in the long run), some health outcomes have competing requirements. For example, P22 describes her fears of hypoglycemic episodes, “I’m not aggressive enough with it [i.e., carbohydrate counting]. I always underestimate. It goes back to my fear of lows.” In this case, P22 believes that maintaining an in-range average blood glucose level increases the chance of hypoglycemia. She negotiates between the immediate and potentially devastating effects of the acute hypoglycemic episodes and the relatively mild but degenerative effects of hyperglycemia. To reduce the chances of the acute episodes, P22 decides to loosen her standards for carbohydrate counting and maintain a relatively high average blood glucose level.

Participants also have other considerations that may compete with their pursuit for better health outcomes. Such considerations reported by participants include quality of life, time, and social life. Participants complain that not being able to enjoy their favorite food affects an important aspect of their quality of life. For example, P6 enjoys a small portion of ice cream every day, but her blood glucose is sensitive to the sugar in the ice cream. In order to manage diabetes, P6 has to cut back on her daily ice cream portion and take extra insulin to cover for the blood glucose spikes. Also, participants found the lack of time due to factors such as the pursuit of a career, caring for family, and traveling a major reason that may compromise their diabetes management endeavor. P8 attempts to maintain the best blood glucose levels with a busy graduate school schedule. Because of her busy schedule, she is not able to guarantee timely food intake, so she keeps snacks at her desk and micro-manages her insulin injection through a pump to obtain the best possible outcomes. Further, participants find that their social lives impact their decision-making processes as well. For example, P17 explains his struggles to negotiate between diabetes management and a normal social life: “...to let down, let's say a friend or not make it to a social arrangement because of a hectic diabetic disruption. It's difficult for someone else to understand, because, in a lot of ways, it's an unreasonable disease. ... I think I have trouble with those moments saying to friends, you know like, it's a long, hard day and I know were aren't right words, but I think it's a psychological weight to kind of carry for this irrational disease that can disrupt at any moment.” Other participants also mention social eating and religious fasting as difficult moments where they must balance healthy social relations and the temptation of food with the possibility of negative health outcomes.

When negotiating between aspects of their lives that compete with health outcomes, rather than giving up or reducing the frequency and intensity of certain actions, participants in this study also report seeking alternative actions that have less impact on their health outcomes. For example, P9 enjoys sweet foods and drinks and finds them to be an important aspect of her quality of life, but they usually create spikes in her blood glucose levels and require a greater insulin dosage. To achieve a balance between quality of life and stable, in-range blood glucose levels, P9 stockpiles Glucerna, a sweet beverage that she discovered would not create sugar spikes that were as severe, and she uses it to substitute her usual breakfast.

**Pattern 4: Setting Visibilities**

When participants use their self-generated health data to make decisions, they have different preferences regarding
the type of data they want to see in different circumstances; they also have different preferences for the quantity and timing of such data.

**Data selection.** All participants do not use all types of data listed in Table 2 for decision-making. Some participants follow their HCPs’ recommendations such as using carbohydrate counting and food consumption to determine insulin dosages, while other participants use other types of data for the process, depending on their daily activities and preferences. For example, P2 performs the same moderate exercises on a daily basis, so he does not consider exercise-related data relevant for decision-making. On the other hand, P12 is a marathon runner with varying exercise schedule, and exercise-related data is a major input for her to make treatment and regimen decisions.

**Quantity and timing.** Participants have different preferences regarding the quantity of data they use for decision-making. Some participants prefer large quantities of self-generated health data because more data means greater possibilities of discovering recurring patterns and hidden connections. On the other hand, participants who do not keep records of their health data (e.g., blood glucose levels) but use it for real time decision support (e.g., test blood glucose to determine the next insulin dosage) tend to prefer smaller quantities of data collected shortly before or during the decision-making episode. The reasons participants give for these preferences are that too much data is overwhelming, and data collected too long before the decision-making episode has little bearing on their ever-changing health statuses (e.g., blood glucose readings).

**Decision-Making Difficulties**

Participants in this study identify various difficulties that they experience with their current decision-making processes and supporting technologies. These findings are reported in Table 3.

The difficulties reported by participants point to three disconnections between their decision-making processes and the support they receive, including: (a) data entry does not reflect data used for decision making, (b) data analysis is difficult to carry out and results are hard to comprehend, and (c) output of analysis is difficult to understand and put to practice. The four decision-making patterns are influenced by different disconnections, with (a) connecting causes and effects and negotiating outcomes mainly caused by data entry and analysis problems, and (b) establishing priorities and setting visibilities mainly related to issues with data output. Decision support technologies that address these three disconnections will offer better utilities and experiences for patients with type 1 diabetes. The next section details some of the ways that these disconnections can be addressed in decision-support technology design.

Table 3 Participants’ difficulties with using self-generated health data for decision-making
Discussion and Implication

This paper describes the multiple types of self-generated data that type 1 diabetes patients use in their everyday decision-making processes, the ways in which they use this data to make decisions, and the difficulties they experience in these processes. These results point to multiple venues for the design and redesign of decision support technologies for patients with type 1 diabetes that will not only provide direct support for patients, but will also harness patient generated data for clinical use. In the clinical environment, individual patients’ longitudinal data that is used by patients in their decision-making processes can enrich and enhance the data used by clinicians for medical decision making in clinical care. Collections of this data, gathered as part of patients’ daily routines, may also enable the identification of cause and effect connections not commonly considered in clinical settings, as well as potential treatments and regimen recommendations used by patients.

Patient-Centered Data Entry

People living with type 1 diabetes use a wide range of self-generated health data for decision-making. The different types of data they generate, collect, store, and use extends beyond HCPs’ requirements. Some of this data is patients’ perception of themselves and their environment, such as mood and weather. The nuances of health data captured by patients and used by them in everyday settings for decision-making are usually not incorporated in the design of decision support systems. To facilitate using patient generated data to support patients’ decision making, allowing patients to define the types of data to enter into their decision support technologies is necessary. For example, P2 considers blood glucose testing location and insulin injection location important for him to interpret his blood sugar readings, especially when he compares his readings across testing and injection locations. In contrast, P11 believes that stress is a major cause of her diabetes and is highly conscientious about work-related stress levels. Considering these highly specialized needs, it is not sufficient to offer these two participants a standard diabetes decision support application that allows them to document their carbohydrate counts and insulin dosages. A better, more flexible solution is to allow patients to define data types that are beyond the standard setup, enabling them to name new data entries (e.g., variables), their measurements (e.g., categorical or continuous), and their entry method (e.g., choose from preset options or enter free text) as well as incorporate this data to support their decision-making processes.

Furthermore, the larger amount of data collected by patients in the home points to the insufficiency of patient data routinely collected in the clinical setting. If patient-generated data is incorporated into clinical records, it may be useful for improving patient-provider communication and clinical care by offering HCPs data-driven approaches from patients’ perspective, rationales of patients’ activities, and possibilities of discovering new working regimen initiated and tested by patients.

Automated Data Entry and Analysis

Participants in this study expressed their needs for decision support systems that can automatically identify potential causes for changes in their health outcomes. Some participants also experienced difficulties with identifying solutions for certain health-related problems and desire decision support technologies that will aid them in finding solutions for these problems. Some participants mentioned that existing technologies (e.g., continuous glucose monitors) can address some of their needs, but others complained that the automated functionalities of these technologies are limited to blood glucose related tracking and recommendations. There is currently not enough support to automate the collection of other types of self-generated data (e.g., diet and exercise). When possible, incorporating existing self-generated data from other devices using open APIs, such as step-tracking software on many mobile phones or weight data collected by smart scales, may be one way to aggregate and store self-generated data for patient use.

In an effort to automate the data entry and decision-making processes, the medical informatics community has made recent developments in consumer-oriented technologies, such as a diabetes wound management app based on image recognition technologies and a meal-camera system used in telemedicine for diabetes patients. More research is needed to facilitate communication between applications that automate the entry and analysis of different data to offer more coherent and meaningful consumer experiences.

Individualize Data Analysis

Findings in this paper demonstrate that type 1 diabetes patients’ decision-making processes are highly personal. Some decisions are made within the participants’ resource constraints and their personal preferences. These constraints and preferences differ between patients and may change over time. This issue points to the need to not only use patients’ personal health data for individualized care, but also to allow patients to shape the underlying logic of how this data can be viewed, analyzed, and used. For example, a piece of decision support technology that
models a type 1 diabetes patient’s blood glucose levels on weekly, monthly, and yearly basis may not clearly show patterns for all three time intervals, particularly if the patient has a non-standard work schedule. In this case, allowing the patient to set her preferred time interval to match her specific schedule may help the technology determine if the patient’s work schedule plays a significant role in affecting her blood glucose levels.

**Humanize Decision Support Output**

Some participants voice their frustration and confusion when engaging in their existing decision support aids for their lack of intuitive interfaces (e.g., continuous glucose monitors and their corresponding applications and carbohydrate counting books). Participants report that they prefer decision support technologies designed for laypeople, who do not have specialized knowledge in medicine or expertise with using search engines. Participants would prefer to communicate with decision support technologies as if they were human (e.g., both the patient and the technology can use and understand plain, natural language), and would like these technologies to help hold them accountable for their health-related decisions (e.g., recording blood glucose test results and maintaining diet) like HCPs would.

These requirements point to three potentially useful aspects of decision support technologies for patients with type 1 diabetes: (a) the ability to translate between natural language and search queries; (b) the ability to translate between medical terms and lay terms; and (c) the ability to socialize with the patient at checkpoints (e.g., making sure that the patient keeps her daily carbohydrate count at under 200 grams). This study does not yield enough information on how to determine what incidents qualify as checkpoints or how frequent these checkpoints should be. The literature on using telemedicine reminders to support self-management and promote adherence in people with chronic conditions does not agree on how frequently reminders should be sent, and there is not enough research on the detection and determination of checkpoints to date. For example, Tao and colleagues argued that the frequency of electronic reminders does not seem to moderate medication adherence. Eleches and colleagues found that the frequency of reminders has an impact on patients’ adherence to antiretroviral therapy (i.e., an HIV treatment) and that weekly reminders seem to have a more significant positive impact than daily reminders. Research also suggests that allowing teenage asthma patients to set the frequency of reminder text messages may enhance patients’ self-management. Therefore, a future direction for this work is to determine when and how to build checkpoints into these technologies. It is possible that, like the recommendation to individualize data analysis, checkpoints should also be a setting that patients can customize to their own preferences.

**Conclusion**

This qualitative study explores type 1 diabetes patients’ decision-making behaviors and designs that can support these behaviors with a focus on patient generated data. The findings have implications for decision support for patients in their everyday lives, and may also extend to the clinical space. As this is a qualitative study with a purposive sample, the results are not generalizable but may be transferrable to other patient populations where decision-making is frequent (e.g. coronary heart disease, lung cancer) or when patients may generate and track data beyond their HCPs’ requirements (e.g., pregnancy). More research is needed to investigate the effects of the design recommendations and explore certain aspects of decision support technology design (e.g., the timing of checkpoints to promote adherence).

Causal Phenotyping for Susceptibility to Cardiotoxicity from Antineoplastic Breast Cancer Medications

Deyu Sun, PhD1, Gyorgy J. Simon, PhD2,4, Steven Skube, MD3, Anne H. Blaes MD4, Genevieve B. Melton, MD, PhD2,3, Rui Zhang, PhD2,5
1School of Statistics, 2Institute for Health Informatics, 3Department of Surgery, 4Department of Medicine, 5College of Pharmacy, University of Minnesota, MN

Abstract
Cardiotoxicity is a relatively common and particularly important adverse event caused by chemotherapy for breast cancer patients. Typical associative phenotypes, such as risk factors associated with diabetes, can often be detected solely based on the data elements existing in electronic health records; however, causal phenotypes, such as risk factors causing cardiotoxicity, require establishing causation between chemotherapy and determining new heart disease, and cannot be directly observed from EHR. We propose three phenotyping algorithms to assess breast cancer patients' susceptibility to cardiotoxicity caused by five first-line antineoplastic drugs: (1) causal phenotype model to predict the patients' risk of cardiotoxicity as the difference between the heart disease risks with exposure and non-exposure to the drugs; (2) regular predictive model; (3) combined predictive model of the above two models. Concordances for three methods were 0.60, 0.62, and 0.68. When considering all exposed patients, concordances were 0.66, 0.58 and 0.65 at 280 days after treatment. The study demonstrates the potential utility of causal phenotyping.

Introduction
Phenotyping is a quintessential tool for constructing patient cohorts that consist of patients with a set of desired physiologic or other physical characteristics (referred to as phenotype) [1-3]. Finding such cohorts is helpful for different applications such as clinical trials or intervening for direct patient care for improved population health. Given an intervention that potentially benefits patients suffering from a particular condition (phenotype), phenotyping algorithms can be used to search large electronic health record (EHR) databases to identify patients who very likely have a particular condition (cases) and also patients who very likely to not have that particular condition (controls).

It has been abundantly demonstrated that machine learning methods can be applied as techniques to help solve the phenotyping problem [4]. From a machine learning perspective, phenotyping is a detection problem, where the machine learned model associates EHR data elements with the condition in question. This approach can be very successful owing to the fact that many diseases have associated data elements that are specific to the disease. For example, the eMERGE phenotyping algorithm for diabetes [5] utilizes factors directly associated with the disease such as diagnosis codes of diabetes, blood sugar levels, and diabetes medications for detecting the disease in the EHR. For this use case, diabetes diagnosis codes are only (or mostly in the case of drugs) given to patients with diabetes and high blood sugar levels are one of the main defining characteristic of diabetes. We refer to phenotypes that can be detected directly with associated EHR data elements as associative phenotypes.

In this work, we propose to explore the concept of causal phenotypes. In contrast to associative phenotypes, causal phenotypes do not have directly associated EHR data elements. For example, cardiotoxicity, which is defined as heart disease due to chemotherapy, is not directly associated with any diagnosis code, lab test, procedure or treatment. From the EHR, we can detect that the patient has received the chemotherapy that may trigger and cause heart disease. We can also identify that the patient has suffered an incident (new) of heart disease after the chemotherapy, but we cannot determine from the EHR whether these two elements have a causal relationship since the patient may have suffered from heart disease even if she had not received chemotherapy.

The eMERGE library of phenotypes [6] does provide an example of causal phenotype: drug induced liver injury. Briefly, the algorithm identifies patients who had normal liver function before taking a drug that may cause liver injury and have abnormal liver function after taking the drug. This algorithm implicitly attributes all deterioration of liver function to the drug. While this algorithm may be mostly correct in the case of liver injury (patients with chronic kidney disease are excluded), such a strategy may also incorrectly attribute liver injury to a drug in cases where patients have polypharmacy or undocumented exposure to other hepatotoxic elements. Also, this approach will certainly be incorrect for some cases of cardiotoxicity. This is because numerous conditions (e.g., ischemia, neutropenic fever,
gradual decompensation) can cause heart disease in a patient outside of chemotherapy. To ascertain cardiotoxicity from chemotherapy, we need to quantify the causal effect of chemotherapy on heart disease.

A second key difference between causal cardiotoxicity and the typical disease phenotyping algorithm is that we are interested in understanding a given patient’s susceptibility to the disease. While many of the existing phenotyping algorithms are particularly apt for detecting existing disease in patients after diagnosis, they tend not to be useful for quantifying susceptibility to disease before or as it develops. Quantifying susceptibility is essentially risk prediction, in which the existing machine learning phenotyping algorithms could be easily re-trained to perform; however, predicting cardiotoxicity requires prediction of the causal effect of an intervention, which is a much more challenging task. This is the task we set out to explore and ultimately solve in this paper.

In our work, we are focusing on cardiotoxicity in breast cancer. Breast cancer is the most common cancer in women worldwide [7]. Chemotherapy is an essential part of the treatment regimen for many patients diagnosed with breast cancer [8]. Chemotherapy can be extremely beneficial to patients with breast cancer by improving survival and decreasing recurrence; however, its utility can also be limited because of adverse events and side effects [8]. Cardiotoxicity is a particularly important and relatively common adverse event caused by chemotherapeutic agents used for breast cancer. Cardiotoxicity is a general term that signifies toxicity affecting the heart [8]. In other words, cardiotoxicity is heart disease caused by chemotherapy. In the Food and Drug Administration Structured Product Labels (FDA SPL), two of the main chemotherapy drugs used in breast cancer treatment have black box warnings of cardiotoxicity. These drugs are doxorubicin (Adriamycin) and trastuzumab (Herceptin or Ado-Trastuzumab Emtansine) [9-11]. Doxorubicin causes Type I chemotherapy-induced cardiotoxicity (cell death, cumulative, permanent) while trastuzumab causes Type II chemotherapy-induced cardiotoxicity (cell dysfunction, not cumulative, reversible) [8]. Risk factors and predictors of which patients will develop cardiotoxicity are still lacking in both doxorubicin and trastuzumab [12-13]. Also, epirubicin (Ellence) and pertuzumab also have black box warnings of cardiotoxicity [14-15]. All of these agents associated with chemotherapy-induced cardiotoxicity were included in this study.

The manifestation of cardiotoxicity in cancer patients is varied and shares similar symptoms as heart disease. Presentation can be acute, subacute, or chronic with the timeline ranging from hours to years after chemotherapy administration [8, 12]. Acute changes associated with cardiotoxicity include tachycardia, arrhythmias, electrocardiogram (EKG) changes, and changes in markers for cardiac injury (troponin). Subacute and chronic changes are often related to decreased ventricular function as noted on echocardiogram, symptoms of congestive heart failure (CHF), and issues with arrhythmias. Less commonly, pericarditis and myocarditis can occur [8, 12, 13]. Patients at risk for chemotherapy-induced cardiotoxicity are often co-managed by cardiologists and followed closely through imaging studies and outpatient assessments. There are also several approaches taken to reduce the potential for cardiotoxicity and to reduce the effects of cardiotoxicity; however, this is more individualized as there is no consensus guideline for the treatment or prevention of chemotherapy-induced cardiotoxicity [8].

We propose three phenotyping algorithms to assess patients' susceptibility to cardiotoxicity in breast cancer caused by five first-line breast cancer drugs: ado-trastuzumab emtansine, trastuzumab, doxorubicin, epirubicin, and pertuzumab. First, we present the casual phenotyping algorithm. This algorithm aims to estimate the causal effect of chemotherapy on heart failure. The algorithm requires labels of heart failure but does not require gold-standard labels of cardiotoxicity. Heart failure is an associative phenotype and thus determining whether a patient has heart disease from EHR is relatively simple. On the other hand, obtaining gold-standard cardiotoxicity labels requires that we determine whether the treatment is causally related to the heart disease and is thus difficult. The second method is the “regular” Cox model. If we have gold-standard labels, we can construct a regular predictive model (Cox proportional hazard model) to directly estimate the patients' risk of cardiotoxicity based on the available physiological data. Third, we can combine the above two models to incorporate the estimated causal effect into the Cox model.

We evaluated the method on retrospective cohort data collected from University of Minnesota Medical Center (UMMC) and a set of gold standards generated by a clinician. We found that the causal phenotype model works reasonably well without being trained with gold-standard labels and the third model which combined the causal phenotype model and regular predictive model works the best. The ability of the causal phenotype to achieve reasonable performance without gold-standard labels is particularly important. Generally, machine learned models cannot be simply ported from one site to another; they typically require re-training [16], which in turn, requires gold-standard labels. When obtaining gold-standard labels is difficult, our proposed model's ability to operate without gold-standard labels is particularly valuable. When gold standard labels are available, the proposed causal effect improves the performance of the machine learned phenotyping algorithm trained on physiological data.
Methods

Data Collection

In this retrospective cohort study, 4084 patients diagnosed with breast cancer and treated with chemotherapy at UMMC from 2000 to 2017 were included. The risk factors of heart failure, including age, body mass index (BMI), high-density lipoprotein (HDL), low-density lipoprotein (LDL), hemoglobin A1c (HbA1c), troponin, B-type natriuretic peptide (BNP), coronary artery disease (CAD), systolic and diastolic blood pressure (systolic BP and diastolic BP), and heart rate (HR), were collected as a baseline prior to the start of chemotherapy treatment. We also included infection markers such as white blood cell count (WBC) and temperature. For patients who took the breast cancer drugs with cardiotoxicity warnings, the baseline is when the first dose of the drug was taken; for patients who received other interventions, the baseline is the first time the breast cancer was diagnosed, because the date of the intervention is not always known. The endpoint is the first time the patients were diagnosed with heart disease related to cardiotoxicity; for patients who did not have symptoms of cardiotoxicity, the endpoint was arbitrarily chosen (12/31/2016). The characteristics of the cohort are shown in Table 1.

* Data are means (SD) or numbers (%).

We used two-sample t-test to compare the risk factors in two groups. No significant differences in risk factors between two groups of patients were detected at the significance level of 0.05. No patient who took the drugs with cardiotoxicity warnings had prior BNP test results. As demonstrated in Table 1, the rate of missingness for a number of these variables is high. A high rate of missingness is a common and difficult problem for many secondary uses of EHR data. For instance, Hu et al. compared various imputation methods for EHR data; in their analyses, imputing the mean values of the cohort while adding an indicator variable signaling imputation (“dummy variable”) not only has acceptable performance but also can correct bias due to higher rates of missingness [17]. Here, we treat the missing values in the risk factors by imputing the mean values of the cohort, and an indicator variable signaling imputation was also added.

Extraction of Heart Diseases Related to Cardiotoxicity

Types of heart disease that may be caused by each breast cancer drug of interest are recorded in the black box warning section of the package inserts or FDA SPLs. Using a previously described approach, we first extracted all diseases from the black box warnings through natural language processing (NLP) algorithms [18]. Then, the clinicians reviewed the extracted diseases and assigned the ICD-9-CM as well as ICD-10-CM codes to each one (Table 2).
Acquisition of Cardiotoxicity Gold Standards

Rather than review all charts including those with no indication of heart disease, the charts of the 80 patients who took the drugs with cardiotoxicity warnings and showed symptoms of heart failure were manually reviewed and adjudicated by a physician (Table 1). Clinical notes, laboratory data, and imaging were reviewed by the clinician. Among 80 patients (with heart failure), 42 patients were found to have chemotherapy-related cardiotoxicity. Common examples of heart failure that is not chemotherapy-related included pulmonary complications with symptoms incorrectly classified as cardiac, cardiac arrhythmias thought to be secondary to acute illness or decompensation rather than chemotherapy, and transient post-operative cardiac issues thought to be unrelated to chemotherapy. The outcome of the physician’s adjudication served as a gold standard to evaluate our phenotyping models.

Figure 1 shows the proportion of patients that truly have chemotherapy-related cardiotoxicity among those with heart failure. We can see that the heart disease that developed 280 days after the initial chemotherapy tends to be more related to the breast cancer treatment (i.e., heart disease before 280 days is potentially more often caused by factors other than the chemotherapy).

Figure 1. The proportions of cardiotoxicity over time. Each circle estimates the proportion of the patients developing symptoms that have cardiotoxicity at a certain time since baseline. The red curve is the estimated trend by fitting the data points. The dashed horizontal line indicates the average proportion (0.525 or 42/80).
Proposed Phenotyping Methods

We designed three phenotyping methods, one of which does not use the gold-standard labels, and then evaluated each algorithm’s performance in terms of concordance. Concordance is the probability that in a randomly chosen pair of patients, where one developed cardiotoxicity earlier than the other (or the other did not develop it), the one with earlier cardiotoxicity has higher risk. We used bootstrapped cross-validation with 100 iterations to estimate the concordance and its sampling distribution.

The Causal Phenotyping method relies on the Neyman potential outcomes framework [19] to estimate the excess risk of heart failure attributable to the chemotherapy agents in this study. In the potential outcome framework, we need to estimate the patients’ risk of developing heart failure when they receive chemotherapy ($\hat{Y}_1$) and the risk of heart failure when they do not receive chemotherapy ($\hat{Y}_0$). For patient $i$, the causal effect of chemotherapy is the difference between these two risks $\hat{Y}_{1i} - \hat{Y}_{0i}$.

As shown in Figure 2, we compute $\hat{Y}_{0i}$ using the patients who did not actually receive chemotherapy. We fit a Cox proportional hazard model (denoted by $M_0$ in Figure 2) predicting heart failure. These heart failure events are clearly not cardiotoxicity because the patients lack exposure to the potentially cardio-toxic agents. We then use this model to make predictions for patients who actually received chemotherapy, obtaining their expected number of (cumulative hazard of) heart failure by the end of the study.

We compute $\hat{Y}_{1i}$ by fitting a Cox proportional hazard model (denoted by $M_1$ in Figure 2) to the patients who received the potentially cardio-toxic chemotherapy agents and make predictions for these patients in a cross-validated fashion using the jackknife procedure (also known as leave-one-out cross-validation). This prediction is the cumulative hazard (expected number) of heart failure events until the end of the study under chemotherapy.

The difference between the two risk estimates is the excess risk of heart failure conferred on the patient by the chemotherapy agent. We call this quantity the causal effect. With higher causal effect, heart failure is more likely to be a result of chemotherapy than an independent reason (e.g. ischemia).

Notice that this procedure does not require gold-standard labels of cardiotoxicity. We only used the gold-standard labels for evaluating the performance of the method.

![Figure 2](image.png)

**Figure 2.** Flow chart of causal phenotype model. $M_0$ is the Cox proportional hazard model fitted for the patients who did not receive chemotherapy drugs with cardio-toxic side effect; $M_1$ is the Cox proportional hazard model fitted for the patients who received chemotherapy drugs with cardio-toxic side effect.

2. Regular predictive model.

The regular predictive model is the Cox proportional hazard model built on the population with exposure to the potentially cardio-toxic chemotherapy agents using physiological variables as predictors and the gold-standard labels as training labels.
3. Combined predictive model.

The combined predictive model integrates the above two models together by adding the causal effect acquired by the causal phenotype model as an additional predictor to the second model. We expected the combined model to take the advantages of both models and perform best.

Results

We first estimated the performances of the model M₀ and M₁ by cross validation. M₀ and M₁ are Cox proportional models which predict the expected number of heart disease events for any individual from the two groups, i.e. without exposure to the drugs and with exposure, respectively, after almost infinite time (10,000 days since the baseline). The concordance of the model M₀ and the model M₁ are 0.76 and 0.63, respectively. Cardiotoxicity can be more of a chronic disease than acute heart disease that can be well predicted by physiological data at baseline. The model built on the population exposed to the chemotherapy mixed the risks of both cardiotoxicity and acute heart diseases. Thus, the performance of the model M₁ is not as good as that of M₀.

Due to differences in baseline characteristics and missingness patterns of information between the exposed and unexposed populations, the distributions of the predicted risks by M₀ and M₁ have similar shapes, but different scales and a minor shift between the modes of the two distributions is also visible. (Figure 3 depicts the two distributions.) This necessitates the recalibration of M₀, which we carried out by a linear transformation of the predictions of M₀ to match the predictions of M₁ by having the same mean and scale.

![Different Predicted Risks, Before Re-calibration](image)

**Figure 3.** The difference in the predicted risks of heart diseases by using M₀ and M₁.

As discussed in the Methods section, the difference in the predicted risks between M₁ and M₀ on the same individual is the net, causal effect of exposure to the drugs on the risk of cardiotoxicity.

Figure 4 shows the concordances of three models estimated by bootstrapped cross-validation. We estimated both the overall performance and the long-term (>=280 days) performances. We can see that the combined predictive model has the best overall performance as well as long-term performance (0.68 and 0.65, respectively), while causal phenotype model has comparable long-term performance to the combined predictive model (0.66 vs 0.65).
In this paper, we proposed the concept of causal phenotyping, where the phenotype is defined as a causal effect of a condition on another. Specifically, we constructed phenotyping algorithms for cardiotoxicity caused by certain breast cancer chemotherapy agents. Cardiotoxicity cannot be directly observed from the her. We can observe directly that the patient has received chemotherapy utilizing the agents in this study and we can also observe that the patient has developed heart failure, but we cannot observe whether the heart disease is a direct consequence of the chemotherapy. We used causal inference to ascertain the degree to which chemotherapy contributed to the heart failure.

In particular, we built three different models. First, we built a causal model, which simply quantifies the causal effect of chemotherapy on heart failure risk for each patient. We can then rank the patients on their personal estimate of causal effect: the patients with the highest causal effect are most likely to develop cardiotoxicity (as opposed to heart failure not attributable to chemotherapy). Overall this model has (median) concordance of .60 when we consider all patients who received chemotherapy and .66 when we only consider long-term (“chronic”) cardiotoxicity. We defined long-term as ‘at least 280 days after treatment initiation’.

**Discussion**

![Figure 4](image)

**Figure 4.** Concordances estimates by bootstrapped cross validation using: (a) all patients and (b) patients with at least 280 days follow-up (patients with heart failure within 280 days are excluded).
Not only does this model offer reasonable performance, but it also does not require gold standard cardiotoxicity labels for training; it only requires heart failure labels, which can be obtained inexpensively with no assistance from clinicians. In contrast, obtaining gold-standard cardiotoxicity labels requires clinicians’ adjudication for each patient, making it labor-intensive and expensive. This is particularly beneficial in light of the observation that machine learned models often require retraining when they are ported from one healthcare provider site to another.

For comparison, we also constructed a “regular” Cox model, using gold-standard cardiotoxicity labels (and time to cardiotoxicity) as outcome. This model was constructed using physiological variables as predictors and achieved superior performance on the entire population as compared to the causal phenotyping algorithm: a median concordance of .63 as opposed to the causal phenotyping algorithm’s .60. Its performance, however, dropped to .58 when we only considered long-term cardiotoxicity.

The key difference between the causal phenotyping and the “regular” Cox model is that causal phenotyping is more sensitive in predicting long-term cardiotoxicity, while the “regular” model built on baseline physiological data is more sensitive towards short-term cardiotoxicity. Cardiotoxicity (“acute cardiotoxicity”) can happen immediately upon the initiation of the chemotherapy, but typically occurs on the longer scale (“chronic cardiotoxicity”) presumably through accumulation of damage. Our Figure 1 supports this common belief. It is interesting that the “regular” model could predict the short-term cardiotoxicity from physiological data, which could suggest that subclinical manifestation of the disease may have been present at the initiation of the treatment.

We also constructed a “combined” model, which uses both the causal effect and patients’ physiological data. As expected, this model utilized the physiological data to predict short-term cardiotoxicity and successfully utilized the causal effect towards predicting long-term cardiotoxicity. Consequently, the “combined” model achieved the highest median concordance of .68 on the entire set of chemotherapy patients; and achieved similar performance to the causal phenotyping algorithm on the long-term cardiotoxicity (median concordance of .66).

We wish to remind the readers that the proposed models are predictive models as opposed to the typical detection models. Predictive models utilize risk factors that are present before the disease manifests itself clinically, while detection models utilize data elements that are consequences of the diagnosis and subsequent treatment of an already existing disease. Therefore, the performance of predictive such models is necessarily much lower than that of detection models. Concordance of .6 to .7 is statistically significantly non-random but is a testament to the limits of predictability. Examples of heart failure in this study not due to chemotherapy include ischemia, rapid deterioration secondary to some other condition, misdiagnosis (patient did not actually have heart failure) and neutropenic fever. Given that the physiological data is collected at the initiation of the chemotherapy, we can possibly detect the incorrect diagnosis and ischemia, but we certainly cannot detect neutropenic fever or rapid deterioration. We did include WBC as an indication of possible immunosuppressive treatment, but baseline levels of WBC and temperature have little relation to neutropenic fever months or years later.

The models introduced in this paper mainly used the risk factors extracted from structured data. Based on guidelines and knowledge of domain experts, in the future we will include more potentially confounding risk factors extracted from both structured and unstructured data, such as smoking status and alcohol use, ejection fraction, dose of chemotherapy drugs taken, history of chest-directed radiotherapy, history of anthracycline use, history of diabetes, and history of related heart diseases. Lastly, since collecting gold standard values requires intensive chart review and is time-consuming, we plan to recruit more physician domain experts to enhance both the quantity and quality of gold standard acquisition, and will include inter-rater reliability as a means to demonstrate internal validation of the gold standard.

**Conclusion**

In this paper, we proposed the concept of causal phenotyping in the context of assessing breast cancer patients’ susceptibility to cardiotoxicity as a result of undergoing chemotherapy utilizing certain potentially cardio-toxic agents. The proposed method achieved reasonable predictive performance even though it does not require gold-standard cardiotoxicity labels for training. Its performance for predicting longer-term (at least 280 days after the initiation of chemotherapy) cardiotoxicity was higher than that of a Cox model trained on the gold-standard labels. The Cox model, in turn, had superior performance in predicting shorter-term cardiotoxicity (less than 280 days after the initiation of chemotherapy). Unsurprisingly, combining these two models achieved the overall best performance, since the model successfully predicted both short- and long-term cardiotoxicity. Training the combined model, however, requires gold-standard labels.

Abstract

Monitoring the future health status of patients from the historical Electronic Health Record (EHR) is a core research topic in predictive healthcare. The most important challenges are to model the temporality of sequential EHR data and to interpret the prediction results. In order to reduce the future risk of diseases, we propose a multi-task framework that can monitor the multiple status of diagnoses. Patients’ historical records are directly fed into a Recurrent Neural Network (RNN) which memorizes all the past visit information, and then a task-specific layer is trained to predict multiple diagnoses. Moreover, three attention mechanisms for RNNs are introduced to measure the relationships between past visits and current status. Experimental results show that the proposed attention-based RNNs can significantly improve the prediction accuracy compared to widely used approaches. With the attention mechanisms, the proposed framework is able to identify the visit information which is important to the final prediction.

1 Introduction

Disease monitoring is often limited by physician experience, test time, economic barriers and so on. The Electronic Health Record (EHR), which consists of longitudinal health information of patients, is a valuable source for exploratory analysis to monitor diseases and assist clinical decision making. However, due to the complexity of EHR data, the efficient mining of EHRs is not trivial. Firstly, EHR data is heterogeneous which contains various types of features. For example, type of visit is a categorical feature while body mass index is continuous. In addition, some features are static through the lifetime while some change dynamically. Models should be able to capture the essence of heterogeneous features. Secondly, the data is inherently sparse and noisy, due to patient’s irregular visits, absence of tests, and incomplete recording, etc. Thirdly, result interpretation in healthcare applications is essential, and the lacking of interpretability often hinders the adaption of models in clinical settings. Thus, how to correctly model heterogeneous and sparse EHR data and reasonably interpret the prediction results is a challenging problem for disease prediction.

Recent work has made rapid progress in utilizing EHRs for predictive modeling tasks in healthcare, including predicting unplanned readmission, early prediction of chronic disease, adverse event detection and monitoring disease progression. In these settings, the EHRs are typically represented as temporal sequences of medical visits, and each visit contains a set of objects (such as diagnosis and procedure codes). The main idea is to learn a good representation of a patient’s historical health information, in order to improve the performance of the prediction for future risks. To capture the progression of the patient’s health status, much effort has been made on regression models and Markov models. However, these models cannot take into account the long-term dependencies of diagnoses, which may miss several severe symptoms in the past and reduce the performance of disease monitoring.

In order to model the dependencies of diagnoses, deep leaning techniques, such as recurrent neural networks, can be employed. Recent work shows that deep learning can significantly improve the prediction performance. To handle the temporality of multivariate sequences, dynamically modeling the sequential data is necessary. Recurrent neural networks (RNNs), in particular Long Short-Term Memory (LSTM) and Gated Recurrent Units (GRU), have achieved state-of-the-art performance in handling long-term dependencies and nonlinear dynamics. Taking advantage of the capability of RNN in memorizing historical records, multiple recent models based on RNNs are employed for deriving accurate and robust representations of patient visits. The work by Lipton et al. applies LSTM to a multilabel classification task for diagnosing multiple diseases in the future, and the contemporary work by Choi et
al.\textsuperscript{11} applies GRU to predict codes for subsequent visits. Both of them show the efficacy of basic RNN models in modeling longitudinal healthcare data. Among the state-of-the-art models, RETAIN\textsuperscript{12} adopts a temporal attention generation mechanism to learn both visit level and code level weights; GRAM\textsuperscript{13} is a graph-based attention model, which uses medical ontologies to handle data insufficiency and combines with an RNN to learn robust representations; and Diploe\textsuperscript{14} uses bidirectional recurrent neural networks (BRNNs) to further improve the prediction accuracy.

The aforementioned models are RNN-based frameworks which use medical codes as inputs to predict whether the diagnosis or treatment will appear in the future visit, i.e., binary prediction. However, for some diseases, the doctor may care about the transition and severity level of the clinical event, i.e., multiple prediction. For example, if a person is likely to have osteopenia, the doctor may suggest more exercises and supplements, while if osteoporosis occurs, medications will be necessary. To measure the severity of diagnoses, the diagnosis values may be discretized into multiple status: normal range and abnormal range of different severity (i.e. low/high abnormal range), following doctor's advice or medical references. As a disease may be characterized by multiple important observations or diagnoses, we need to monitor these variables simultaneously.

In this paper, our goal is to predict the status of multiple diagnoses (or observations), with each diagnosis having multiple severity levels. We form our problem as multi-task learning, which first learns a shared representation from all the features, and then performs task-specific predictions. We propose an attention-based RNN model to monitor patient’s longitudinal health information. First, we use an RNN to memorize all the information from historical visits, and then attention mechanisms to measure visit importance. Based on the latent representation, we train multiple classifiers and each focuses on the prediction of a specific task. We perform our model on two applications: predicting chronic states for bone health, and monitoring BloodTest values for cardiovascular disease. Our main contributions can be summarized as follows:

- We propose a multi-task framework to monitor the future status of different clinical diagnoses. We process the monitored diagnoses to multiple severity status following medical references, which can help doctors to make more precise decisions on controlling risks.
- We employ three attention mechanisms to evaluate the importance of previous visits to prediction tasks. This gives the explanation of visit importance, which can provide suggestions for doctors to pay more attention on the information from a specific timestamp.
- Our experiments show promising results of using RNNs to handle historical health information from longitudinal records. We empirically show that the proposed attention-based RNNs outperform widely used methods in multi-diagnoses prediction on real world EHR datasets.

This work will result in an effective tool for the physicians to monitor disease progression for early treatment in a more efficient way. This framework can be used real-time on a regularly scheduled basis which highlights patients whose disease state is more likely to worsen.

2 Method

In this section, we first introduce the format of our healthcare datasets and some basic notations. Then we describe the details of the proposed framework, including the preliminary of RNN structure, proposed attention mechanisms, and the multi-task model. Finally, we describe the interpretation for analyzing the importance of different visits.

2.1 Basic Notations

The EHR data contains heterogeneous variables such as diagnosis results, lab data, and physical functions. Among them, diagnosis results are what we care about most, and we want to monitor their progression. Other variables are risk factors that may potentially influence patient’s health status. Assume that there are $N$ patients and $M$ diagnoses to be monitored, and the total number of visit records for the $n$-th patient is $T^{(n)}$. The health record of a patient can be represented by a sequence of visits $V_1, V_2, \ldots, V_{T^{(n)}}$. Each visit $V_t$ is denoted by a vector of feature variables $x_t$. To monitor patient’s health status progression, the diagnosis results are discretized into several classes, indicating
the severity level of the disease, following doctor’s opinions or medical references. For example, in a patient’s visit for bone health test, bone mineral density (BMD) in different areas such as femoral neck and intertrochanteric is measured, and the X-ray scan results can be diagnosed as normal, osteopenia and osteoporosis. We want to predict the severity range of BMD value in each bone area in this patient’s next visit. For simplicity, we describe the proposed method for a single patient and drop the superscript \((n)\) in the following notations when it is unambiguous. Figure 1 illustrates the health records of one patient in our data. The patient has multiple visits, and each visit contains multiple variables. Each monitored variable falls into a severity range. Suppose that we are currently at time \(t\) and want to know the diagnoses at time \((t+1)\), this patient’s historical records from \(V_1\) to \(V_t\) can be utilized for the training of the model.

2.2 Model

The basic component of our framework is gated recurrent unit, which is a state-of-the-art deep learning architecture for modeling long range sequences. To further improve its performance, we apply attention mechanisms to measure the importance of historical sequences. To predict the status of multiple diagnoses, we add a multi-task classification layer on top of the learned representations.

Recurrent Neural Network

Recurrent neural network (RNN) captures the characteristics of the input sequence by recursively updating its internal hidden states. Figure 2(a) shows the unfolded RNN structure for a general classification task. For the first visit \(V_1\) (i.e., \(t = 1\)), RNN learns a hidden state \(h_1\) to represent the input feature vector \(x_1\); as time moves to \(t = 2\), feature vector \(x_2\) together with \(h_1\) are fed into the RNN to update parameters in the network, and the learned hidden state \(h_2\) contains information from both \(x_2\) and \(x_1\). Through updating the network parameters recursively, the hidden state \(h_t\) learns all the previous information from \(x_1\) to \(x_{t-1}\). Then a softmax classifier is applied on \(h_t\) to perform classification. As the parameters of the network are shared by each visit, RNN can handle patients with different visit lengths.

We implement our RNN with Gated Recurrent Units (GRU)\textsuperscript{15}, which has been shown to have comparable performance as Long-Short Term Memory (LSTM), while employing a simpler architecture. The structure of GRU is shown in Figure 2(b). A GRU has two gates, a reset gate \(r\) and an update gate \(z\). Intuitively, the reset gate determines the combination of the new input and the previous memory, which allows the hidden layer to drop irrelevant information that is not useful to the prediction, and the update gate controls how much information from the previous hidden layer
Attention Mechanism

As mentioned in the above section, RNN can remember the past information for future prediction. However, it is limited to only a few latest steps, with more impact from later ones, and may not be able to discover major influences from earlier timestamps. Therefore, we apply attention mechanisms to memorize the effect from long-time dependencies, which have gained success in many tasks. In neural machine translation, the attention mechanism can be intuitively described as follows: given a sentence of length $S$ in the original language, RNN is adopted to generate the word representations $h_1, \ldots, h_{|S|}$. To find the $t$-th word in the target language, we assign each word in the original language an attention score $\alpha_{t,i}$, and then calculate a context vector $c_t = \sum_{i=1}^{S} \alpha_{t,i} h_i$ to perform prediction. Through attention mechanism, RNN can focus on specific words when generating each target word. Similarly, in diagnoses prediction, we use a temporal attention mechanism to predict medical results in the $(t+1)$-th visit, according to visit time $t$. The mathematical formulation of GRU can be described as follows:

$$
\begin{align*}
    z_t &= \sigma(W_z x_t + U_z h_{t-1} + b_z), \\
    r_t &= \sigma(W_r x_t + U_r h_{t-1} + b_r), \\
    \tilde{h}_t &= \tanh(W_x x_t + r_t \odot U h_{t-1} + b_h), \\
    h_t &= z_t \odot h_{t-1} + (1 - z_t) \odot \tilde{h}_t
\end{align*}
$$

where $\odot$ denotes the entry-wise product, $\sigma$ is the activation function, $r_t$ and $z_t$ represent the reset gate and update gate at time $t$ respectively, $h_t$ is the intermediate memory unit, and $h_t$ is the hidden unit. Matrices $W_r, W_z, W, U_r, U_z, U$ and vectors $b_r, b_z, b$ are model parameters to be learned. At time $t$, we take the hidden state $h_t$ to predict the labels of time $(t+1)$. The figure illustrates both location-based attention and general attention mechanisms.
records from \( x_1 \) to \( x_t \). The hidden state \( h_t \) from the \( t \)-th visit can be estimated as a representation for the \((t + 1)\)-th visit. However, it may not contain enough long-term visit information. Therefore, we need to derive a context vector \( c_t \) which captures relevant information to help prediction. We propose three methods to compute attention score \( \alpha_t \) in order to obtain the context vector \( c_t \): location-based attention, general attention and concatenation-based attention.

The attention mechanisms are illustrated in Figure 3. The general procedure goes as follows: we first obtain a set of hidden states through the GRU layer, and then calculate the attention score \( \alpha_i \) for each of them, in order to obtain the context vector \( c_t \): an attentional hidden state \( h_t \) is then calculated by combining \( c_t \) and \( h_t \). Thus \( h_t \) contains both current and historical information. Location-based attention, as in Figure 3(a), calculates the attention score solely from each individual hidden state \( h_i \) (\( 1 \leq i \leq t - 1 \)) using formula: \( \alpha_{ti} = W_{ai}h_i + b_{a} \), where \( W_{a} \) and \( b_{a} \) are parameters to be learned. Since location-based attention mechanism only considers each hidden state individually, it does not capture the relationships between the current hidden state and all the previous hidden states. The other two attention mechanisms, as shown in Figure 3(b), calculate attention weight \( \alpha_{ti} \) by considering the relationship between \( h_t \) and \( h_i \). General attention uses a weight matrix \( W_{a} \) to connect \( h_t \) and \( h_i \) through formula: \( \alpha_{ti} = h_{ti}^T W_{a}h_i \). For concatenation-based attention, we first concatenate the current hidden state \( h_t \) and the previous state \( h_i \), and then calculate a latent vector by multiplying a weight matrix \( W_{a} \). Thus the attention weight vector is generated as: \( \alpha_{ti} = u_{a}^T \text{tanh}(W_{a}[h_t; h_i]) \).

After obtaining \( \alpha_t \), we can obtain the context vector \( c_t \) through formula \( c_t = \sum_{i=1}^{t-1} \alpha_{ti} h_i \), which contains the weighted hidden representations of the past visits from \( x_1 \) to \( x_{t-1} \). To combine the information from context vector \( c_t \) and the current hidden state \( h_t \), we employ a simple concatenation layer to generate an attentional hidden state \( h_t \) using \( \tilde{h}_t = \text{tanh}(W_{c}[c_t; h_t]) \), where \( W_{c} \) is the weight matrix to be learned. \( h_t \) contains all the information from \( x_1 \) to \( x_t \), such that the prediction task can be performed on top of \( h_t \).

**Multi-task Diagnosis Prediction**

Our task is to predict the status of multiple measurement results at the time \((t + 1)\) given the historical records from \( x_1 \) to \( x_t \). Figure 4 shows a high-level overview of the proposed model. Given the information from time 1 to \( t \), the \( i \)-th visit’s health record \( x_i \) is fed into an RNN network, which outputs a hidden state \( h_i \) as the representation of the \( i \)-th visit. Along with the set of hidden states \( \{h_i\}_{i=1}^{t-1} \), we compute their relative importance \( \alpha_i \), and then obtain a context state \( c_t \). From the context state \( c_t \) and the current hidden state \( h_t \), we can obtain an attentional hidden state \( \tilde{h}_t \), which is used to predict diagnoses in the \((t + 1)\)-th visit. For the prediction, we use \( M \) softmax classifiers, which correspond to the \( M \) different diagnoses, to predict the severity level for each diagnosis. The representation \( h_t \) contains the visit information of all the input features, and the task-specific classifier focuses on the prediction of each diagnosis.

![Figure 4: Overview of the proposed model.](image-url)
To perform the multi-task classification, we feed the hidden state $\tilde{h}_t$ into each task through a classification layer. Thus the information of the $k$-th diagnosis in the $(i+1)$-th visit can be produced by $\hat{y}^k_t = \text{Softmax}(W^k_s\tilde{h}_t + b^k_s)$, where $W^k_s$ and $b^k_s$ are parameters to be learned. We use cross-entropy between the ground truth $y_t$ and the predicted $\hat{y}_t$ to calculate the classification loss. The total loss is the sum of cross-entropy among all the diagnosis categories in predicted visits of patients. The loss function $L$ can be described as:

$$
L = -\frac{1}{N} \sum_{n=1}^{N} \frac{1}{T^{(n)}} \sum_{t=1}^{T^{(n)}} \sum_{k=1}^{M} \left\{ (y^k_t)^{\top} \log(\hat{y}^k_t) + (1 - y^k_t)^{\top} \log(1 - \hat{y}^k_t) \right\},
$$

where $N$ is the number of patients, $M$ is the number of monitored diagnoses, and $T^{(n)}$ is the number of visits of the $n$-th patient. In the training procedure, we estimate parameters in the proposed models by minimizing the loss function (2).

**Interpretation**

In healthcare applications, giving interpretation of the learned representations is important. Here we evaluate the contribution of the past visits to the prediction of future status in the process of learning latent representations. Since we adopt attention mechanisms, the importance of each visit can be found by analyzing its attention score. For example, for the $t$-th prediction, if the attention score $\alpha_{ti}$ is large, then the probability of the $(i+1)$-th visit information related to the current prediction is high. In most cases, the last visit is usually important for chronic diseases, as patient’s health status usually does not change much during two visits. However, since disease progression is complex and affected by many factors, the disease can get better or worse. Thus the health information of specific earlier visits may be more important for some patients. Therefore, the attention mechanism can help doctors to pay attention to specific important visits in the past.

3 Experiments

We conduct experiments on two real-word datasets, and evaluate the performance of the proposed attention-based RNN models compared to other prediction methods. Moreover, we use case studies to understand the behavior of the proposed models.

**Datasets**

*Study of Osteoporotic Fractures Dataset.* The study of osteoporotic fracture (SOF)\textsuperscript{20} is the largest and most comprehensive study focused on bone diseases. It includes 20 years longitudinal data about osteoporosis of 9,704 Caucasian women aged 65 years and older. Potential risk factors and confounders belong to several groups such as demographics, family history, and lifestyle. We process people’s bone health diagnoses of different areas using the bone mineral density (BMD) values by comparison with young healthy references\textsuperscript{17}, resulting in three BMD levels: normal, osteopenia and osteoporosis.

*BloodTest Dataset.* This dataset\textsuperscript{21} contains multivariate blood tests of 3,000 patients affected by cardiovascular disease from the University Hospital of Catanzaro, Italy. For each patient, there are several blood tests during their in-hospital stay, such as hemoglobin, triglycerides, glucose, and calcium. As suggested by doctors, we pick 12 blood analytes variables which are important to cardiovascular. Each variable has a normal range provided by doctors. Knowing variable transitions in advance can alarm doctors to take actions before the abnormal occurs, in order to reduce the risk of diseases.

As a common issue of EHR, these datasets are irregular sampled and sparse, so that data preprocessing is needed. For each person, we remove those visits without any monitored variables recorded, and remove patients with less than three visits. We use simple imputation to fill missing variables. For the SOF data, we fill the missing variables with the values in the previous visit. For the BloodTest data, we impute missing sequences (where a single variable is missing entirely) with a clinical normal value. This is based on an assumption that clinicians believed it to be normal so that they did not measure it. Other missing variables are filled with the median value of other patients. After data preprocessing and extraction, we obtain the datasets with statistics shown in Table 1.

Experiment Setup

For each patient, we want to predict the diagnosis results of each visit based on his/her previous records. To validate the performance of the proposed models in this diagnosis prediction task, we conduct experiments on two categories of methods: baselines and RNN-based models.

We set up two kinds of baselines. The first baseline is to use the median value of each monitored variable from \( V_t \) to \( V_t \) to predict \( V_{t+1} \) for continuous variables. This is based on a heuristic assumption that the most frequent state is more likely to occur. For each patient, we use his/her most popular health status as the current status, regardless of time variations. The second baseline is a multi-task logistic regression (LR). To predict information at \( V_{t+1} \), we feed the health records at \( V_t \) to a logistic regression model with multiple softmax classifiers. This can be viewed as a simplified model of Figure 4 without using RNNs and attention mechanism to learn latent states. This model only considers the effect from previous one time step, rather than long time history.

For the proposed methods, we have several variants, including a plain RNN or attention-based RNNs. For RNN, the architecture is similar to the proposed model, but without the attention mechanism. RNN\(_l\), RNN\(_g\) and RNN\(_c\) are three attention-based RNN models, whose architecture is shown in Figure 4. RNN\(_l\), RNN\(_g\) and RNN\(_c\) stands for location-based, general and concatenation-based attention respectively. The attention mechanism of RNN\(_l\) can be seen in Figure 3(a), and attention mechanism of RNN\(_g\) and RNN\(_c\) can be seen in Figure 3(b).

The proposed approaches are implemented with Theano 0.7.0\(^{22}\), Adadelta\(^{16}\) with a mini-batch of 50 patients is used to optimize Eq. (2). To evaluate prediction performance, we define the accuracy as the ratio between correctly predicted severity status and the total number of variables to be predicted.

Results of Diagnosis Prediction

Table 2 shows the accuracy of the proposed approaches in comparison with baselines on the two datasets. For each patient in the testing set, we predict the health conditions for the subsequent visits using his/her historical health records. For the SOF dataset, we predict the probability of BMD states of normal, osteopenia and osteoporosis for different measurements such as hip and femoral neck. For the BloodTest dataset, we predict the probability of each blood analyte falling into normal, low abnormal and high abnormal. The results are averaged over 5 random trials of 5-fold cross validation. \( \text{Avg.\# Correct} \) represents the average number of correctly predicted claims of 5 random trials. \( \text{Accuracy} \) represents the ratio between correctly predicted claims and total number of claims to be predicted.

We can observe that RNN based methods outperform other baselines. The method of predicting with median values considers each variable separately, without taking into account the time trend and feature relationships. This intuitive method is very sensitive to noise, and cannot capture the correlation between variables. It performs the worst in the BloodTest dataset, possibly due to the reason that variables in that dataset are not independent but have strong correlations (e.g. MYO-CKM-TRHS-GPT-GL-GOT-LDH). Logistic regression (LR) takes the whole inputs into a classifier with multiple softmax functions, in order to classify each monitored variable. The structure of LR can be viewed as the framework of Figure 4 without latent representations to memorize historical information. The inputs of
LR include all the features, such that features can impact on each target task. However, there is no way for logistic regression to memorize historical information, as it only takes information from the nearest one visit. Attention-based RNNs outperform the above baselines. This owes to the capability of RNN in memorizing long-term dependencies of patient’s longitudinal health records, and the attention-based mechanisms can further enhance this capability. For the two datasets, RNN\(_l\), RNN\(_g\) and RNN\(_c\) can clearly outperform plain RNN. Since the prediction of RNN mostly depends on recent visits, it may not memorize all the past information. Through attention-mechanism, RNN\(_l\), RNN\(_g\) and RNN\(_c\) can fully take all the previous visit information into consideration, assign different attention scores for past visits, and achieve better performance compared to RNN.

Visit Interpretation

The attention mechanism can be used to understand the importance of historical visits to the current visit. As an example, here we analyze the concatenation-based attention mechanism on the SOF dataset. Figure 5 shows a case study for predicting the diagnoses in the sixth visit through the previous five visits. The concatenation-based attention weights are calculated for the visits from \(V_2\) to \(V_5\), according to the hidden states \(h_1, h_2, h_3\) and \(h_4\). Thus, we have four attention scores corresponding to the visits from \(V_2\) to \(V_5\). In Figure 5, we select five patients for visualization. The X-axis represents patients, and Y-axis is the attention score calculated for each visit. We can observe that for different patients, the attention scores learned by this attention mechanism are different.

For chronic diseases, the last visit is often the most important since patients’ health conditions change slowly. As in the figure, for the first, fourth and fifth patients, the importance of visit increases with time going on. However, this is not always the case due to the complexity of disease progression and impact from risk factors. Table 3 shows the variation of bone mineral density (BMD) diagnoses and attention scores of different visits of the second patient. In each visit, there are five different BMD diagnoses, and the values in the table indicate the severity of bone density.
Table 3: BMD diagnoses and attention scores of one patient with six visits on SOF dataset. 0 is normal, 1 is osteopenia, and 2 (osteoporosis) does not occur for this patient.

loss. Although V_4 and V_5 are closer to V_6 in terms of time, V_2 and V_3 have the same condition as V_6. Thus health records of V_2 and V_3 are more important to V_6. We can see that the attention mechanism correctly assigns larger weights to V_2 and V_3. As for the BloodTest dataset, using attention mechanism to memorize all the past information is also important. An abnormal blood analyte can temporarily turn into normality via medicine, but it may fall back after some time. Therefore, interpreting visit importance through the attention mechanism can help to better monitor disease progression.

In diagnosis prediction, making decisions using very recent record is usually not enough, and it is important to lookup long term health information. To understand the relationship between the length of patient medical history and the prediction performance, we select 1,000 patients from the BloodTest dataset with more than seven visits. Table 4 shows the accuracy of RNN in predicting the diagnoses from V_2 to V_7. We can see that with the number of visit increasing, the performance can often improve. We believe that it is due to the fact that RNN is able to learn better estimates of patient information as it memorizes longer health records.

4 Conclusions

In this paper, we introduce attention-based RNN architectures to predict patients’ disease progression. In particular, we monitor multiple diagnoses status simultaneously, based on patients’ historical health records. By employing recurrent neural network, our model can remember hidden knowledge learned from previous visits. Three attention mechanisms allow us to interpret the prediction results reasonably. Experimental results on two real world EHR datasets show the effectiveness of the proposed attention-based RNN models for simultaneously predicting multiple diagnoses. Analysis shows that the attention mechanisms can assign meaningful weights to previous visits when predicting the future visit information. The proposed approach can be widely used for the prediction of a variety of different diseases.

Abstract
Delirium has the highest occurrence rate of any complication in hospitalized adults over the age of 65. The study objective was to determine physician information needs for use in the development of electronic clinical decision support for physicians managing the care of patients with delirium. Critical incident interviews were conducted with 8 experienced internal medicine physicians and 1 cardiologist. Thematic analysis revealed the following 6 themes: 1) Clinician’s experience an impoverished information field for mental status, 2) Uncertainty is pervasive, 3) Extensive information foraging effort is required for cohesive story building, 4) Goal Conflict leads to missed diagnosis and early closure, 5) Diffusion of Responsibility for treating delirium is common, and 6) Use of structured delirium resources is minimal. Elicited information needs were identified and physician recommendations for improving access to information needed in managing the care of patients with delirium are reported. Information elicited in this study is useful for designing delirium clinical decision support that supports physician cognition.

Introduction
Delirium is acute confusion with attention deficits, which may fluctuate. It is the most common complication of hospitalized adults over age 65, occurring in 14-56% of hospitalized patients, depending on the associated conditions. Delirium is costly, as it is associated with increased complications, longer hospital stays, increased rates of institutionalization, and increased mortality. The annual economic burden in the United States has been estimated as high as $164 billion. Identification of delirium is an imperative because it is often confused with other conditions having a similar appearance. In addition, delays in treatment have been shown to decrease the chance of a full recovery. Studies have shown that delirium can be prevented and when it is caught early and treatment is begun, duration can be reduced. However, delirium is harder to reverse once it has occurred and because delirium is undiagnosed in up to 2/3 of cases, identifying risk is essential, decision support is needed.

Multidisciplinary efforts to reduce incidence of delirium have effectively reduced severity, duration, and incidence of delirium rates. However, previous decision support for attending physicians has had mixed results. For example, a letter and phone call from a geriatrician and pharmacist informing primary care providers of a patient’s ‘Drug Burden Index’ (a measure of exposure to anticholinergic and sedative medications), and advising them to consider whether anticholinergic and sedative medications could be reduced did not reduce the number of these medications that patient’s were receiving in the intervention group any more than in the control group. Physicians reported 1) being uncomfortable altering specialist initiated prescriptions; 2) previous failure at reducing medication, 3) patient unwillingness to alter medication, 4) unawareness that patient was receiving anticholinergic/sedative medications, and disagreement with recommendation. However, geriatric consultation in the hospital reduced delirium by 1/3 and severe delirium by 1/2. In another informatics implementation, physicians received a computer generated highly specific ‘interruptive’ alert that the patient’s delirium associated medication put them at risk for cognitive impairment and a recommendation for preferred alternative medications. This method of alerting physicians did not change prescribing behavior. Alternative methods of designing delirium CDS should be developed. An important first step in a radical design change is an investigation of the information needs and decision-making processes or cognitive tasks of doctors managing the care of these complex patients. Cognitive task analysis (CTA) or a variant of it such as critical incident interviews has been shown to be effective for elicitation of decision processes data.

Objectives
Characterize the decision process, strategies and information needs of physicians managing diagnostic dilemmas in patients with delirium.
Methods
The design of the study was a Qualitative Descriptive Study using Critical Incident Interview methodology. Eight internal medicine physicians (4 of whom reported that they were experienced geriatricians) and 1 cardiologist (N=9) were recruited from the inpatient medical wards at Salt Lake City VAMC and University of Utah Hospital. They were selected because of their extensive experience and all self identified as having overseen the care of an elderly patient with delirium. Clinicians were recruited either in person or through email. A time was set aside for the interview at the physician’s convenience.

Interview Procedures: Physicians were asked to report a complex case in diagnosing a patient over age 65 with delirium. Critical Incident Interview technique, an effective method for elicitation of cognitive processes, judgments, and decision20 was used to elicit qualitative and descriptive aspects of diagnosis and orders through the following steps: 1) The participant is asked to recall and give a brief report of a recently hospitalized patient with delirium where there was a diagnostic dilemma; 2) The researcher asked the participant to create a timeline of critical decision points in order to promote deeper recall and a common reference; 3) Probing was then used to elicit deeper processing of information seeking and the decision processes, including expectations, goals, surprises and “what if” scenarios. After the critical incident interviews, physicians were asked to make recommendations for improving access to the information that they needed in managing patients with acute mental status changes. The interviews, which took approximately 30 minutes, were audio recorded and then transcribed to a word document with any identifying information removed and the recordings were erased.

Data Analysis: Bradley, et al.21 described a method of data analysis and coding to uncover themes in health services research, “for understanding phenomena within their context, uncovering links among concepts and behaviors, and generating and refining theory.” Themes are recurrent and emergent unifying concepts that characterize the specific experiences of individual participants. Thematic analysis has been widely used in understanding decision processes and facilitates the move from a description of what is happening to an understanding of the process by which it is happening.22-24 This study uses Bradley’s methods applied to a cognitive task analysis of a critical incident interview investigation to identify information relevant in designing clinical decision support in the context of acute onset mental status change.

Qualitative analyses were conducted, including thematic analysis and development of content coding taxonomy. Analysis began with three investigators independently reading and identifying relevant text and applying pre-codes to three interview transcripts using procedures recommended by Patton.24 Then the investigators met to discuss and refine the pre-codes. After several iterations the remaining transcripts were independently coded, with additional pre-codes added and further discussion as the need arose. Finally, codes were aggregated into higher-level constructs. Sub-categories emerged which were grouped into themes.

Results
The results are presented in three parts. The first is the alerting method by which physicians became aware of the patient’s altered mental status, the second is the result of the thematic analysis, the third is a report of information needs and recommendations given by the physicians for improving access to information within the medical record.

Altered Mental Status Alerting & Features: Physicians reported on patients with delirium caused by adverse drug events, infection, dehydration, dementia, blood gas imbalance, and distress about hospitalization. For every case reported in our study an initial alerting event prompted investigation by the physician. Physicians reported that this alerting always came from human sources who knew the patient well enough to judge that there had been an acute change from the patient’s normal baseline mentation (as there is no lab value available). The reported sources of the verbal alert were family members, visitors, clinical staff, nursing home staff, and the physician’s own personal knowledge of the patient. In the absence of a verbal alert or personal knowledge, clinicians often reported initially assuming the patient had dementia (because the patient described was older).

Identifying features of delirium, in the cases reported by our study physicians, were: changes in personality, looking frightened or confused, inability to focus, uncooperativeness in a usually compliant patient, inability to recognize family or friend, post hoc diagnosis based on delayed recovery from altered to normal mentation, inability to cooperate, reduced ability to converse, fidgeting, talking crazy, disorientation, agitation, pulling on lines, decreased responsiveness, lack of interest in addiction, and not making connections.

Thematic analysis revealed six major categories. 1) Clinician’s experience an impoverished information field for mental status, 2) Uncertainty is pervasive, 3) Extensive information foraging effort is required for cohesive story
Theme 1. Impoverished Information Field: Interviews revealed that medical records lack information needed to establish mental status baseline. Physicians did not consider an acute mental status change to be definitive for delirium, however, diagnosis required a rule out, “Is this a case of delirium or is it confusion better explained by psychosis, depression, withdrawal, brain injury or a new baseline mentation (dementia)?” Physicians often lacked information needed in making this determination; people who knew the patient and could provide baseline information were often not present when the attending physician was available. Even when information was available, physicians reported that it was often inaccurate, lacked credibility or was hidden in voluminous notes. They often felt that family/friend reports were not accurate. Physicians trusted their personal knowledge and judgment of the patient’s baseline mental status. Physician’s reported that mental status data is difficult to locate in the volume of clinical notes that often accompany elderly patients and terms describing delirium varied a great deal among providers. The following subthemes of ‘Impoverished information field’ were identified: 1) Baseline data is sparse or missing, 2) Medication lists in the record are not accurate, 3) Available information often lacks credibility or is of low value, 4) Mental Status Data is embedded in the note, 5) Searching is complicated by vague terms. See Table 1 for examples.

Theme 2. Uncertainty Is Pervasive: The lack of credible information in complex settings related to mental status and delirium gives rise to a pervasive sense of uncertainty. Not only did physicians have difficulty determining baseline mental status and the timing of the patients mental status change, they often had significant difficulty finding a cause. Attribution of the mental status change was ambiguous and multifactorial. Regardless of family reports, delirium was often viewed as dementia if clinical staff did not directly observe fluctuations in mental status in these older patients. Clinicians made assumptions to build sensible stories when credible information was unavailable, often assuming dementia. Physicians reported that delirium can only be diagnosed if it responds to treatment (the treatable medical cause is found). Post-hoc confirmation following the patients return to normal mentation was sometimes needed before a clinician was confident attributing the altered mental status to delirium. The following subthemes of ‘Uncertainty is Pervasive’ were identified: 1) Difficulty determining baseline mental status & timing of change, 2) Attribution is ambiguous and multifactorial, 3) Assumptions of dementia in elderly patients with altered mental status. See Table 2 for examples.

Theme 3. Extensive Effort is Required to Forage for Information: Physicians reported that significant time and effort is required to get the needed mental status information as mental health information comes from a variety of disparate sources: (1) from outside care providers and other people who personally knew the patient, (2) from within the EMR, and (3) through home investigation and monitoring of the patient. In addition, significant effort is required to coordinate the information, to put it in sequence and to match it with other information. Creating a coherent story and mental model could take hours of sorting through notes, contacting care-givers, and talking to nurses and family. Physicians reported that compensation for these efforts was minimal. The following subthemes of ‘Extensive Effort is Required to Forage for Information’ were identified: 1) Requesting Records from external healthcare providers, 2) Tracking down a person who knows the patient 3) Searching for information hidden in the EMR, 4) Home Analysis, 5) Continuous monitoring. See Table 3 for examples.

**Theme 4. Goal Conflict Leads to Early Closure:** Analysis revealed that competing goals result in distribution of attention and often the result is to obscure mental health information and reduce the emphasis on delirium. Physicians reported disparate goals such as treating co-existing problems, seeking an attribution for the delirium, keeping the patient safe, discharging patients to appropriate care once they had stabilized, and addressing family concerns. Co-occurring health conditions, although not always the reason for hospitalization, often took precedence over delirium and this sometimes resulted in loss of mentation information during transfer between one hospital department and another. Physicians in our study did not feel it was appropriate to add a delirium diagnosis to a patient’s problem list, explaining that delirium is temporary and fluctuating by definition and that patient’s are discharged only after they have stabilized, therefore they no longer have delirium. Patient’s who did not recover from delirium prior to discharge were given an official diagnosis of altered mental status or dementia. The following subthemes of ‘Goal Conflict Leads to Early Closure’ were identified: 1) Treating co-existing problems, 2) Cost/benefit, 3) Managing Patient behavior, 4) Early closure defaults to dementia. See Table 4 for examples.

**Theme 5. Diffusion of Responsibility:** There was a significant hesitance to claim jurisdiction over the problem of delirium or an acute mental status change. Physicians reported that delirium is more effectively treated in a setting
outside the hospital or should be under the purview of psychiatrists. Despite being a physiological problem, physicians were not comfortable making a diagnosis of delirium without a psychiatric consult. The following subthemes of ‘Diffusion of Responsibility’ were identified: 1) No easily discernable treatment that can be solved during my period of responsibility, 2) Mental health is often viewed as the arena of psychiatrists, even though delirium is a medical problem, 3) Significant Hesitance to Claim Jurisdiction over the Problem of Solving Delirium. See Table 4.5 for examples.

### Theme 6. Minimal Use of Formal Clinical Decision Support Tools:

Despite knowledge of their existence, physicians in our study did not use anticholinergic load calculators, lists of medications to avoid in the elderly, or specific delirium screening tools, and physicians reported that they usually do not see medical record alerts. The use of general mental status assessment tools was also minimal as physicians reported that they could get a sense of the patient’s mental status by speaking with them, therefore, they did not require a formal evaluation. The following subthemes of ‘Minimal Use of Formal Clinical Decision Support Tools’ were identified: 1) Recommended delirium assessment tools are not used, 2) Medication guidelines & tools are rarely used, 3) Alerts don’t reach the right people or are ignored. See Table 4.6 for examples.

Physician Information Needs & Recommendations: Analysis of the transcripts also revealed a list of specific information needs in managing the care of patients with altered mental status. This list is reported in Table 7. Physicians made the following 7 recommendations for improving access to information for managing patients with acute mental status changes. 1) “Have a mechanism to review things faster...mental status evaluations, decision making capacity in the past,” 2) “Assess functional capacity prior to hospitalization in older adults,” 3) “If something like a mini-mental status exam gets done ... have a separate place where you can record the raw score,” 4) “It would be nice if when you type in the term and search the notes, ‘the system’ not only pulled up the notes with that term, but the term was already highlighted,” 5) “The medical record is helpful, but it’s hard to know how much of that is just copied and pasted from visit to visit,” 6) “do the CAM [Confusion Assessment Method] daily for patient’s at risk of delirium,” and 7) “Automatically showing trends for common lab tests, hematocrit, platelets, creatinine, BUN, sodium graphic presentation could key us into a problem developing delirium.”

Discussion
Delirium is a non-specific sign of a generalized failure of the body to maintain physiological homeostasis, the conditions necessary for normal cognitive function. It is a symptom that is extremely worrisome to patient’s families and is associated with patient safety events, increased healthcare utilization, and increased rates of death and higher rates of institutionalization at long-term care facilities. Our study revealed that physician’s may frequently assume dementia when managing the care of a cognitively impaired elderly patient whose baseline is unknown, creating diagnostic errors. This assumption is counter to the recommendations of assuming normal baseline mentation in the absence of information. This error in judgment may be explained by the uncertainty around mental status data and
the reported high “costs” of finding information combined with the low pay-off (delirium interventions do not produce observable differences in outcomes when compared with good care unless a specific treatable cause is identified).

Physicians in our study reported alerting features of their patients with delirium, including observable changes in personality, mood, appearance, cooperativeness, and cognitive skill that may be quickly recognized by family or caregivers familiar with the patient. The importance of obtaining mental status information from these people, when diagnosing delirium, has been previously reported.

Designing an effective computerized cognitive decision support will require creating several layers of organizing and displaying information, including better extraction of historical data across roles in order to view trends over time and a better integration of potential causes in order to support diagnosis and treatment. The distributed nature of mental status information makes creating such a design particularly difficult, because it must go beyond physicians alone. Integrating each of these steps into a coherent cognitive support design requires an innovative approach.

**Mental status documentation:** Providing support to clinicians in documenting mental status more precisely is an important step in providing CDS. Mental status information is often very “muddled” and clinicians often use terms that are imprecise and ambiguous. The result is that it is hard to determine when the mental status change occurred and subsequently difficult to identify a cause. The result may be a certain sense of “helplessness” leading to diffusion of responsibility. Any decision support intervention would benefit from improved precision in the identification and measurement of altered mental status. Because the largest benefit, in delirium, is achieved in prevention, providing physicians with information that enables them to reduce risk may improve outcomes the most. Awareness of the patient’s altered mental status, in the study cases always came from personal knowledge or verbal report of human sources who knew the patient well enough to judge that there had been an acute change from the patients normal baseline mentation. Currently, physicians report that they rarely read nurses’ notes, and the way that mental status information is documented by nurses is quite different than the way it is documented by physicians. Nurses almost universally report and measure Level of Consciousness (Alert and Oriented: A&O). This measure is not commonly displayed in a usable form nor tracked over time; although it reasonably correlates with other measures of delirium. Another step in improving delirium care and providing cognitive support to clinicians would be to improve communication about mental status across clinical roles.

Patient symptoms that prompted delirium investigation were visual or social/behavioral. Only a companion or caregiver is likely to notice these changes and because these types of changes are common in hospitalized people, reporting of the delirium is not likely to occur until it has existed for some time or is severe. At this point, damage to cerebral function may be difficult to reverse. Improving the communication process between patients, their families and providers is complex and requires integration of information across multiple roles (nurses, physicians, social workers, pharmacists, etc.) Methods of monitoring and earlier physician notification of delirium risk are important in this vulnerable population. Campaigns to teach the public early warning signs of heart attack and stroke have been quite successful. Perhaps it is time for a campaign to promote public awareness of delirium.

When delirium has not cleared prior to release from hospital the diagnosis often defaults to a dementia diagnosis, simply because there is no evidence that the delirium will clear. This erroneous dementia diagnosis may lead to inappropriate treatment that fails to support the conditions needed to correct the delirium. The need for a diagnosis of unresolved delirium rather than dementia may be essential for a patient to receive appropriate care.

**Attribution of Cause:** An attribution of cause is often required for humans to initiate treatment. This is especially true in delirium where diagnosis requires “evidence from the history, physical examination or laboratory findings that the disturbance is a direct physiological consequence of another medical condition, substance intoxication or withdrawal, or exposure to a toxin, or is due to multiple etiologies.” Providing support for physicians to collate and integrate the necessary information in a way that would support a causal attribution would be a core and important function of a decision support tool. Physicians do not often enter a diagnosis of delirium on their patient’s problem list. Some reasons that physicians may not diagnose delirium are: 1) Delirium is fluctuating by definition; it comes and goes. Physician’s who only see patient’s at the same time each day may not witness these fluctuations; and nurses commonly attribute evening changes in mental status to “sun-downing,” which they may not consider noteworthy; 2) Delirium is expected during the course of many hospitalizations and is not perceived as important; 3) Testing associated with a diagnosis of delirium may not be reimbursed; 4) Delirium is viewed as a symptom of a medical problem (such as over-medication, electrolyte imbalance, oxygen deficiency, infection, or dehydration) not a disease, per se, and 5) there is a tendency to diagnose acute altered mental status as dementia if it has not cleared prior to hospital discharge. Although these reasons might justify the decision not to add delirium to the problem list,
prior history of delirium imparts a higher risk of subsequent delirium to the patient. Knowledge of this risk may be important for future delirium risk prevention. Linking of the delirium incident and the attributions or associated patient conditions might be especially useful in subsequent medication and procedure decisions. Finally, delirium often extends past the hospitalization into other settings resulting in a diffusion of responsibility regarding identification of cause.

**Electronic Medical Record Design:** Mental status information is commonly documented in free-text notes using a wide variety of words. 25,30 Electronic medical records do not currently possess the capacity to support physician’s efforts in identifying mental status changes and fluctuations in an efficient manner. Design methods that (1) enable confirmation of accuracy of mental status information and (2) display mental status information in relevant groups and patterns may decrease cognitive load and support confidence in medical information for decision-making. There is a need for easy access to validated mental status information of older patients in the electronic medical record, prior to hospitalization. Trending display of fluctuations in mental status would support delirium workup. EMRs should alert clinicians of patient specific delirium risk factors and changes in patient mental status.

A concern in our findings is that physicians reported that alerts don’t reach the right people or are ignored, and medication guidelines and tools are rarely used, despite clinician knowledge of the existence of these tools. Presenting this information to providers without giving them a disruptive alert should be investigated.

Mental status information is sometimes lost as patients transition from setting to setting. Not only is the specific information lost, but the causal attribution or links of that information to other related information in the chart, such as when medications were started, is also lost. Interoperability tools and standards need continued development and promotion to improve access to records from external healthcare institutions. Improvements to search mechanisms are needed to improve efficiency in locating mental status data embedded in the medical record.

**Limitations:** This study was conducted in one location; therefore verification of themes is needed in other settings. Additional themes may be identified in future work. These results may only be applicable to physicians treating geriatric patients because all cases reported were older patients. Eight of nine cases were internal medicine; therefore the results may not be generalizable to other specialties. Physicians selected cases to report, and only reported cases that were memorable, difficult, and where the delirium was eventually identified, therefore, cases where the delirium was not identified is beyond the scope of this study.

**Conclusion**
Clinicians had significant information access and cognitive demands when dealing with a patient with delirium or acute onset mental status changes and substantial uncompensated effort was needed to try to uncover information. Uncertainty due to the lack of verifiable mental status information created problems with sense making for the clinical providers.

Facilitating Cohort Discovery by Enhancing Ontology Exploration, Query Management and Query Sharing for Large Clinical Data Repositories

Shiqiang Tao, PhD¹, Licong Cui, PhD², Xi Wu, MS², Guo-Qiang Zhang, PhD¹
¹Institute for Biomedical Informatics, University of Kentucky, Lexington, KY
²Computer Science Department, University of Kentucky, Lexington, KY

Abstract

To help researchers better access clinical data, we developed a prototype query engine called DataSphere for exploring large-scale integrated clinical data repositories. DataSphere expedites data importing using a NoSQL data management system and dynamically renders its user interface for concept-based querying tasks. DataSphere provides an interactive query-building interface together with query translation and optimization strategies, which enable users to build and execute queries effectively and efficiently. We successfully loaded a dataset of one million patients for University of Kentucky (UK) Healthcare into DataSphere with more than 300 million clinical data records. We evaluated DataSphere by comparing it with an instance of i2b2 deployed at UK Healthcare, demonstrating that DataSphere provides enhanced user experience for both query building and execution.

Introduction

In the last decade, electronic health records (EHR) technologies have been increasingly adopted across the United States. According to a data brief from the Office of National Coordinator for Health Information Technology, the adoption of basic EHR technology between 2008 and 2015 rose from 9.4 to 83.8 percent¹. This exponential growth directly resulted in a significant increase in the rise of the secondary use of clinical data. Secondary use of clinical data aims to reuse the data captured from clinical care for purposes of research or quality improvement ². A major source of valuable information for clinical and translational research resides in Enterprise Data Warehouses (EDWs) or integrated clinical data repositories (IDRs), as they are designed to integrate multiple facets of data generated from patient care. Surveys³, 4 show that many IDRs are built on the transaction-based clinical care systems in recent years. Previous research ⁵–⁸ also suggests that IDRs have facilitated researchers to conduct biomedical research in various areas such as monitoring infectious diseases, mining patterns between disease progression and management, and identifying eligible subjects for clinical trials.

A typical IDR query engine consists of 4 necessary components( see Figure 1): Ontology Concepts, Observational Facts, Query Interface, and Query Execution. The Ontology Concepts component manages terminology and knowledge information such as ICD-9-CM or ICD-10-CM diagnosis codes, RxNorm medication codes, and LONIC lab test codes. Observational Facts contain patient clinical information including but not limited to demographics, diagnoses, lab tests, procedures, and medications that are structured and coded by the concepts provided by the ontology concepts component. Query Interface is the component that directly interacts with end users providing them the interface to enter query terms and review query results. The Query Interface determines the effectiveness of an IDR directly. Behind the Query Interface is the Query Execution component, which translates queries composed in the Query Interface into query language of the backend database and retrieves query results.

Query exploration tools implemented as parts of query engines make IDRs easier and more practical to use. Existing query engines such as i2b2⁹ and Harvest¹⁰ provide direct support for data query needs. These systems incorporate powerful interfaces to allow researchers to explore clinical data, build queries, and execute queries without the need for the users to understand the underlying data models. Previous research shows that properly designed query interfaces significantly lower decision maker’s mental workload¹¹. However, the query interface is increasingly recognized as a bottleneck for the rate of return for investments and innovations in clinical research ¹²–¹⁴. Therefore, query interfaces need to continue to improve with the availability of advanced information technologies.

Figure 1. A typical IDR query engine structure.
A challenge of current popular IDR query engines is that they use relational database management system (RDBMS) such as MySQL, PostgreSQL, Oracle and Microsoft SQL Server to manage IDR data. The relational database has been the foundation of enterprise applications for decades, but with the explosion in both the volume and variety of data in recent years, researchers have found that the traditional RDBMS has become a performance bottleneck and NoSQL database management systems such as MongoDB outperformed it in management of large complex biomedical data\textsuperscript{15,16}.

Because of the rich variety of data sources integrated in an EDW, existing approaches to data integration leverages an amalgamation of controlled vocabularies (or ontologies) such as ICD, CPT, LOINC, and SNOMED CT. Too close of a coupling between the roles of these controlled vocabularies play, both for data coding/annotation, as well as for the interface for query construction, can limit the benefits of what informatics innovations can offer. The strategy of decoupling of the backend annotation and front-end query interface roles has been previously used successfully in three projects: VISAGE/PhysioMIMI\textsuperscript{17}, x-search for the NHLBI-funded National Sleep Research Resource\textsuperscript{18}, and the epilepsy-ontology-driven query interface for the NINDS-funded Center for SUDEP Research\textsuperscript{19}. Since 2010, we have been applying an ontology-driven methodology to the interface design of clinical data management tools. A series of tools have been created under this philosophy including VISAGE (2010) \textsuperscript{17}, OPIC (2012) \textsuperscript{20}, FEMI (2013)\textsuperscript{21}, MEDCIS (2014)\textsuperscript{22}, and Neuro3D (2016)\textsuperscript{23}. Using the role-decoupling strategy, we developed a prototype system called DataSphere, which incorporates ontologies in a streamlined interface with dynamic browsing, searching capabilities to facilitate the construction, management and sharing of queries for cohort discovery. We performed limited-scale comparative experiments both on usability and performance of DataSphere on UK Healthcare’s clinical data by porting our i2b2 data store to MongoDB to achieve enhanced flexibility and performance.

1 Background

1.1 Biomedical Ontologies

Biomedical ontologies play an important role in IDRs, which provide a standard and formalized way to specify entities (or concepts), their attributes and relationships among the entities. This enables integration, query, and exchange of heterogeneous biomedical data and interoperability between computer systems. The ontologies involved in this paper include International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM) and International Classification of Diseases, Tenth Revision, Clinical Modification (ICD-10-CM) for diagnoses coding, Logical Observation Identifiers Names and Codes (LOINC) for lab tests coding, Current Procedural Terminology (CPT) for medical, surgical, and diagnostic procedures coding, and RxNorm for clinical drugs coding. DataSphere imports these ontology concepts into database and visualize them with its “Concept Finder.”

1.2 VISAGE

The VIStual AGgregator and Explorer (VISAGE) is a domain ontology-driven interface for a federated approach to data integration. Interface design features in VISAGE include auto-generated slider bar, selection boxes, and built-in charting. DataSphere’s user interface is an extension of VISAGE, with new features (Section 2.2) developed such as: Concept Finder with browse and search modes to locate ontology concepts, Widget Canvas with single and disjunctive concept containers, logical annotation between different concept containers and widgets, and collapsable organization of different interface modules. All these new features work together to make query building more intuitive and efficient.

1.3 MongoDB

As an open-source, cross-platform document-oriented database, MongoDB\textsuperscript{24} provides us with advantages such as flexible data model, scalability, and improved performance. MongoDB uses a different set of terms for database storage and operations. The terms involved in this paper include “Collection,” “Document,” and “MQL” similar to the concepts “Table,” “Row,” and “SQL” in the traditional relational database. Unlike the traditional relational database that stores data in tables and uses structured query language (SQL) for data access, MongoDB stores data in JSON-like documents that can vary in structure. Therefore, in MongoDB, related information can be stored together for fast access using MongoDB query language (MQL), which is the main motivation for choosing MongoDB as the backend database for DataSphere.

1.4 i2b2 and UK Healthcare IDR

i2b2 is an open source clinical data analytics platform originally developed with funding from the National Institutes of Health. i2b2 is widely used for querying patient data to address research questions. i2b2 aggregates a copy of the patient data from an EHR system and provide query services in parallel to the EHR system for research purposes. i2b2 provides a web client with which users can build customized queries and retrieve results. As an excellent query engine for IDRs, i2b2 has over 100 instances deployed internationally in various organizations including CTSA sites, academic health centers, HMOs, and companies.25

UK HealthCare is the hospitals and clinics of the University of Kentucky. It has captured clinical data for more than one million patients since 2006. The data include, but are not limited to, demographics, financial classification, provider level details, medical diagnoses, medical procedures, lab tests and results, medications, visit details, and vital signs. An i2b2 instance was deployed at UK Healthcare in 2016. It has more than 350 active users and has handled more than one thousand queries from UK Healthcare community. In this paper, we import UK Healthcare IDR data into DataSphere and evaluate it by comparing with UK Healthcare’s i2b2 instance.

2 Methods

2.1 Architecture Design

DataSphere follows the web-interface driven development methodology created in our Neuro3D work23 to involve the end users closely in the process of system design and implementation. As illustrated in Figure 2, DataSphere consists of four critical modules: Data Import, Query Interface, Query Translation and Optimization, and Query Management. First, DataSphere imports data from IDRs to its own MongoDB database; then based on the imported ontology concepts, it renders a query building interface with two critical components: Concept Finder and Widget Canvas. Following that, users can customize data queries using the building interface and the queries will be translated into MongoDB query language and optimized to run against the imported clinical data. At last, the queries can be saved for reuse or shared with other DataSphere users.

Table 1 shows the architecture differences between DataSphere and the traditional IDR i2b2. DataSphere’s allows a flexible ontology library and the ontology library dynamically determines the rendering of DataSphere’s query interface. Instead of relying on specific extract, transform, load (ETL) process, DataSphere import patient data from files of common formats such as csv and json, which provides the general applicability of DataSphere to various IDRs. DataSphere adopts MongoDB as the backed database to replace the traditional RDBMS to avoid potential data processing bottlenecks. For query management tasks (save, load, share), DataSphere provides comprehensive supports to encourage the collaborations between researchers. In the following section, we describe in detail how each module works.

2.2 IDR Data Import

The Data Import module handles the process of importing two kinds of data: data files and ontology concepts. Data files contain patient demographic (age, gender, race, etc) information and clinical (diagnoses, lab tests, procedures, medications, etc) information. Ontology concepts provide a standard way to describe patient data. Multiple ontologies are involved in IDRs. In our work, ICD-9-CM and ICD-10-CM are used for coding diagnoses, LOINC is used for coding lab tests, CPT is used for coding procedures, and RxNorm is used for coding clinical medications. DataSphere imports patient demographic information into a collection called “Patients,” clinical information into another collection called “Observational Facts” and ontology concepts into the third collection called “Concepts” with specific collection data schema. Figure 3 depicts the key fields of each collection and relationships among the collections.
2.3 Query Interface Design

DataSphere’s query interface consists of two critical components: Concept Finder and Widget Canvas.

Concept Finder – A Query of IDRs is built from the concepts that are used to code the patient data. Therefore, an appropriate way of locating or navigating concepts is a necessary component of the query interface. In DataSphere, we implement this component as “Concept Finder.” Concept Finder provides two modes: browsing and search. In browsing mode, concepts are organized in a hierarchical structure that users can navigate down level by level. Search mode performs keyword-based searches against concept names according to the user entry. These two modes are designed for users with different skill levels: more skilled users can search concepts directly by concept names within the searching mode, while less experienced users can navigate concepts level by level using the browsing mode. Designing the browsing mode for large-scale IDRs is a challenging task due to the large size of concepts. For example, UK Healthcare’s IDR contains about 200,000 concepts. Rendering the hierarchical structure of these concepts within a web page takes more than five minutes, which is not ideal for an interactive web application. Concept Finder overcomes this challenge by implementing a tailored concept hierarchy, which initially renders several top levels of concepts and displays the subsequent levels in real time with AJAX calls. In addition, the number of levels displayed initially is configurable. With appropriate configuration, the tailored hierarchy can tremendously reduce the size of concepts for initial display so that the rendering process is instant.

Widget Canvas – DataSphere users can add concepts to the Widget Canvas after they find their target concepts. Widget Canvas can render specific query widgets for concepts automatically according to their properties. For example, as illustrated in Figure 4(a), the concept “Age Today” is a numeric concept so that Widget Canvas renders a slider bar for it. Another example in Figure 4(a) is the concept “Gender” that is categorical with options “Male,” “Female,” and “Unknown.” Then Widget Canvas renders three checkboxes for it. Widget Canvas provides two kinds of concept containers: single concept container and disjunctive concept container. Intuitively, a single concept container only allows one concept in it while disjunctive concept container can consist of multiple concepts. The logical relationship among all concept containers is conjunctive while the relationship among all concepts within one disjunctive container is disjunctive. Semantically, the query displayed in Figure 4 is to find all adult (age ≥ 18) female patients with Parkinson’s disease or Dystonia.
2.4 Query Translation and Optimization

In DataSphere, all query widgets are eventually translated into MongoDB query statements and executed.

Query Translation – As illustrated in Figure 4(b), every concept container is translated to certain MongoDB query statements. The number of translated query statements is equal to the number of query widgets within each concept container since the translation from query widget to query statement is a “one to one” correspondence. The translation is directed by both concept properties and query widget details. In the first query container of Figure 4(a), the “Age Today” concept contains information that its target data collection is “Patients” and its matching column is “Age” And the query widget in the first concept container specifies that the age range to query is from 18 to 216. Therefore, the translated query (S1) is to scan patients collection with the condition as column age between 18 and 216. On the other hand, the last concept container in the figure is a disjunctive concept container with two diagnosis concepts in it: Parkinson’s Disease and Dystonia, with concept codes “ICD10:G20” and “ICD10:G24,” respectively. These two concepts state their target data collection is “Observational Facts” and matching column is “Concept Code” and there is no additional query widget information so that the translation results are two individual statements looking for documents in “Observational Facts” collection with column “Concept Code” as “ICD10:G20” and “ICD10:G24.” In summary, the query composed in Figure 4(a) is translated into query statements: S1, S2, and S3, within which S3 contains two individual MongoDB query statements. In DataSphere, we call S1, S2, and S3 together as a query statement workflow. Therefore, any semantic query in DataSphere is built into a set of query widgets and then translated into a query statement workflow.

Query Optimization – Without any optimization, a query statement workflow is naturally executed by its creation order or translation order. For the example in Figure 4, the query statement workflow should be executed in the order: S1 → S2 → S3. However, the order matters. Queries in DataSphere look for the number of unique patients with characteristics specified in the query widgets. Each statement returns a list of patient ids. The latter executing statement can query within this patient list to reduce its searching space. As stated in the above section, every concept itself defines its target data collection and matching column. We can pre-compute the number of documents within the target data collection match to a concept without additional query widget level restriction. This number is the maximum number of document scanning needed when executing an individual MongoDB query statement translated from the concept. In DataSphere, we call this number “Concept Selectivity.” Concept selectivity intuitively tells us how long it takes to execute a statement because statement execution time is proportional to the number of documents to scan. In addition, a translated query statement’s selectivity is defined as the sum of concept selectivities of all involved concepts. To be clear, the selectivity of a query statement translated from a single concept container is equal to the concept’s selectivity within the container, whereas the selectivity of a query statement translated from a disjunctive concept container is equal to the sum of all concepts within that disjunctive concept container. We optimize the statement execution order.
Table 2. Data import results from UK Healthcare.

</tr>
</tbody>
</table>

by evaluating the selectivities of statements. We pre-compute all concepts’ selectivities so that the evaluation process is instant. We order all statements by selectivity in ascending order and execute them one by one. Using the above query as an example, it takes 24.66 seconds to complete the query in order: \( S_1 \rightarrow S_2 \rightarrow S_3 \). After optimization, the execution order is: \( S_3 \rightarrow S_2 \rightarrow S_1 \) and the execution time is 0.08 second.

2.5 Query Management

DataSphere supports collaboration by providing researchers with the ability to save and share queries.

**Save a query** – After building and executing a query, DataSphere users can choose to save the query and give it a name and description. Saved queries can be found in each user’s own query library: “My Queries.” Users can search by name or description in their own library and click query name to load the query details in the Widget Canvas. Saving queries in DataSphere is very straightforward and similar to taking “screenshots” for Widget Canvas. As mentioned above, a query is built with several concept containers and every concept container can have multiple concept widgets. When saving queries, every concept container is saved as a “Query Concept Group” and each concept widget is saved as a “Query Concept” within one specific “Query Concept Group.”

**Share a query** – DataSphere provides two ways to share queries: public sharing and private sharing. Public sharing means users can make their saved queries public so that all DataSphere users can view these queries. Private sharing means users can select specific users to share their queries with. Within “My Queries”, each user can see all public queries and shared queries. Users can choose to save public queries and shared queries into their own libraries, in which case the query will not be affected by the owner’s further changes.

2.6 Evaluation Method

We implemented one instance of DataSphere for the IDR of UK HealthCare and evaluated two aspects of DataSphere: usability and performance. UKHealthCare is currently using an i2b2 instance to support patient cohort identification for clinical research. We evaluated the DataSphere instance by comparing it with the i2b2 instance. We selected 8 representative queries from i2b2 query logs, and interpreted them into the human readable language.

**Usability** – We invited 4 data scientists as evaluators to build these 8 queries with both the i2b2 web client and DataSphere. We asked each evaluator to record the query building time in seconds. System usability is considered better if users require less time to build the same query.

**Performance** – To evaluate the performance, we performed the 8 selected queries independently in two systems. We executed each query in each system three times and calculate the average execution time. The system performance is better if the execution time is shorter for the same query.

3 Results

3.1 Data Import

We loaded a total of 24GB de-identified data from UK Healthcare, which contained over one million patients data with more than 300 million observational fact records. We imported the data into DataSphere’s data collections and Table 2 shows the details of the data import results. The data loaded to DataSphere followed the same ETL process of UK Healthcare’s i2b2 ETL pipeline so that the two systems eventually contain the same data set.
3.2 Interactive Interface for Query Building

Figure 5(a) is a screenshot of the query interface of DataSphere consisting of four parts labeled 1 to 4. Label 1 shows Concept Finder’s browsing mode. Six top concepts are displayed in the figure. Hovering mouse over each concept will show the subsequent level of concepts. Each concept is clickable and clicking on the concept will add it to the right area labeled as 2. Label 2 denotes Widget Canvas. Widget Canvas contains a number of concept containers. These concept containers are connected with logical notation “&” indicating they are conjunctive. Concepts within a disjunctive container are connected with logical notation “|” indicating they are disjunctive within that container. Label 3 is the query control panel consisting of three buttons. The first query button triggers the query translation, optimization, and execution process. The second save button populates a form with fields name and description to save together with the query widgets. The last reset button removes all the query widgets in the current Widget Canvas. Saved queries can be found with the link “My Queries” labeled 4.

3.3 Query Management

Figure 5(b) shows “My Queries.” Three different sections are displayed in my queries: “My Own Queries,” “Queries Shared With Me,” and “Public Queries.” “My Own Queries” are queries created by users themselves; “Queries Shared with Me” are queries that are shared privately by other users; and “Public Queries” are queries that are made public by other users. At the end of each row in my own queries, the button “Share” allows users to make their own queries public or visible to specific users. At the end of each row in “queries shared with me” and “public queries” the button “save” allows users to save these queries to their own queries.

4 Evaluation

The evaluation was designed to assess DataSphere’s usability and performance by comparing it with the i2b2 instance deployed at UK Healthcare. To perform the evaluation, we chose some representative queries from the i2b2’s query logs with three goals: (1) these queries should at least cover multiple concepts; (2) all queries should cover all the categories of concepts, and (3) every query should have a clear clinical meaning. With these goals in mind, 8 queries were filtered as shown in Table 3. These 8 queries covered all categories of concepts we imported: Demographics, Diagnoses, Procedures, Lab Tests, Medications, and Visit Details. The smallest number of involved concepts in the queries was 3 and each query had clear clinical meaning. The general purpose of each query was to find the number of patients that satisfied the query’s requirements.

4.1 Deployment Environment

UK Healthcare’s i2b2 environment is deployed on a dedicated server with 72 CPU cores and 378 GB of random-access memory (RAM). The i2b2’s deployed version is 1.7.08 and the backend database is PostgreSQL of version 9. On the other hand, the DataSphere instance is deployed on a high-end research server provided by the Institute for Biomedical Informatics of University of Kentucky with 80 processors (10 CPU cores for each processor) and 1 Terabyte RAM. Although the physical environments of deployment are different, neither of the two systems detect bottlenecks about physical configuration so that we assume these two systems are running on sufficient configurations of RAM and processing power.
4.2 Usability Evaluation

As we have stated in the methods Section 2.5, the usability measurement was the time cost to compose queries. We invited four non-technical users to complete the query building task and counted the time cost. These four users have no development experience with either i2b2 or DataSphere. i2b2 web client also provides browsing and search modes to find concepts. Therefore, we asked the evaluators to build the 8 queries in browsing and search modes separately in the two systems. Table 4 shows the average time cost in seconds to build the 8 selected queries. To avoid potential bias introduced by the order of building these queries in the two different systems, two of our evaluators were requested to build queries first in DataSphere then in i2b2 and the other two evaluators completed the query construction in the opposite order. The results show that DataSphere’s query building efficiency is consistently better than i2b2 in both browsing and search modes for all 8 queries. On average, evaluators built same queries with 36.99% less time using DataSphere’s browse mode than using i2b2’s browse mode; evaluators composed the same queries with 37.14% less time using DataSphere’s search mode than using i2b2’s search mode. Two paired t-tests were conducted to compare query building time in DataSphere and i2b2 within browsing and search mode respectively. Test results show that: in browsing mode, there is significant difference in the scores for DataSphere (Mean=46, SD=10) and i2b2 (Mean=73, SD=13) with a p value < 0.0001; in search mode, the difference between DataSphere (Mean=44, SD=9) and i2b2 (Mean=70, SD=17) scores is also very significant with a p value 0.0016.

4.3 Execution Time

We ran the 8 queries in i2b2 and DataSphere and recorded the running statistics in Table 5. We ran each query in the two systems for 10 times respectively and Table 5 shows the average execution time for each query. For each of the evaluated queries, i2b2 web client took more than five seconds while DataSphere took less than one second. The last row shows that the i2b2 web client took 81.4 seconds to run all 8 queries which were more than 30 times of
Table 5. Performance statistics of query running of i2b2 web client and DataSphere.

<table>
<thead>
<tr>

<td>0.9 seconds</td>
</tr>
<tr>
<td>No. 8</td>
<td>7.5 seconds</td>
<td>0.1 seconds</td>
</tr>
<tr>
<td>Total</td>
<td>81.4 seconds</td>
<td>2.6 seconds</td>
</tr>
</tbody>
</table>

DataSphere’s running time. DataSphere showed much better performance for the selected evaluation queries. A paired t-test was conducted to compare query execution times in i2b2 and DataSphere. There was a significant difference in the scores for i2b2 (Mean=10.2, SD=6.1) and DataSphere (Mean=0.3, SD=0.3) with a p value 0.0029. These results suggest that DataSphere has a better query execution performance than i2b2.

5 Discussions

For a query engine for IDRs, effectiveness (or usability) and efficiency (or performance) are two important aspects to optimize for researchers to achieve better user experience.

Usability – For effectiveness of query engine DataSphere, we described two modes of concept finding in this paper: browse and search. We stated that search is for more skilled users and browse is for less experienced users. We expected search mode to be faster than browse mode in composing queries, but results suggested that also depended on specific queries. For example, in our comparative usability evaluation (Section 4.1), search mode outperformed browse mode for most queries except for query No. 7 when all evaluators reported that browse mode was faster. The reason for that is the evaluators spent a lot of time deciding on the proper search terms for concept “Malignant Neoplasms of Breast.” All combinations except the full name returned too many results, which made it difficult to find the correct concept. Therefore, an appropriate ranking algorithm is a key factor for a successful search function.

Performance – For the efficiency or performance of DataSphere, we observed significant improvement compared to i2b2’s web client. The query workflow optimization contributed substantially to the performance improvement. We verified that by running same queries with query workflow optimization disabled. Results showed that queries ran much slower. For example, query 6 took 19.5 seconds to complete in DataSphere without query workflow optimization, which is much slower than 0.7 seconds with optimization reported in Table 5.

General Applicability The simplicity of DataSphere’s data models makes it easy to integrate heterogenous clinical data from different data sources. Although we did not have a chance to import data from multiple IDRs into DataSphere, we expect it to do so in the future. One type of IDRs in mind are the ones following ETL process for OMOP Common Data Model.

Limitation – First, we were only able to have four evaluators complete the usability testing. Second, the selection process of the evaluation queries is subjective although we stated 3 goals to direct the query selection (Section 4). DataSphere is in a prototyping stage with additional functionalities to complete such as temporal queries and federated search across different data sources.

6 Conclusion

In this paper, we introduced an ontology-driven, enhanced, general query framework DataSphere for large scale integrated data repositories. It uses document-oriented NoSQL MongoDB as the backend database, creates an interactive query interface that renders hierarchical Concept Finder automatically from concepts imported from IDRs, and applies query optimization strategies to improve query execution performance. The comparative evaluations with i2b2 demonstrated superior usability and performance of DataSphere, revealing the potential of DataSphere to support queries for large-scale IDRs.

Abstract Big data coupled with precision medicine has the potential to significantly improve our understanding and treatment of complex disorders, such as cancer, diabetes, depression, etc. However, the essential problem is that data are stuck in silos, and it is difficult to precisely identify which data would be relevant and useful for any particular type of analysis. While the process to acquire and access biomedical data requires significant effort, in many cases the data may not provide much insight to the problem at hand. Therefore, there is a need to be able to measure the utility/relevance of additional datasets for a particular biomedical research task without direct access to the data. Towards this, in this paper, we develop a privacy-preserving approach to create synthetic data that can provide a first-order approximation of utility. We evaluate the proposed approach with several biomedical datasets in the context of regression and classification tasks and discuss how it can be incorporated into existing data management systems such as REDCap.

Introduction

Today, we have the unprecedented opportunity to gather genomic, transcriptomic, clinical, behavioral, and social data, in ways relevant to health. Analysis of this data can enable new pathways to discovery and can improve the understanding, prevention and treatment of complex disorders such as cancer, diabetes, depression, etc., which are significantly on the rise. Indeed, the Precision Medicine Initiative crucially depends on data-driven science and research.

However, unfettered use of data poses significant concerns regarding patient privacy and the abuse of access to sensitive data. Indeed, the digitization of health information, without appropriate controls, magnifies the risk to privacy, due to the ease of retrieval, analysis, and linkage. Privacy and confidentiality are critical to healthcare. Improving privacy protection encourages people and organizations to share data and realize hidden insights. For example, orphan diseases can be treated more effectively when more observations from different regions in the world are shared and aggregated. Similarly, personalized medicine can be targeted to individuals more accurately if more patients similar to the person of interest are observed and analyzed.

Preserving privacy is a non-trivial task because any protection scheme essentially involves a tradeoff with data utility. Simple strategies may lead to private but uninformative data disclosure, and vice versa. This is especially challenging if the data required for a study resides at several different institutions. Note that in the early stages of any study, the researcher needs to explore the data to understand its utility for the study purpose. Often, the researcher needs to iteratively access the data across the different sources. Even though data exploration may not require fine grained access to all of the data, researchers have to spend an inordinate amount of time trying to get access to relevant data. In many cases, they may not even know whether the data would actually help their particular analysis. For example, consider a researcher at Rutgers Biomedical Health Sciences (RBHS), Newark, carrying out a survival analysis of pancreatic cancer patients using the clinical trials data collected in the local REDCap instance. Since the Newark population is overwhelmingly African-American, who typically have higher incidence rates and suffer from more aggressive forms of cancer, the researcher would like to carry out a comparative analysis of survival after adjuvant radiotherapy and/or chemotherapy with respect to the general population. To do this, the research requires access to linked cancer registry data from the Surveillance, Epidemiology, and End Results (SEER) Program 1 to get information about the cancer site, stage, grade, etc., as well as access to the corresponding Medicare/Medicaid data from the Centers for Medicare & Medicaid Services (CMS) to get information of the specific therapy. If the researcher would like to study the health costs associated with patients having other comorbidities such as diabetes and contrast them with patients who do not, the researcher would also need access to data from the Healthcare Cost and Utilization Project (HCUP) data provided by AHRQ 2, and/or to clinical data such as DMITR1 from the National Center for integrating Data for analysis, Anonymization, and Sharing (iDASH) 3. The researcher would like to confirm which of
these data sources would be relevant to his/her study, and find out which specific data files from these sources should be retrieved. Note that, at this stage, it is sufficient for the researcher to get this confirmation from an approximate analysis without extensive data integration for each different source, and to then retrieve only the relevant data.

Our goal is to precisely enable such exploratory analysis by providing an assessment of the data with respect to utility while preserving its privacy. Towards this, we develop a technique to generate sample datasets that preserve the structure and semantics of the original data, but not exact values, thus preserving its privacy. We evaluate the proposed approach with several different biomedical datasets in the context of classification and regression and demonstrate its effectiveness. While our approach for generating synthetic data does not directly provide a measure quantifying the utility of the dataset for a specific type of analysis (e.g., regression), our evaluation does show that the area under the curve (AUC) / root mean squared error (RMSE) of models built from synthetic data are comparable to that of models built from real data. Thus, a researcher can get a first-order approximation of the overall usefulness of the real data. For example, suppose that a researcher is interested in exploring the relationship between Vitamin D levels and Cancer diagnosis, and is interested in looking at three different datasets which have been collected at institutions in different geographic regions in the country. Using the corresponding synthetic data, the researcher might be able to get an estimate of where such a relationship might exist, or whether the strength of this relationship is more significant in a particular region of the country, or whether the combined data shows the same relationship or not.

An overview of random decision trees

The proposed data generation approach is based on Random Decision Trees (RDT), developed by Fan et al.⁴ The Random Decision Trees algorithm builds multiple (or m) iso-depth (i.e., equal depth) random decision trees. As opposed to typical decision tree learning, the trees built in RDTs are completely random in structure – i.e., the structure of a random tree is constructed completely independent of the training data. However, the statistics recorded for each node are computed based on the training data. Thus, the RDT training phase consists of building the trees (BuildTreeStructure) and populating the nodes with training instance data (UpdateStatistics). It is assumed that the number of attributes is known based on the training dataset. The depth of each tree is decided based on a heuristic – Fan et al.⁴ show that when the depth of the tree is equal to half of the total number of features present in the data, the most diversity is achieved, preserving the advantage of random modeling.

The process for generating a tree is as follows. First, we start with a list of features (attributes) from the dataset. We then generate a tree by randomly choosing one of the features without using any training data. The tree stops growing once the height limit is reached. Then, use the training data to update the statistics of each node. Note that only the leaf nodes need to record the number of examples of different classes that are classified through the nodes in the tree. The training data are scanned exactly once to update the statistics in multiple random trees. Based on the statistical analysis as well as conducted experiments, from 10 to at most 30 trees are sufficient for most applications⁴–⁶. When used for classification, the new instance is evaluated with respect to all of the random trees constructed and the average class probability distribution is output. In our case, we do not need to worry about the classification phase, and after constructing the RDT model, we can use them for synthetic data generation as discussed in the following section.

An important question is why choose RDTs as a way to encode the underlying training data. There are several reasons for this. First, an important property of RDT is that the same code can be used for multiple data mining tasks: classification, regression, ranking and multiple classification⁴–⁶. As shown previously, the random decision tree is an efficient implementation of Bayes Optimal Classifier (BOC)⁴, effective non-parametric density estimation⁶, and can be explained via high order statistics such as moments⁷.

While the use of Random Decision Trees may seem counterintuitive, there are any many benefits in terms of performance and accuracy, that are gained by using this method versus traditional algorithms. The use of the multiple random decision trees in various learning tasks offers many benefits over other traditional classification/tree building techniques, because its structure and progression lends itself to modification for distributed/parallel tasks⁸. At the same time, RDT outperforms other models in terms of computational speed, due to the inherent properties of random partitioning used in tree construction. Indeed, one of the key advantages to RDT is the efficiency gained by the way the model is trained, as well as its minimal memory requirement⁹. Finally, RDTs are also extremely well suited from the privacy perspective since:
1) Randomness in structure rather than simple perturbation of input/output is more effective – perturbing the input or output from a database to achieve privacy works, but the utility of the information garnered from data mining can be diminished if the perturbations are not carefully controlled, or conversely, information can be leaked if the information is not perturbed enough. Instead, we can exploit the design properties of RDT to generate trees that are random in structure, providing us with a similar end effect as perturbation without the associated pitfalls. A random structure provides security against leveraging a priori information to discover the entire classification model or instances.

2) Purely cryptographic approaches are often too slow to be practical and can become computationally expensive as the size of the dataset increases and intercommunications between different parties increase. RDT provides a convenient escape from this paradigm thanks to its structural properties, and furthermore can be computed in a distributed fashion thus preserving privacy even if the data are distributed.

3) An additional security advantage of RDTs are that they are amenable to meeting the privacy requirements of the differential privacy model. As shown by Jagannathan et. al, the node statistics can be viewed as queries over the training data. Therefore, standard techniques can be used to return differentially private results, without significant loss of accuracy.

Proposed Approach

The proposed approach follows a two-step process for generation of synthetic data as shown in Figure 1. In the first step, we generate multiple parameterized RDTs using the original dataset. In the second step, we perform random walk over the RDTs to recreate instances.

The procedure for generation of RDTs is given in steps 1-13 of Algorithm 1. The input to Algorithm 1 is the original dataset, D, and number of RDTs to be generated. The dataset D may include both nominal and numeric attributes. For discretization of numeric attributes, the algorithm takes two discretization parameters as input: i) f is a function that gives the number of splits for each numeric attribute – for example, the numeric attribute Age with range [0, 100] can be split into four discrete values by setting f(Age) = 3; the function g gives the discretization split points for each numeric attribute – for example, g(Age) = (30, 50, 70) discretizes the Age into 4 non-uniform age ranges [0, 30), [31, 50), [51, 70), [71, 100].

After discretization, we build the structure of the required k RDTs by following the standard BuildTreeStructure procedure of RDTs. Next, we use the given dataset D to compute the conditional probability of visiting any node in the RDT. Note that this is the conditional probability of visiting a node given that we are currently visiting that node’s parent, and is given by:

\[
pr(n) = \frac{\text{# instances in } D \text{ reaching node } n}{\text{# instances in } D \text{ reaching node } parent(n)}
\] (1)

For the root of the tree, the probability is 1, since we start from the root. We illustrate the process of creating the RDT through the following example. Consider, as mentioned before, a cancer study. The data set records the cancer site, stage, grade, and other features along with the survival months. Table 1 shows a small dataset sample with 5
Algorithm 1 Synthetic data generation using RDTs

Require: Original Dataset $D$
Require: Number of random decision trees to be generated, $k$
Require: Degree of discretization for each numeric attribute, $f : A \rightarrow \mathbb{Z}^+$

Figure 2: Example RDT

instances. Figure 2 shows one possible RDT that can be learned from the data in Table 1. Since this tree serves as a partial summarization of the data, multiple such RDTs are created. In this RDT, as mentioned before, the conditional probability of reaching a node is computed as stated in Equation 1. Thus, for example, the probability of reaching the node Diabetic? is \( \frac{2}{5} \) since only 2 out of the 5 instances have stage 1 or 2. Similarly, the probability of reaching the Cancer Site node in the left subtree is \( \frac{1}{2} \) since only 1 of the 2 instances with Stage 1 or 2 cancer is diabetic.

Synthetic data is generated instance by instance by performing random walk over RDTs. For each instance, we randomly choose an RDT and traverse through it using the node probabilities. The attribute values of the instance are assigned based on the path taken during the random walk. After reaching the leaf node, the next RDT is randomly chosen for assignment of remaining attribute values. We continue this process until all the attribute values of the instance are assigned or all the \( k \) trees have been traversed. Traversal of multiple RDTs for any instance may result in different branches for the same attribute. We keep the attribute value that was assigned first and ignore subsequent values. In case, an instance has missing attribute values after traversal of all \( k \) RDTs, we discard all the assigned values for that instance and restart the random walk for that instance. However, this happens very rarely in practice. The specific procedure for creating synthetic data is listed in steps 14-28 of Algorithm 1.

As depicted in Figure 1, the proposed synthetic data generation approach can generate different data views corresponding to the privacy levels of different classes of users. For example, physicians may require accessing data at the finest granularity without any suppression. Therefore, the data view generated for physicians is generated without any generalization of nominal attribute values and splitting of numeric attributes at the finest granularity level. However, for student researchers access may need to be provided at a coarser granularity. Therefore, the data view generated for student researchers is generated with generalization/splitting of attributes at coarser granularity level.

Integration with REDCap

We are currently working on integration of the proposed synthetic data generation approach into a data collection and sharing infrastructure REDCap\(^{12}\), which is widely used in the medical community for building and managing online surveys and databases. The overall architecture of the extended REDCap system for privacy-preserving analysis and sharing of data is depicted in Figure 3. The system will enable different types of users to access external data from different sources through the REDCap application. The access to data will be provided based on user authorizations defined in the access control policy of the data owner. The system allows data owners to specify authorizations for different classes of users in their access control policies. Accordingly, different views
of synthetic data are generated as shown in Figure 3. The system also includes a distributed data access module that enables retrieval and integration of data from multiple sources in response to a user query or exploratory data analysis task. For exploratory data analysis, the system allows a user to integrate data from multiple data sources and assess its utility.

Note that within our architecture, the data owner is still responsible for generating the synthetic dataset. This is not different from the current practice in multi-level secure databases where different views of the data are generated for different users. The idea is that the data owner creates multiple versions of the synthetic data based on his/her access control policy and the privacy requirements of the data to be shared. The synthetic data can be generated offline and the appropriate version be made available to a researcher based on the authorization of the researcher requesting access. This access will be mediated by the data access module. Furthermore, the synthetic data looks just like the real data (i.e., the records have precisely the same structure). Therefore, it can be processed the same way as the real data, and the researcher can run any standard query in REDCap pertaining to that dataset, though the exact answer to the query may vary from the answer computed over the original data.

Since the synthetic data is only an approximation of the real data, the models built from the synthetic data and the real data are likely to be different to some extent. It would be useful for a researcher to know the degree of discrepancy in results based on use of either real or synthetic data. This can be easily incorporated into the REDCap architecture, wherein the utility assessment module can measure the difference between the results of the posed query on both the real and synthetic data and provide a measure of the difference.

**Experimental Evaluation**

We now evaluate the efficacy of the RDT framework in creating synthetic data that can give an approximation of the utility of the original data. For this, we use three different real datasets obtained from the UCI Machine Learning Repository: 1) the Breast Cancer Wisconsin (Original) Data Set\(^{13}\) 2) the Parkinsons Telemonitoring Data Set\(^{14}\) 3) the Diabetes 130-US hospitals for years 1999-2008 Data Set\(^{15}\). We processed the data to remove the instances with missing values. We also removed attributes where the overwhelming majority of instances have the same single value. We also discretized all of the numeric attributes into 10 discrete ranges using equal width discretization. Table 2 gives the characteristics of each individual dataset after preprocessing. The Breast Cancer dataset and the Diabetes dataset were used for classification (since they have a single categorical variable to be predicted). On the other hand, the Parkinsons Telemonitoring dataset had two independent numeric response variables. Therefore, linear regression was independently performed with both response variables. Note that the original RDT paper recommends that the depth

of each RDT be set to \(n/2\) where \(n\) is the number of attributes, and that at least 10 RDTs be generated. Following this, for the classification tasks, we created 20 RDTs, where as for the regression task, 15 RDTs were generated. However, unlike the datasets considered in the original RDT paper, the biomedical datasets considered here have several nominal attributes with many values. For example, each of the three diagnosis attributes in the Diabetes dataset has over 700 distinct values, which leads to a significant fan-out. Note that the depth and the fan-out of the tree together determine the size of the tree and thus the memory requirements of the RDT. For Diabetes, since the fan-out of the three diagnosis attributes is extremely high, this tremendously increases the memory requirements, and therefore, we had to limit the depth of the RDT. As such, based on the characteristics of the different datasets, different depths were chosen as noted in Table 2.

The experiments were run on a 24-core Intel(R) Xeon(R) server with the CPU E5-2670 v3 2.30GHz and 264 GB RAM. However, only one of the cores (i.e., no parallelization) was used and the memory heap size was restricted to only 48GB. We now discuss the results obtained. For each dataset, 10-fold cross-validation was carried out. Essentially, the data was split into 10 folds with 9 folds used for training and the remaining fold used for testing. When generating the synthetic data, we built the RDTs from the folds of data kept for training, and then generated synthetic data from the RDTs. This synthetic data was used for training the model, and the model built from the synthetic data was tested over the fold of real data held out earlier for testing. We then compare the accuracy of the model built from the real training data to the accuracy of the model built from the synthetic data. Since we are performing 10-fold cross validation, the accuracy compared is the average accuracy over all of the iterations. For classification, since the classes are not unbalanced, we directly compare the overall accuracy of the classifier using the AUC (area under the curve) metric. For regression, we compare the root mean squared error (RMSE) obtained. One point to note is that once the RDTs are generated, any amount of synthetic data can be regenerated. Therefore, we tested with generating the same number of instances as in the original training set, ten times more instances, and 100,000 instances (note that for the diabetes dataset, the training set size was itself close to 100,000, therefore we did not oversample this dataset). Table 3 gives the results obtained for classification with Naïve Bayes classifier while Table 4 gives the results obtained for linear regression. Note that we did try other classifiers such as decision trees as well and the results obtained were similar. The results show that for classification, the model generated from synthetic data achieves almost the same accuracy as the model generated from the original data in terms of the AUC. Indeed, the AUC of Breast Cancer with synthetic data is 0.9937 even with no oversampling while the AUC with the original data is only marginally higher at 0.9945. Similarly, the reduction in AUC for diabetes is also nominal. For Parkinsons, the RMSE with original data for motor_UPDRS is 6.51. Instead we get an RMSE of 7.05 with the synthetic data with no oversampling. Similarly, the RMSE for total_UPDRS is 8.14 for the original data, whereas it is 8.93 for the synthetic data with no oversampling. Since, lower is better for RMSE, it can be seen that the performance of linear regression is slightly worse with the synthetic data but is still very comparable. Furthermore, in all cases, increasing the degree of oversampling tends to improve the results. Though the accuracy for Diabetes is low with synthetic data, it is also quite low for the original data, since this dataset is quite difficult in terms of classification. The critical point is that from the perspective of exploratory analysis, the models generated from synthetic data do give a similar view of the data as compared to the models generated from the original data. For example, there was significant overlap in the variables identified as significant in the regression model built from the training data and that built from the synthetic data, though the p-values varied.

One point worth noting is that the synthetic data generation process is extremely efficient. Once the RDTs are built, it takes very little time to generate new synthetic instances. For example, generating 100,000 instances only took a few minutes. The process for building the RDTs is memory intensive. However, if the memory required is capped by limiting the depth of the tree, then this process is also extremely efficient. i.e., in our case, it only took a few seconds...

to generate a single RDT. In general the time taken to build an RDT increases linearly with the size of the training data, which is extremely efficient.

Related Work

There is a lot of prior work on privacy-preserving distributed analytics\(^{16}\). For example, specific analytics tasks such as classification\(^{17,18}\), clustering\(^{19,20}\), association analysis\(^{21,22}\), and outlier detection\(^{23}\) can be carried out in a distributed manner. Privacy-preserving analytics has also been applied in the biomedical domain, for example for Grid LOGIstic REgression (GLORE)\(^{24,25}\), Distributed Cox proportional hazards model\(^{26}\), and Distributed Privacy Preserving Support Vector Machine (DPP-SVM)\(^{27}\) to allow accurate model construction while respecting individual institutions’ data privacy policy, and medical data integration\(^{28}\). All of the above techniques are designed for specific data analytics tasks. The proposed synthetic data generation approach enables exploratory analysis of the data, and can be used for any of the above data analytics tasks. There is some existing work on anonymizing data or for generating synthetic data. For example, techniques for k-anonymity\(^{29–31}\) will give a k-anonymized version of the dataset. However, this can lose significant data utility, and selecting an appropriate value for k is difficult. Aggarwal and Yu\(^{32}\) present an alternative condensation approach that clusters the data and regenerates synthetic data for each cluster – however, this does not keep track of combinations of attributes and may not fully specify all of the various combinations in the existing data.

Conclusion

Exploratory analysis is crucial to scientific innovation and often requires iterative exploration of the data. When the data are distributed across different organizational boundaries, this may lead to significant privacy concerns. Our aim in this paper is to enable exploratory analysis for the biomedical domain that is both privacy-preserving and scalable. Towards this, we develop a synthetic data generation technique using the framework of random decision trees to preserve the structure and semantics of the original data, while protecting privacy. We evaluate the proposed approach with several real biomedical datasets and typical tasks such as classification and linear regression. Our evaluation shows that the proposed approach is effective and can provide a sense of the utility of the data while protecting privacy.

Note that since our goal was simply to provide a first-order approximation of utility, we did not use standard HIPAA de-identification methods at this point. Since RDTs are amenable to meeting the privacy requirements of the differential privacy model, in the future we plan to compare and contrast the synthetic data generation approach with Safe Harbor/statistically de-identified data in more detail. We also plan to explore how other analytics tasks can be carried out and provide more accurate estimates of utility for specific tasks, and measure the uniqueness of a specific dataset for a particular task.

Abstract
Scientific reproducibility is critical for biomedical research as it enables us to advance science by building on previous results, helps ensure the success of increasingly expensive drug trials, and allows funding agencies to make informed decisions. However, there is a growing “crisis” of reproducibility as evidenced by a recent Nature journal survey of more than 1500 researchers that found that 70% of researchers were not able to replicate results from other research groups and more than 50% of researchers were not able reproduce their own research results. In 2016, the National Institutes of Health (NIH) announced the “Rigor and Reproducibility” guidelines to support reproducibility in biomedical research. A key component of the NIH Rigor and Reproducibility guidelines is the recording and analysis of “provenance” information, which describes the origin or history of data and plays a central role in ensuring scientific reproducibility. As part of the NIH Big Data to Knowledge (BD2K)-funded data provenance project, we have developed a new informatics framework called Provenance for Clinical and Healthcare Research (ProvCaRe) to extract, model, and analyze provenance information from published literature describing research studies. Using sleep medicine research studies that have made their data available through the National Sleep Research Resource (NSRR), we have developed an automated pipeline to identify and extract provenance metadata from published literature that is made available for analysis in the ProvCaRe knowledgebase. NSRR is the largest repository of sleep data from over 40,000 studies involving 36,000 participants and we used 75 published articles describing 6 research studies to populate the ProvCaRe knowledgebase. We evaluated the ProvCaRe knowledgebase with 28,474 “provenance triples” using hypothesis-driven queries to identify and rank research studies based on the provenance information extracted from published articles.

Introduction
Reproducibility of biomedical study results is essential for advancing science as it enables researchers to build on sound results and allows patients as well as their families to have confidence in the resulting drugs, diagnosis tools and related aspects of patient care (1-3). However, there is growing concern in the research community regarding the decreasing reproducibility of published results. For example, a recent Nature journal survey of 1500 scientists found that 70% of researchers were not able to replicate results from another research group and more significantly about 50% of researchers were not able to replicate their own research results (1). This lack of reproducibility has a major impact on multiple aspects of biomedical research and patient care, including cost of clinical trials that are not based on sound study design, and diversion of funding resources from suitable projects to research studies that cannot be replicated (2, 4). In addition, the inability of researchers to replicate published studied affects the confidence of peer researchers and the wider public in results, such as drugs and diagnostics, that are generated from experiments (5). To address this growing “crisis” of reproducibility in biomedical research, there is increasing focus on developing guidelines together with suitable data management tools to support scientific reproducibility. For example, the National Institutes of Health (NIH) released the “Rigor and Reproducibility” guidelines in 2016 to improve existing reporting standards in biomedical research, which focused on rigorous statistical analysis plan, transparency in reporting, and facilitating material sharing (6).

An important component of the NIH “Rigor and Reproducibility” guidelines is the systematic collection, processing, and analysis of provenance metadata, which describes the source or origin of data and underpins scientific reproducibility (10). Provenance information is widely used in computer science research to trace the origin of data and validate data quality, for example database provenance research has focused on provenance of database entries (7, 8). Similarly, workflow provenance records the various steps involved in processing and analyzing data in scientific workflow system to support replicability of results (9). In 2013, the World Wide Web Consortium (W3C), which is the Web technology standards organization, recommended PROV specifications for standardized modeling and accessibility of provenance information (10). The PROV specifications include the PROV-Ontology (PROV-O),
which uses Web Ontology Language (OWL2) to develop a formal model of the provenance information using a common minimum set of terms (11). The W3C PROV-O and related components of the PROV specifications are being widely used in a variety of domains to model and analyze provenance information. However, there has been limited work in the biomedical research domain to adapt and extend the PROV specifications to manage provenance information and support scientific reproducibility. As part of the NIH Big Data to Knowledge (BD2K)-funded data provenance project, we are developing the Provenance for Clinical and Healthcare Research (ProvCaRe) framework to: (a) define a provenance model for biomedical research; (b) evaluate the quality of provenance metadata in published biomedical literature; and (c) enable users to develop rigorous study designs using provenance information of existing studies.

The provenance metadata associated with clinical research studies include study design, statistical analysis model, raw material used in an experiment, inclusion and exclusion criteria, and intervention techniques used in a research study (2, 3). Other metadata are relevant to basic science, such as testing reagents, assays, cell lines, and model organisms. The growing focus on data sharing through NIH-funded initiatives, such as The Cancer Genome Atlas (TCGA) (12), the Human Connectome Project (13), and the National Sleep Research Resource (NSRR) (14), provides opportunities to evaluate the quality of provenance metadata available to support replicability. In particular, there is a critical need to address two essential aspects of scientific reproducibility in biomedical research:

1. **What provenance metadata terms are required to enhance replicability of research results if original study data is already available (e.g., through TCGA or NSRR)?**
2. **How to leverage the provenance metadata available from previous research studies to adapt “best practices” in study designs?**

To address these two important issues, the ProvCaRe project has created a knowledgebase of semantic provenance metadata, which was automatically extracted from published literature describing research studies that have made their data available through the NSRR project. NSRR is a NIH-funded project that is building the largest repository of sleep research data from more than 40,000 sleep studies involving more than 36,000 participants (14). The NSRR project enables a researcher to access large amounts of study data after receiving an Institutional Review Board (IRB) approval and completing a Data User Agreement (DUA) with NSRR.

The development of the ProvCaRe knowledgebase involved development of: (1) a ProvCaRe ontology for modeling provenance metadata terms; (2) a Natural Language Processing (NLP) pipeline that extends the clinical Text Analysis Knowledge Extraction System (cTAKES) (15) with a new “provenance-triple” generator module and dynamic ontology-lookup tool, and (3) an intuitive user interface using the Django Web framework based on the Model View Template (MVT) software architecture pattern. In the following section, we provide additional details regarding the resources and technologies used in the development of the ProvCaRe knowledgebase as well as work related to use of provenance metadata for reproducibility in scientific research.

**Background**

**NIH Guidelines for Rigor and Reproducibility.** The NIH “Rigor and Reproducibility” guidelines released in January 2016 describe the key components of experimental design, transparent reporting, and data management to support scientific reproducibility (3). The guidelines encourage clear description of the statistical analysis methods used in a research study, adoption of best practices for reporting of study results including: (1) use of common reporting standards recommended by the community, (2) repeated performance of experiments, (3) use of randomization as well as blinding techniques, and (4) description of inclusion and exclusion criteria used to select participants, among other aspects related to the conduct of research studies (2). The “Rigor and Reproducibility” guidelines also encourage the establishment of best practices for management of data as well as biological resources used in experiments to ensure data quality, for example antibodies, cell lines, and animals (6). The guidelines also recommend sharing of datasets to evaluate reproducibility of reported results. In this paper, we build on “Rigor and Reproducibility” guidelines to develop the ProvCaRe knowledgebase using a new ontology to formally model provenance metadata designed to enhance efforts at replicating biomedical research studies.

**National Sleep Research Resource (NSRR).** The National Sleep Research Resource (NSRR) is creating one of the largest repositories of de-identified physiological signals and clinical data elements that were collected from multiple research cohorts and clinical trials (14). NSRR aims to provide free access to over 40,000 sleep studies collected from about 36,000 participants, which include demographic, physiological, clinical, and raw physiological signal data as well as annotation files from polysomnograms with scored events (14). Researchers can use the curated and well-defined sleep data from multiple NIH studies to develop large cohort studies with more diverse population that was
not possible with a single study cohort. This is expected to significantly accelerate the pace of research in role of sleep and sleep disorders in pathogenesis of chronic illness such as cardiovascular and metabolic diseases.

**W3C PROV Ontology.** The PROV Ontology (PROV-O) models common provenance metadata terms and properties using the description logic-based Web Ontology Language (OWL2) (16) defined in the W3C PROV specifications. The three foundational provenance terms modeled in PROV-O are Entity, Activity, and Agent, which are linked to each other using seven properties, namely wasDerivedFrom, wasAttributedTo, wasGeneratedBy, wasAssociatedWith, actedOnBehalfOf, wasInformedBy, and used (11). The PROV-O is designed as an upper-level reference ontology that can be used as a common foundation to build interoperable domain-specific provenance applications such as the ontology for ProvCaRe knowledgebase. The use of PROV specifications in the ProvCaRe knowledgebase allows us to leverage a large number of Semantic Web technology tools.

**cTAKES** The ProvCaRe knowledgebase is built using a NLP pipeline that extends the cTAKES tool, which combines rule-based and machine learning approaches for knowledge extraction from clinical free text. The cTAKES builds on the Apache Unstructured Information Management Architecture (UIMA) framework (17) and OpenNLP toolkit. cTAKES consists of six components, namely (1) Sentence boundary detector, (2) Tokenizer, (3) Normalizer, (4) Part-of-speech (POS) Tagger, (5) Shallow parser, and (6) Named Entity Recognition (NER) annotator, which are invoked sequentially to create an annotated dataset from unstructured text. The downloadable version of cTAKES was trained on GENIA, Penn TreeBank (PTB), and a corpus derived from the Mayo Clinic Electronic Medical Record (EMR) repository consisting of 273 clinical notes (15). cTAKES is built using an extensible architecture and this feature has been used in the ProvCaRe framework to customize the NLP pipeline for identifying and extracting provenance metadata from published literature.

**Related Work.** Reproducibility has been a cornerstone of scientific advancement, however there has been growing focus on the lack of replicability of scientific studies as summarized by a review of published studies (4, 18) and survey of researchers (1). The survey of 1500 researchers by Baker et al. suggested that poor reporting and statistical analysis techniques are responsible for irreproducible results (1). To address some of the underlying factors for limited reproducibility in biomedical research, Landis et al. recommended a core set of standards for reporting scientific experiments to support evaluation of results (2). These reporting standards focused on rigorous study design and included: (1) randomization techniques used to assign tasks in a research group, (2) blinding techniques to allow concealment of allocation, (3) specification of statistical methods for estimating sample size; (4) predefined rules for inclusion and exclusion of data; (5) consistency in addressing the issue of missing data, and (6) repetition under different conditions (2). These recommendations form a core component of the NIH Rigor and Reproducibility guidelines. As we discussed in the previous section, the practical implementation of the NIH Rigor and Reproducibility guidelines requires the development of an integrated platform to extract, model, and analyze provenance information to evaluate the reliability of previous findings. To the best of our knowledge, the ProvCaRe framework is the first medical informatics project that is implementing the “Rigor and Reproducibility” guidelines using the W3C PROV specification and provenance metadata analysis for reproducibility. In the next section, we describe the three-stage development of ProvCaRe knowledgebase, which is the first publicly available repository of provenance metadata extracted from published articles describing biomedical research studies.

**Method**

The ProvCaRe knowledgebase has two primary objectives:

1. Develop a repository of semantic provenance metadata extracted from published research studies that can be queried and analyzed to evaluate research studies; and
2. Enable researchers to perform hypothesis-driven search of previous research studies (with associated provenance information) and facilitate development of rigorously designed experiments for reproducible results.

These two objectives closely align with the aim of the NIH Rigor and Reproducibility guidelines (2, 3). We implemented the ProvCaRe semantic provenance knowledgebase in three stages (Figure 1 illustrates the ProvCaRe architecture). In the first stage, we developed the ProvCaRe S3 Model to represent provenance metadata for scientific reproducibility in biomedical research. In the second stage, we implemented a provenance focused NLP pipeline for entity identification, extraction, and generation of “provenance-triple” from published articles. In the third stage, we implemented the ProvCaRe semantic provenance knowledgebase with a powerful hypothesis-driven search and query functionality together with a new ranking algorithm that evaluates the provenance of research studies. We describe the details of each stage in the following sections.

1690
Stage I: Development of the ProvCaRe S3 Model for Biomedical Research. Many clinical researchers follow the Population, Intervention, Comparison, and Outcome (PICO) model to frame research questions and the PICO framework is an integral component of evidence-based medicine (EBM) (19). Similarly, the Ontology for Clinical Research (OCRe) project has characterized different phases of clinical research and formalized the relevant terms in the OCRe ontology (20). The ProvCaRe S3 model builds on these templates and defines three categories of provenance metadata, namely **Study Method**, **Study Tools**, and **Study Data**, which are important for scientific reproducibility. The three top-level S3 model terms can be mapped to the W3C PROV Ontology terms of prov:Activity (prov corresponds to the W3C PROV Ontology namespace http://www.w3.org/TR/prov-o/), prov:Agent, and prov:Entity. These three terms represent multiple subcategories of provenance metadata as follows:

1. **Study Method**: represents provenance metadata describing the protocol used to conduct the experiment (e.g., observational study or interventional study), the method used for recording of experimental data and the statistical analysis plan used for data analysis (e.g., covariance analysis or correlation analysis). Provenance information modeled by Study Method and its sub categories are important components in assessing reproducibility, as it helps identify potential differences in methods used to conduct research studies.

2. **Study Tools**: represents information describing the tools used for both data recording and data analysis. For example, electrocardiogram (ECG) data may be recorded using a bipolar, one lead, three lead, or a twelve lead electrocardiogram, which represents important contextual information required to ensure correct interpretation.
and analysis of the ECG data. The resolution of imaging instruments, recording parameters associated with an instrument, and related tool-specific metadata is essential for transparent reporting of experiment studies and evaluating the reliability of results.

3. **Study Data:** represents information describing the context of study data collections, for example timestamp of the recorded data, the different categories of study variables used (e.g., continuous variables or categorical variables), how data were collected (e.g., sitting, supine), and valid range of values for a study variable. The provenance metadata represented by Study Data and subcategories of this term allows researchers to accurately identify and extract the relevant subsets of study variables for replicability.

The ProvCaRe S3 model is formalized in the ProvCaRe ontology by extending the W3C PROV Ontology (PROV-O), which uses the description logic-based W3C Web Ontology Language (OWL2) (16). The ProvCaRe ontology (available at: [http://provcare.case.edu/](http://provcare.case.edu/)) extends the three core PROV-O classes to model the terms constituting the S3 model. The `prov:Activity` class models `provcare:StudyMethod`, `provcare:DataAnalysisMethod`, `provcare:DataCollectionMethod`, and `provcare:Intervention` as its subclasses (provcare refers to the ProvCaRe ontology namespace: [http://www.case.edu/provcare](http://www.case.edu/provcare)). These ontology classes are further extended to model additional provenance information, for example different categories of statistical data analysis techniques including `provcare:DescriptiveStatisticalAnalysis` and `provcare:InferentialStatisticalAnalysis` classes. Similarly, the W3C PROV-O `prov:Agent` class is extended to model `provcare:StudyInstrument`, and `provcare:StudyParticipant`. The `provcareStudyInstrument` models many different categories of data recording instruments including `provcare:Actigraph`, `provcare:Audiometer`, `provcare:Thermistor`, `provcare:ImagingInstrument` among other (Figure 2 illustrates a segment of the ProvCaRe ontology class hierarchy). To model the `provcare:StudyData` class, we extended the `prov:Entity` class and defined `provcare:StudyOutcome`, `provcare:StudyPopulationData`, and `provcare:TemporalEntity` classes.

It is important to note that given the extremely large number of provenance metadata terms used in biomedical research, it is not practical to model all provenance-related terms in the ProvCaRe ontology as precoordinated class expressions (21). Therefore, we have extended the postcoordination compositional grammar syntax defined for the Systematized Nomenclature of Medicine Clinical Terms (SNOMED CT) (21) to create new provenance-specific ontology class expressions in the ProvCaRe ontology for use across different domains. The new provenance-specific compositional grammar syntax enables us to re-use ontology classes from more than 500 existing biomedical ontologies listed at the National Center for Biomedical Ontologies (NCBO) (22) in the ProvCaRe ontology. For example, the expression `[Electroencephalogram]: [hadStudyInstrument] = [ScalpElectrode], [wasAssessedUsing] = [EpworthSleepinessScale]` represents provenance of electrophysiological signal recording in neurology and `[DayTimeSleepiness]: [wasScoredAt] = [CentralReadingCenter]` represents provenance of sleep medicine data measurement, which are defined using our ProvCaRe compositional grammar syntax. A detailed description of the ProvCaRe postcoordination expression syntax is provided in our paper submitted for review to AMIA 2017 titled “An Extensible Ontology Modeling Approach using Post Coordinated Expressions for Provenance Metadata”. The ProvCaRe ontology is used as the reference knowledge model to identify and extract provenance information from published research and generate structured provenance information.

**Stage 2. Automated Provenance Metadata Extraction from Research Study Articles.** Using the S3 model as reference, the ProvCaRe NLP pipeline extracts provenance information from published research studies and generates “provenance triples” for populating the ProvCaRe knowledgebase. The “provenance triples” conform to the provenance model used in the W3C PROV specification and allows search as well as query functionalities. For example, provenance information extracted from a research study that analyzed the association between sleep-disordered breathing and hypertension (23) can be represented as “DataAnalysis → wasPerformedUsing → GeneralizedEstimatingEquation(GEE)” and “SleepData→wasScoredAt→CentralReadingCenter”. These provenance
triples describe the provenance of data analysis as well as processing techniques used in the research study and can be aggregated to form a “provenance graph” as described in the W3C PROV specifications (10). The two end terms (e.g., DataAnalysis and GeneralizedEstimatingEquation (GEE)) represent the nodes of a graph and the intermediate term (e.g., wasPerformedUsing) corresponds to a relationship or an edge in the graph (10).

The identification and extraction of both the provenance terms and relations from unstructured biomedical text is a difficult task (automated extraction of structured information from text is a focus of extensive research in biomedical informatics (24)), therefore we used a combination of techniques to address this challenge. First, we extended cTAKES with additional ontology-lookup and provenance triple generation modules to process the published articles (15). In addition to cTAKES, we used the MetaMap tool, which uses the Unified Medical Language System (UMLS) as reference knowledge model (25), for named entity recognition (NER) task. In addition to MetaMap and cTAKES, the ProvCaRe-NLP tool uses the National Center for Biomedical Ontologies (NCBO) Open Biomedical Annotator tool (26) for NER task also (in previous section, Figure 1 shows the architecture of the ProvCaRe-NLP pipeline). We developed the ontology lookup module (OLM) to allow use of multiple OWL ontologies for provenance-specific NER tasks. The OLM uses the open source OWL Application Programming Interface (OWLAPI) to parse and index classes and properties in an OWL ontology (27).

Table 1 describes the distribution of the 28,474 provenance triples extracted from the 75 published articles describing sleep research studies. Two experts working in the NSRR project selected 75 published articles describing 6 NIH-funded sleep medicine research studies that have made their data available through NSRR: (1) Sleep Heart Health Study (SHHS1) Study: SHHS1 is a multi-center cohort study to determine the consequences of sleep-disordered breathing on risk for coronary heart disease, stroke, all causes of mortality, and hypertension; (2) Multi-Ethnic Study of Atherosclerosis (MESA) Study: The MESA study is a multi-center project involving 6 field centers to study the characteristics of subclinical cardiovascular disease (CVD) and risk factors that predict progression to clinical CVD; (3) Childhood Adenotonsillectomy Trial (CHAT) Study: The CHAT study is a multi-center, single blind, randomized controlled trial to test whether children aged between 5 to 9.9 years with mild to moderate obstructive sleep apnea randomized to early adenotonsillectomy (eAT) show greater neurocognitive functioning as compared to children randomized to watchful waiting plus supportive care after a 7 month observation period; (4) Heart Biomarker Evaluation in Apnea Treatment (HeartBEAT) Study: The HeartBEAT study is a multi-center Phase II randomized controlled trial to evaluate the effects of supplemental nocturnal oxygen or Positive Airway Pressure (PAP) therapy compared to optimal medical preventive therapy over 3 months intervention period; Osteoporotic Fractures in Men (MrOS) Study: The MrOS study is a large observational study of the determinants of fracture in older men involving 5994 participants living in communities with age of 65 years or older across 6 clinical centers; and (5) Cleveland Family Study (CFS): CFS is a family-based study of sleep apnea worldwide 2,284 individual enrolled from 361 families and studied on 4 occasions over a period of 16 years designed to identify genetic and non-genetic risk factors for sleep apnea and related traits.
Algorithm for Generating Provenance Triples. We have developed a new algorithm to construct provenance triples from cTAKES output using the annotation functionalities of the clearNLP semantic role labeler (SRL) module (15). Specifically, the SRL module generates a “predicate-argument” structure for each sentence in the text based on a transition-based SRL approach (28). For example, two terms *measurements* and *parent* occurring in a sentence “…measurements of height and the circumference of waist and hips [argument] were obtained from [predicate] parent study [argument]…” are linked by the predicate *were obtained from*. Using a set of heuristics-based rules, the provenance triple generator algorithm uses the position of the arguments in the sentence with respect to the predicate to generate triple structure *Measurements → wereObtainedFrom → ParentStudy*. After processing the 75 published articles related to the six sleep research studies, the algorithm generated a total of 28,474 provenance triples, which are stored in the ProvCaRe knowledge for query and analysis.

Stage 3. ProvCaRe Knowledgebase: Hypothesis-driven Search and Query of Provenance Metadata. To meet the two key objectives of the ProvCaRe project, that is: (a) allow researchers to search for research studies related to a hypothesis based on their provenance information; and (b) enable researchers to develop rigorously designed experiments, we implemented a Web-based user interface for querying the ProvCaRe knowledgebase (Figure 3 shows the different features of the user interface, which is available at: [http://provcare.case.edu](http://provcare.case.edu)). The ProvCaRe knowledgebase consists of the provenance triples generated during Stage 2 (described above) that are indexed by their source text articles, which allows users to query for provenance metadata of individual research studies. The ProvCaRe interface supports hypothesis-driven search functionality that allows users to form query expressions corresponding to their research hypothesis. To help users to formulate accurate query expressions, the user interface supports an “auto complete” feature that is similar to functionalities offered in Google or Bing search engines (Figure 3 illustrates the auto complete feature of the user interface). The auto complete feature is implemented using a powerful open source text-indexing tool called Apache Solr, which supports search queries over unstructured text using efficient inverted indexing structures (29).

Using the high-performance Apache Solr indexing system enables the ProvCaRe knowledgebase to quickly identify relevant publications for a given set of keywords in a hypothesis. After a relevant set of publications is identified for a user-specified research hypothesis, a new provenance-based ranking algorithm ranks the result of the user query. The provenance-based ranking algorithm incorporates the frequency of provenance terms extracted from the published studies and ranks studies with a greater number of provenance triples higher in the search results. The weight assigned to the provenance triples extracted from each study represents the potential for scientific reproducibility of a research study. The default setting of the ranking algorithm assigns equal weight to the three components of the S3 model namely, Study Method, Study Tools, and Study Data. However, different weights can be assigned to different terms of the S3 model based on user preferences, which will allow users to find research studies that have more provenance information about their experiment protocol (Study Method), instrument details (Study Tools), or dataset (Study Data). In the next section, we discuss additional results and an evaluation of the ProvCaRe knowledgebase search and query feature.

Results and Evaluation

Provenance Metadata Extracted from Published Research Studies. Table 2 shows the distribution of the provenance terms extracted from the 75 published articles corresponding to the three components of S3 model. We note that all 75 published articles include a description of “Study Variables”, whereas only 43 articles include
provenance information related to temporal information (“Time Point”). Similarly, all 75 publications include provenance metadata describing the method used for data analysis and statistical model, which is encouraging as both the details of the data analysis techniques and the statistical model are critical for ensuring transparency in reporting of studies as well as reproducibility.

Table 3 shows the 15 most frequent provenance terms in the ProvCaRe knowledgebase and the corresponding ProvCaRe ontology term. A comparison with Table 2 shows that provenance terms corresponding to the data analysis techniques and statistical models used in research studies match the ontology classes modeled in the ProvCaRe ontology. The provenance term Study describing the experiment constitute a little less than one fourth (22%) of the provenance terms in the ProvCaRe knowledgebase. It is interesting to note that although 71 of the 75 articles include provenance information about the software tools used in a study (Table 2), the frequency of occurrence of provenance term describing instrument (including hardware instruments) is only 2% (Table 3).

Hypothesis-driven Study Search and Query Performance. To evaluate the hypothesis-driven search feature of the ProvCaRe interface, we used a set of five hypotheses defined by a clinical domain expert:

**Hypothesis 1**: Sleep disordered breathing is associated with an increased incidence of cardiac arrhythmias.

**Hypothesis 2**: Early adenotonsillectomy improves neurocognitive outcomes in children with obstructive sleep apnea.

**Hypothesis 3**: Specific genetic polymorphisms are associated with an increased risk of sleep disordered breathing;
Hypothesis 4: Sleep disordered breathing is associated with an increased risk of developing the metabolic syndrome characterized by changes in markers of systemic inflammation; and

Hypothesis 5: Short sleep duration is associated with increased cardiovascular morbidity and mortality

We performed hypothesis-based search in the ProvCaRe platform using the above listed hypothesis and evaluated the performance of the ProvCaRe knowledgebase with respect to: (a) time taken to query and retrieve relevant research studies, and (b) time taken to rank the research studies using the provenance information extracted from these research studies. Figure 4 shows the performance of the provenance-ranking module, which clearly shows that the additional overhead for provenance-based ranking of the research studies is less than the time required to search for research studies that are relevant to a given hypothesis. This demonstrates that the additional functionality of the ProvCaRe knowledgebase to allow users to search and query for previous research studies and rank the results based on their provenance metadata is practical and does not lead to additional computing costs. We also note that query performance across the five research hypotheses does not vary significantly due to the effectiveness of the inverted indexing feature of Apache Solr. This is important for ensuring the scalability of the ProvCaRe knowledgebase as additional studies are processed and added in the future.

Discussion and Conclusion

The Resource Description Framework (RDF) is a well known and widely used graph-based data structure for ontology-based datasets (30). The RDF/XML syntax is often used to represent provenance metadata, which naturally forms a graph structure (10). Therefore, as part of our ongoing work, we plan to transform the “provenance triples” currently stored in the ProvCaRe knowledgebase into RDF triples, which will allow us to implement the SPARQL query language for advanced query and retrieval of provenance information. In addition to the use of RDF, we are using the different components of the ProvCaRe project to process and extract provenance information from all publications related to sleep medicine research studies. We are developing an automated pipeline to retrieve new publications available in both NCBI PubMed and PubMed Central, which will be processed using the ProvCaRe-NLP pipeline. This will allow users to search and query for provenance information of newly published research studies. In addition to extending the ProvCaRe knowledgebase, we are developing new query algorithms for provenance graphs to efficiently compare the provenance information of multiple research studies.

In conclusion, the ProvCaRe knowledgebase described in this paper is one of the first publicly available repositories of provenance metadata extracted from published biomedical research studies. The ProvCaRe S3 Model serves as key provenance knowledge model for representing provenance terms and the ProvCaRe ontology enables the identification of provenance information necessary to support scientific reproducibility in biomedical research. Using the ProvCaRe-NLP pipeline, we demonstrate an efficient and scalable approach to automatically identify and extract provenance metadata information from 75 published articles corresponding to sleep medicine research studies that have made their data available through the NSRR. Users can search and query the provenance metadata of research studies using an intuitive Web-based ProvCaRe interface that uses a provenance-based ranking algorithm to search and retrieve relevant study related articles. The various components of the ProvCaRe project are allowing us to support the objectives of the NIH Rigor and Reproducibility guidelines by developing and implementing a set of practical tools to model, extract, and analyze provenance information associated with research studies.

Abstract
Marginalized communities are rarely included in the planning of research relevant to their own health or have access to research data. We implemented a community-based participatory research approach in developing a new health informatics system, WARP (Web Analytics Research Platform), to enable stakeholders to access and analyze research data. We leveraged data from a cohort study of 751 patients in the Transitions Clinic Network (TCN), a network of clinical programs serving patients with a history of incarceration. WARP holds de-identified, patient data, streamlines data processing (i.e. transformation, archival, and partitioning), and has a web analytic tool for users to perform statistical analyses. We used feedback from focus groups of patients with a history of incarceration and workshops with TCN research teams, including patients, community health workers and policymakers, to develop WARP. Our approach advances mechanisms to engage stakeholders in research. Future work will evaluate its effect on community-engagement in research.
Patients are rarely engaged in research design or planning of studies affecting their own health. This lack of engagement in research delays the translation of research into actual improvements in health for patients, since the dissemination of evidence-based information often takes 10 to 25 years. Community-based participatory research (CBPR), which includes community members in every step of the research process, promises to facilitate the more efficacious adoption of findings into action, especially among marginalized communities. Yet, CBPR’s potential in analysis and dissemination is largely untapped. Even CBPR projects often fail to engage all stakeholders in analysis or disseminate study findings because limited statistical, analytic, or technologic experience among stakeholders. In addition, researchers using a CBPR approach do share data with community partners or participants until analyses have been completed.

The CBPR approach in informatics is in its nascency. One recent manuscript highlighted the projects that utilized both CBPR and informatics approaches to engage community stakeholders. The authors summarized that informatics researchers have primarily applied CBPR to use technology to explore and understand health-related problems in marginalized communities, the technologic practices in a specific community, or to develop context-appropriate technologic interventions. In these studies, there was increased participation of community stakeholders in the design and development of informatics platforms to address the health needs of communities. In one study, researchers shared data with participants, but only after analyses have been completed, e.g. working with communities in the development of infographics to display health data.

To improve engagement of patients in research, we use a CBPR approach to create a web-based platform that enables patients to both access and analyze de-identified data. Our use case population to improve engagement is among the most marginalized populations, i.e. those with a history of incarceration, who are rarely included in the planning of research relevant to their own health or have access to research data. We developed and designed, with optimal input from patients with a history of incarceration, a functional prototype of a web-based platform that enables exploration of a population’s health at a local and national level. We leveraged data from the Transitions Clinic Network (TCN), a network of clinics providing specialized services to individuals returning home from prison. In this paper, we describe our research setting and approach and the web-based platform that enables access to and analysis of research data.

**Methods**

**The Setting**

The Transitions Clinic Network (TCN): Founded in 2006, the TCN is the largest national collaboration of patients, clinician researchers, and policymakers whose primary focus is improving the health of individuals returning home from prison. The TCN provides healthcare based on a three-pronged approach: (1) community health workers with a history of incarceration as care coordinators; (2) early coordination of care that begins prior to release from prison to identify patients with chronic medical conditions and facilitate improved care coordination; and 3) culturally-competent care specific to people returning to the community from prison to reduce stigma and distrust of medical professionals. TCN is guided by local community advisory boards comprised mostly of individuals with a history of incarceration and a National Advisory Board whose expertise includes leadership in the Association of State Correctional Administrators and civil rights and advocacy organizations for formerly incarcerated individuals, like All of Us or None and JUSTUSA.

**TCN Cohort Study:** The TCN has established the largest prospective cohort of individuals with chronic medical conditions leaving prison as part of a Health Care Innovation Award from the Center for Medicare & Medicaid Innovation. Data were collected from participants using surveys (collected by tools such as SalesForce© and Qualtrics© prior to our web prototype development), and electronic medical records at 13 clinics and community health centers nationwide, located in: New Haven, CT; San Francisco, CA; Richmond, CA; San Jose, CA; Boston, MA; New York City, NY; Bronx, NY; Rochester NY; Baltimore, MD; Birmingham, AL; and Caguas, PR. Data collected include: patient sociodemographics, housing, employment, incarceration history, past medical diagnoses, health outcomes (including physical, mental health, and substance misuse), health care utilization, and re-incarceration in three-month increments. To be eligible for the TCN cohort, a person has to have been released from prison within 6 months, have a chronic medical condition (including chronic physical, mental health, or substance use conditions) which warrants longitudinal primary care or be older than 50 years of age, speak English or Spanish, and not plan to leave the area for at least 12 months. The TCN Cohort Study enrolled 751 participants, some of whom were followed for more than 12 months.
The SHARE project, funded by the Patient-Centered Outcomes Research Institute (http://www.pcori.org/research-results/2015/share-project) (PCORI) is a sub-study within the TCN whose main goals are to integrate the principles of CBPR and patient centered outcomes research to improve patient outcomes by engaging patients in the research process. One prong of the SHARE project is the development of a web-based platform to share de-identified TCN cohort data that is accessible to patients and other stakeholders. We used baseline data from the TCN cohort study of returning individuals to pilot the development of the web-based platform prototype.

The Web Analytics Research Platform (WARP)

Development Approach and Methods:

Community Participation: The SHARE project created a study advisory board of patients with a history of incarceration and a community health worker from the New Haven Transitions Clinic program. They were engaged in the development of the idea and submission of the PCORI grant. With grant funding, they were then involved in brainstorming the functionalities of WARP, gave input on the display of the data, and participated in curriculum development by participating in focus groups.

These advisory board members were selected to represent the diversity of the TCN patients. There were seven individuals identified by the TCN clinic staff who were available and willing to participate and are reflective of the diverse TCN population. There were 3 women and 4 men, whose self-identified ethnicity/race categories were Black, Latino/a, and white. Focus group participants’ employment ranged from unemployed to health professionals, their ages ranged from 32-67, and they reported having limited to proficient computer usage.

Data: We used the TCN Cohort Study data (Table 1) to develop and design the web-based platform prototype to share de-identified data with end-user stakeholder groups (patients with a history of incarceration, researchers, providers, and policy makers). Table 1 shows some of the data types in the study.

Methods: We used the rapid cycle prototyping approach and adapted the principles of participatory design to understand anticipated user requirements and research needs so that the needed functionality would be implemented rapidly and iteratively.15-17
From March to September 2016, we convened three focus groups of four to seven advisory board members for end-user input and feedback. Topics of discussion included the design of the interface, user-friendliness, and their understanding of the data summaries (e.g. prevalence and correlations) and relationships between two variables.

The focus groups lasted two and a half hours. For the first focus group, participants reviewed different types of images for displaying data (e.g. icon arrays, graphs, pie charts) and chose the ones that were easiest to understand and the types of images they preferred. The second and third focus groups introduced the latest versions of the web-based platform. For each focus group, we had an interview guide to elicit participant responses about the platform. The interview guide had general questions to elicit initial thoughts about the platform, such as “what do you think about the way the website looks,” “what do you think about the way the website functions,” “what are some things that you would like to see changed,” and “is there anything you would like to see added to the site that is not there now?” Participants were asked to demonstrate how they would find specific information, such as finding information about people in the cohort who are male, have diabetes, or length of prison term. Then they were asked to provide an answer to a specific question about the information they found. For example, one question was “how would you look at the length of prison term and those who screened positive for depression” followed by “which group had the most people who screened positive for depression.” A social worker trained in qualitative research methods whose own research focuses on criminal justice-involved populations conducted each of the focus groups. The social worker took detailed notes from the focus groups.

The web-platform was changed based on feedback from each focus group to ensure that people with varying degrees of computer and data literacy could use it. In addition to the focus groups, four TCN teams made up of patients and community health workers with a history of incarceration, policymakers, and researchers provided feedback about the web-based prototype and used it to begin to develop a research question for future work.

Description of System

![System Overview](image)

**Figure 1. System Overview**
Figure 1 depicts the main components of our data and analytics system. It consists of the following components:

1. **Data conversion tool.** For the TCN cohort study, patients’ data (e.g., surveys) had been collected by each TCN site using tools such as SalesForce© and Qualtrics©. We then integrated all TCN study data collected from these tools into the TCN database and used this to develop WARP. The TCN datasets were exported using SPSS format, a metadata-rich format for statistical data analysis. We developed a data conversion tool to transform and load SPSS datasets into the EAV/CR (Entity Attribute Value with Classes and Relationships) data model. EAV/CR is derived from the triple-store model used in clinical trials and was enhanced to deal with domain variability. EAV/CR data model allowed for creating several virtual databases with their own set of administrative users. Each study or version of it (by cut time or partition) was stored as a separate EAV/CR database. During transformation, each instrument was converted into a separate EAV/CR Class. Elements on each Class were related to others using internal object IDs from the Subject (pivot) Class. Classes had attributes that were related to questions in the surveys and supported strong data types. The EAV/CR database enabled capturing of all questions’ metadata (data type, labels, option text, value, boundaries, etc.). Once the data was transferred, as part of the data transformation process, we performed data harmonization by mapping local variable names/types to common variable names/types.

2. **Centralized database.** Our EAV/CR database was implemented into a SQL Server 2016 relational database. It provided all system required data capabilities for: a) data warehouse, b) system administration, c) security, and d) online analytic processing.

3. **Metadata-driven framework and special enhancements to enable WARP capabilities.** Our prototype required extensible data and system needs that can evolve over time. For these capabilities, we leveraged and extended the flexible metadata driven approach within EAV/CR programming framework. This framework provided extensible metadata description of datasets including their structure, mappings (between local data elements and common data elements) and metadata-driven user interface configuration. The system provided a web-based dashboard for the system developer to view/modify the metadata. EAV/CR enhancements to support special WARP capabilities include but are not limited to:
   a. Vertical security: Data elements can be made visible depending on user role. We used metadata to configure which data fields are included as part of a query and to display query output based on user roles (e.g., patient role vs. researcher role vs. policymaker role). However, for this project, this functionality was removed as the research teams wanted equitable access to the data.
   b. HIPAA values: Data that could potentially be identifiable cannot be queried. We defined metadata to hide questions and used annotations to limit or mask values that will make information identifiable. For example, no results were provided when the total number of individuals with a particular characteristic were less than ten or when a TCN site had less than 100 individuals.
   c. Data type conversions: We developed a tool to convert attribute data types. For example, this tool can convert values from questions that are provided as a string into an integer or a date.
   d. Question groups: For improved data display and analysis, we clustered questions together. A new type of attribute was created (grouping attribute) to enable this functionality.
   e. Metadata analysis tools: We developed tools to analyze questions for misspelled values, completeness, and data type validation.
   f. Metadata curation and data normalization tools: We developed tools to allow attribute data curation using global value replacements (used to correct invalid or misspelled values) and normalization (to spawn an attribute into a new class).

4. **Web interface for data queries and visualization.** We created the “WARP Navigator.” This interface is used to display the data and statistical findings for a study. The interface consists of a variable list on the left panel and a graphical dashboard on the right panel (See Figures 2 and 3). The variables list shows all questions using an accordion control, which collapses and expands content domains within the survey. Some questions are hierarchically arranged and placed in groups. The graphical dashboard provides controls to choose: a) type of graph (bar/line/pie), b) type of values (numbers/percentages), and c) style: color/pattern. In addition, bivariate analysis is available to compare two variables. The WARP Navigator is dynamically driven and configured based on the metadata given by the study protocol and security constrains on user roles. For graphics, we used the JS chart component by amCharts (https://www.amcharts.com/).
Figures 2 and 3 illustrate the basic components of WARPs web-interface. Users can select from the list of variables on the left side of the display to describe the population, and the right side of the display depicts the format in which the data are presented. The image on the left is prior to end-user input about the display and interactive capabilities. The image on the right is after incorporating user input, demonstrating different graphics and more functionalities. WARP allows the display of data as bar graphs or pie charts and has functionalities for users to change the display (e.g. view the data as counts or percentages). Users can also change the font size and color of the display, and there is a screen reader for those who prefer to listen to the text.

Figure 2. Data display pre-and post-user feedback

Figure 3 demonstrates an interactive function in which an end-user can conduct a bivariate analysis. For example, an end-user who was interested in looking at the relationships between the number of years a person is incarcerated to the number of chronic diseases would see the display in Figure 3.

Figure 3. Data analysis functionality in WARP
Discussion

Our work highlights 1) a novel mechanism to advance the engagement and authentic participation of communities in research by providing a user-centered platform in which consumers can directly interact with (i.e. visualize and analyze) research data and 2) the importance of incorporating stakeholders’ feedback and perspectives into the design and development of the user interface early in the process.

We believe through the integration of CBPR principles in the development of this web-based platform, we have engaged patients who have traditionally been marginalized from the research process, increased the capacity of end-users to use the data, and have shared data back to end-user groups who will be instrumental in catalyzing improvements in health outcomes for this population. We believe this platform enables TCN patients to become more engaged in data collection and participate equitably in the analysis and interpretation of data. Although more research is needed, this approach and the web prototype initiates a mechanism to enrich our understanding of how to improve the health of this population and other marginalized communities. WARP allows for transformation of research data from survey instruments and other formats that have been processed by software, such as SPSS, to be accessible to end-users for analysis. This functionality can be utilized to support the transformation of other types of data from the TCN and other research studies. In addition, WARP Navigator allows end-users to conduct bivariate analysis via the web-platform. WARP will be used by TCN sites and their patients to analyze, interpret, and generate new hypotheses and identify strategies or potential targets to improve the health outcomes of patients with a history of incarceration. This type of data access and interactive capabilities customized to patient end-users shortens the time between data collection and dissemination and may enable more rapid translation of research data into meaningful changes for communities.

One of the main lessons we learned as a part of this work was developing a mechanism for a common understanding and communication between our interdisciplinary team members consisting of patients and community health workers with a history of incarceration, clinician researchers, informatics researchers, and a systems architect. In the initial development of the interactive platform and the data visualization, researchers proposed the use of iconographs to display data based on existing literature, however the patient end-users preferred basic graphs. Through this work, our feedback loop from patients to researchers to systems architect was continuous and frequent to ensure patient feedback was incorporated accurately. Another lesson was the need to transform research data in its different formats for availability via the web-platform. While we attempted to harmonize the data elements (i.e., variables including their names and value sets) within the TCN, there is a broader common data element effort taking place to harmonize variables used by different research projects across different networks and research communities. For example, the NIH Common Data Element (CDE) resource portal (https://www.nlm.nih.gov/cde/) consists of a CDE repository that provides access to CDEs and forms that group certain CDE’s together for research questions. Our project can potentially benefit from and contribute to the CDE effort.

We have already experienced and anticipate several challenges with the refinement and dissemination of the platform. One challenge is and will continue to be balancing the needs of diverse platform user groups—from patients to policy makers to other researchers. As the goal of the platform is to serve as a tool to produce patient-centered research by enabling full interaction of patients with the platform, we prioritized the perspective of patients with a history of incarceration and accommodated their specific needs. Therefore, all users have access to the same data; and the visualization and interactive capacities are targeted to address their needs and not the researchers or policymakers. Another challenge will be continued integration of new TCN data into the platform and ensuring the continued use and improvement of the platform.

This team approach and platform prototype are only part of the initial stages to meet our objective to build collective capacity among patients, community health workers with a history of incarceration, policymakers, and clinician researchers to improve the health of people returning to the community from prison. We have outlined several more stages in this project in Figure 4, including the integration of publicly available data with the patient-level data.
Interested end users with limited health, data, or research literacy, and other stakeholders such as correctional and community health policymakers

Enhanced CBPR to activate patients and engage communities

Rich, rigorous PCOR with outcomes that matter to hard-to-reach populations

Better understanding of how to improve the health of former prisoners

Integration of patient-level data with publicly available health data, relevant to individuals with history of incarceration

Data platform that incorporates local and national health data of TCN patients with publicly available health data and allows users to view aggregate and individual patient data

Functional prototype to enable exploration of a population's health at local and national level

Workshop on CBPR, data and use of data

• Organizing data from prospective cohort study of the Transitions Clinic Network (TCN)
• Visualization of data based on patient needs and preferences

• Fully developed sharable WARP system in other populations
• Model for using a CBPR in health informatics research to engage patients
• CHW who are data informed

Current Stage

Figure 4. Community-based participatory research merged with health informatics

Since the finalization of the prototype, we have conducted a three-day in-person training session about CBPR and patient centered outcomes research principles, research design, and partnership development for the TCN teams, with curriculum adapted from Data & Democracy. In addition, one half-day session was focused on the importance and use of data in research and the use of WARP. We also held four webinars focusing on research design, creation of patient-centered research proposals, community-engagement, and using research for advocacy. With more training, we anticipate increased use of the system and an increased capacity for collaboration that will enable new patient-centered outcomes research ideas. Our immediate plans for the WARP navigator include: adding drill-down filtering of results, user annotations, and sharing of graphical queries. While the current web interface supports data queries only, it can potentially be expanded to support data entry as part of the collection process in the future. We are also in the process of linking WARP to the main webpage for the TCN. This platform will be accessible to the TCN network only with user log-ins. Once available on the TCN webpage, our plan is to conduct follow-up studies to evaluate the use of this system among the TCN population.

Conclusion

Data sharing is occurring in multiple different forms in the biomedical sciences, mostly among researchers with limited consideration of patient stakeholders, especially from marginalized communities. The development of WARP with basic functionalities has the potential to allow researchers to share and feedback data to the communities who contributed to the data. Moreover, WARP is a tool that can potentially engage patients in research by providing a mechanism to access and analyze the data. Alongside the curriculum to increase research capacity, these capabilities may help accelerate the translation of research into actual improvements in health for patients. We believe this work advances the work at the intersection of community-engaged health informatics and CBPR and will have broader applicability to researchers employing a CBPR approach or those employing methods of patient-centered research outcomes. We will explore the utility of this web-based platform for other research programs and conceive of future functionalities, including a mobile platform and a prospective data entry platform for transparency and rapid dissemination.

Abstract

Prostate cancer (PC) is the most common cancer and the third leading cause of cancer death in men worldwide. Despite its high incidence and mortality, the likelihood of a cure is low for late-stages of PC. There is an unmet need for more effective agents for treating PC. Here, we present a drug repositioning system, GenoPredict, for finding innovative drug candidates for treating PC. GenoPredict leverages upon a large amount of disease genomics data and a large-scale drug treatment knowledge base (TreatKB) that we recently constructed. We first constructed a genetic disease network (GDN) that comprised of 882 nodes and 200,758 edges and applied a network-based ranking algorithm to find diseases from GDN that are genetically related to PC. We developed a drug prioritization algorithm to reposition drugs from PC-related diseases to treat PC. When evaluated in a de-novo prediction setting using 27 FDA-approved PC drugs, GenoPredict found 25 of 27 FDA-approved PC drugs and ranked them highly (recall: 0.925, mean ranking: 27.3%, median ranking: 15.6%). When compared to PREDICT, a comprehensive drug repositioning system, in novel predictions, GenoPredict performed better than PREDICT across two evaluation datasets. GenoPredict achieved a mean average precision (MAP) of 0.447 when evaluated with 172 PC drugs extracted from 172,888 clinical trial reports, representing a 164.5% improvement as compared to a MAP of 0.169 for PREDICT. When evaluated with 72 PC drugs extracted from 43,811 ongoing clinical trial reports, GenoPredict achieved a MAP of 0.278, representing a 231.1% improvement as compared to a MAP of 0.084 for PREDICT.

The data is publicly available at: http://nlp.case.edu/public/data/PC_GenoPredict and http://nlp.case.edu/public/data/treatKB.

Introduction

Prostate cancer (PC) is the most common cancer and the third leading cause of cancer death in men worldwide. In the United States alone, an estimated 238,590 men were diagnosed with PC in 2013 and 29,720 died from their disease [1]. Despite its high incidence and mortality, the likelihood of a cure is low for patients diagnosed with late-stage PC [2]. Docetaxel, the standard treatment for metastatic PC, provides a median overall survival improvement of roughly 3 months. While the PC market is expected to grow to $8.2 billion in 2019, there is an unmet need for more effective drug treatments for PC [2].

Computation-based drug repositioning approaches that assimilate vast amounts of genetic, genomic, chemical, and phenotypic data for thousands of drugs and diseases can greatly speed up the traditional drug discovery process [3]. Here we present a computational drug repositioning system, GenoPredict, that capitalizes on comprehensive disease genetic data generated by Genome-Wide Association Studies (GWAS) [4] and a unique large-scale drug treatment database that we recently constructed [5-7]. Our study is based on the premise that the genetic inter-relationships among diseases often reflect pathophysiological relevance. Though the majority of such shared pathophysiological features remain unknown, treatment insights from one disease may be used to inform our knowledge of others and potentiate their treatments. Existing approaches have directly inferred drug targets from disease genetics generated by GWAS studies [8-11]. Here, we present a complementary strategy to indirectly infer repositioned drug candidates from disease genomics data and demonstrated its utility in PC drug repositioning: diseases that share high genetics with PC were used as a starting point for both discovering repositioned drug candidates and gaining insights into the common mechanisms of action underlying identified candidates.

In order to systematically reposition drug treatments from one disease to another, it is critical to have a comprehensive drug treatment knowledge base. We have recently constructed a large-scale drug-disease treatment knowledge base
(TreatKB) from multiple heterogeneous and complementary data resources [5-7]. We previously showed that TreatKB is critical for our computational drug repositioning tasks [12-13]. We evaluated GenoPredict in identifying and prioritizing FDA-approved PC drugs and compared GenoPredict to PREDICT, a comprehensive drug repositioning system [14], in novel predictions for PC. We demonstrated that GenoPredict is effective in prioritizing FDA-approved PC drugs and achieved better performance than PREDICT in novel predictions.

Materials and methods

Data

Drug-disease treatment relationship knowledge bases (TreatKBs) TreatKB contains 208,330 unique drug-disease treatment pairs, representing 2,484 drugs and 24,511 unique disease concepts [5-7]. TreatKB includes 9,216 drug-disease treatment pairs extracted from all FDA drug labels, 111,862 pairs extracted from the FDA Adverse Event Reporting System (FAERS), a database supporting the FDA’s post-marketing drug safety surveillance; 34,306 pairs extracted from 21 million published biomedical literature abstracts, and 69,724 pairs extracted from 172,888 clinical trials. The data is publicly available at http://nlp.case.edu/public/data/treatKB/.

Disease genetics data from the GWAS catalog Disease-gene association data from the Catalog of Published Genome-Wide Association Studies (the GWAS catalog) was used to construct disease networks and to identify PC-related diseases. The GWAS catalog is an exhaustive source containing the description of disease- and trait-associated single nucleotide polymorphisms (SNPs) from published GWAS data and currently contains 22,470 disease-gene pairs for 882 diseases and 8,689 genes [4]. Recent studies have shown that disease genomics data in the GWAS catalog is a rich resource for drug discovery [8-11].

ICD10 for disease classification We identified diseases that are genetically related to PC (PC-related diseases) and analyzed PC-related diseases using the 10th revision of the International Statistical Classification of Diseases and Related Health Problems (ICD10) [15]. The 22 highest-level disease classes (e.g., “Neoplasms” and “Diseases of the nervous system”) were used in categorizing PC-related diseases.

The Anatomical Therapeutic Chemical (ATC) classification system for drug classification The ATC system was used to classify and analyze repositioned drugs. The ATC classification system consists of 13 first-level codes, 94 second-level codes, 267 third-level codes, 882 fourth-level codes, and 4580 fifth-level codes, which are individual drugs [16].

Drug target genes and genetic pathways data Drugs’ gene targets were obtained from DrugBank [17], a comprehensive database containing information on drugs and drug targets. Gene-associated pathways were obtained from the Molecular Signatures Database (MSigDB), which contains 10,295 annotated genetic pathways [18].

Methods

The experiment framework of GenoPredict consists of the following steps: (1) we constructed a genetic disease network (GDN) and applied a network-based ranking algorithm to find diseases that are genetically related to PC; (2) we developed a drug prioritization algorithm to identify candidate drugs; GenoPredict was tested using 27 FDA-approved PC drugs and was compared to PREDICT in novel predictions; and (3) we performed drug classification and pathway enrichment analysis to analyze top ranked repositioning drug candidates.

Construct genetic disease network (GDN) and find PC-related diseases from GDN

Construct GDN We constructed GDN using disease-gene association data from the GWAS catalog. On GDN, two diseases were connected if their associated genes overlapped. The edge weights were determined by the cosine similarity coefficients of disease-associated genes [19]. GDN comprised of 882 disease nodes and 200,758 edges.

Apply network-based ranking algorithm to find diseases that share high genetic relevance with PC (PC-related diseases) We have recently applied a commonly used network-based ranking algorithm [20] for disease genetics dis-
covery [21-23], human gut microbial metabolite prediction for diseases [24-25], and drug repositioning [12-13]. In this study, we directly used the network-based ranking algorithm to identify PC-related diseases from GDN. The iterative ranking algorithm is defined as: 

$$p_{t+1} = (1 - r)Mp_t + rp_0$$

wherein $M$ is the column-normalized adjacency matrix of GDN, $\gamma$ is a preset probability of restarting from the initial seed node ($\gamma=0.1$ in this study), and $p^t$ is a vector in which the $i_{th}$ element holds the normalized ranking score of disease $i$ at $t_{th}$ iteration. The initial probability vector $p^0$ contains normalized probability values for input. In our study, $p^0$ contains PC, with a probability of 1.0. Diseases were ranked according to values in the steady-state probability vector, which was obtained by iterating the algorithm until the change between $p_{t+1}$ and $p_t$ was less than $10^{-6}$.

We expect that top-ranked PC-related diseases should be enriched for cancers since cancers are known to share genetics with each other. To evaluate the network-based disease ranking approach and to systematically study PC-related diseases, we classified PC-related diseases based on the ICD10 classification scheme[15], and examined distributions of 22 disease classes at ten ranking cutoffs (top 10%, 20%, . . . 100%).

**Drug prioritization algorithm**

**Drug repositioning algorithm** We developed an approach to systematically reposition drugs from PC-related diseases to treat PC. We prioritized drugs based on the number of PC-related diseases that they could treat as well as the ranking scores of these diseases. For example, if drug X treats 25 top-ranked PC-related diseases, it will rank higher than drug Y, which treats only a few lower-ranked diseases. The drug prioritization algorithm is defined as: 

$$R_{drug} = \sum_{i=1}^{n} R_{disease,i}$$

wherein $n$ is the number of PC-related diseases that a drug can treat and $R_{disease,i}$ is the disease ranking score (output from the network-based disease ranking algorithm).

**De-novo validation using FDA-approved PC drugs** We evaluated GenoPredict using 27 FDA-approved PC drugs. The drug prioritization algorithm used only PC-related diseases and their drug treatments. PC and its known drug treatments were not used, therefore the evaluation was a de-novo validation. We calculated recall, mean and median rankings of these 27 FDA-approved drugs among all drugs.

**Compare GenoPredict to PREDICT in novel predictions** We compared GenoPredict with PREDICT using two evaluation datasets constructed from TreatKB: (1) 172 PC drugs extracted from 172,888 clinical trials; and (2) 72 PC drugs extracted from 43,811 ongoing clinical trials. The 27 FDA-approved PC drugs were removed from the evaluation datasets. The output from GenoPredict is a ranked list of 2484 drugs with the 27 FDA-approved PC drugs removed. In PREDICT, 48 drugs were classified as positives for PC among a total of 593 drugs. These 48 drugs along with their corresponding probabilities (ranging from 0.543-0.994) are publicly available [14]. For the remaining 545 drugs that were predicted as negatives by PREDICT, we assigned to each drug a value that was randomly picked from 0.0 to 0.5 (the random process was repeated 10 times).

Precision-Recall (PR) curves were used to evaluate and compare GenoPredict to PREDICT. Studies have shown that in domains where the number of negatives greatly exceeds the number of positives such as in drug repositioning and many other biomedical classification problems, PR curves are better than the more commonly used receiver operating characteristic (ROC) curves in avoiding overly optimistic view of an algorithm’s performance [26]. Using each of the two evaluation datasets as gold standard, we calculated precisions at 11 different recall cutoffs (0.0, 0.1, 0.2, ... 1.0) for both GenoPredict and PREDICT and plotted the PR curves. Mean Average Precision (MAP), which approximates the area under the precision-recall curve [27], was used to quantitatively compare GenoPredict to PREDICT.

**Analyze top-ranked repositioned drug candidates**

**Analyze drug classes for top-ranked drug candidates** To understand the commonalities shared by top-ranked drug candidates, we examined class distributions of top 124 (top 5%) repositioned candidate drugs. Drugs were classified based on the ATC classification system [16]. For each ATC code, we assessed its probability of being associated with these 124 drugs (e.g., the code “immunosuppressants” is associated with 30 of the 124 drugs) as compared to its probability of being associated with the same number of randomly selected drugs (e.g., the same code is on average
Cancers and metabolic diseases are enriched among top-ranked PC-related diseases

It is known that cancers often share genetics. We analyzed the distributions of cancers among diseases at different ranking cutoffs to evaluate the network construction and disease-ranking algorithms. As shown in Fig.1, cancers are enriched among top-ranked diseases. For example, at the 100% cut-off (all 822 retrieved diseases), 7.24% of the diseases are “Neoplasms”. At top 10% cutoff (top 82 diseases), 16.28% are “Neoplasms,” representing a 124.8% increase as compared to that for all diseases. The enrichment of cancers among top-ranked diseases demonstrated the validity of both network construction and ranking algorithms. Interestingly, the disease class “Endocrine, nutritional and metabolic diseases” was also enriched among top-ranked diseases. Recent studies demonstrated that certain metabolic disorders - including obesity, high blood pressure and high cholesterol - can impact the development and progression of prostate cancer [28]. Other disease classes were not enriched among top-ranked diseases.
GenoPredict found 25 of the 27 FDA-approved PC drugs and ranked them highly

We validated GenoPredict in predicting known PC drugs using 27 FDA-approved PC drugs. GenoPredict achieved a recall of 0.925, an average ranking of 27.3%, and a median ranking of 15.6%. There is a big difference between the mean and median rankings, demonstrating a skewed ranking distribution of these FDA-approved drugs (Fig. 2). While 16 of the 25 PC drugs were ranked within top 20%, some drugs were ranked very low, including degarelix at top 70.49%, abarelix at 86.76%, triptorelin at 89.21%, and histrelin at 91.22%.

Compare GenoPredict to PREDICT in novel predictions

We plotted PR curves for both GenoPredict and PREDICT using 172 novel PC drugs extracted from 172,888 clinical trial reports as the evaluation dataset. As shown in Fig. 3, the PR curve for GenoPredict clearly dominates that for PREDICT. The mean average precision (MAP) is 0.447 for GenoPredict and 0.169 for PREDICT, representing a significant 164.5% improvement.

Fig. 4 shows the PR curves when 72 novel PC drugs extracted from ongoing clinical trials were used as the evaluation set. While the MAPs for both algorithms were lower than previous ones, the curve for GenoPredict dominates that for PREDICT. The MAP is 0.278 for GenoPredict and 0.084 for PREDICT, representing a significant 231.1% improvement.

Analyze top-ranked drug candidates: drug classification and genetic pathway analysis

We examined drug classes enriched among top-ranked drugs. The highly enriched drug classes may offer insight into the mechanisms of action underlying repositioned drug candidates. Fig. 5 shows the top 15 drug classes. A total of 18.8% of top 124 drug candidates belong to the class “other antineoplastic agents” as compared to 3.9% based on random expectation. The other top-ranked drug classes include “immunosuppressants” and “corticosteroids for systemic use, plain.” We performed the same enrichment analysis for top 248 (top 10%) and top 372 (top 15%) drug
Figure 3: The Precision-Recall curves for GenoPredict and PREDICT. The evaluation data consists of 172 PC drugs extracted from 172,888 clinical trial reports.

Figure 4: The Precision-Recall curves for GenoPredict and PREDICT. The evaluation data consists of 72 novel PC drugs extracted from 43,811 ongoing clinical trials.
This study focused on integrating disease genetics with drug treatment data for drug repositioning. To build a more resource of human disease genetics is computation-based candidate disease genetics discovery. We recently showed genetics from rare Mendelian disorders represents another valuable source of novel drug targets [31]. Another rich catalog, additional drug repositioning opportunities will arise through human genetic analysis. Additionally, disease TreatKB includes 24,511 diseases and their drug treatments. With new studies being continually added to the GWAS catalog, even though the limited number of diseases (882 diseases) in the GWAS catalog, even though TreatKB includes 24,511 diseases and their drug treatments. With new studies being continually added to the GWAS catalog, additional drug repositioning opportunities will arise through human genetic analysis. Additionally, disease genetics from rare Mendelian disorders represents another valuable source of novel drug targets [31]. Another rich resource of human disease genetics is computation-based candidate disease genetics discovery. We recently showed that computationally-predicted disease genetics can lead to novel drug discovery [21-22].

This study focused on integrating disease genetics with drug treatment data for drug repositioning. To build a more candidates and obtained similar results (data not shown).

We then examined genetic pathways that are predominantly targeted by top-ranked (top 124) drug candidates. As shown in Fig. 6, the pathway “pathways in cancer” was targeted by 19.05% of the top 124 candidate drugs as compared to 7.92% based on random expectation. The pathway “prostate cancer” was also ranked at top, demonstrating the validity of our pathway analysis. In addition, four of the top fifteen pathways are related to immune systems. Currently, Immunotherapy holds great promise for cancer treatments. For example, the drug ipilimumab targets a checkpoint molecule called CTLA-4 on certain immune cells. This drug is now being tested in men with advanced PC, with early results showing treatment benefits [29-30]. Consistent with these published clinical studies, GenoPredict ranked ipilimumab at top 15% among 2484 drugs.

Discussion

GenoPredict exploited genetic and drug treatment connections among tens of thousands of diseases. We applied GenoPredict to identify repositioning drug candidates for PC and performed in-depth analysis of top repositioned drug candidates. GenoPredict found 25 of 27 FDA-approved PC drugs and ranked them highly. GenoPredict performed significantly better than PREDICT, a comprehensive drug repositioning system, in novel predictions for PC. However, the performance of GenoPredict is not optimal as seen in its PR curves for drug repositioning for PC. We are further improving GenoPredict by incorporating more comprehensive disease genetics data and will evaluate it in broad types of diseases (e.g., all diseases in the GWAS catalog).

Our current study is restricted by the limited number of diseases (882 diseases) in the GWAS catalog, even though TreatKB includes 24,511 diseases and their drug treatments. With new studies being continually added to the GWAS catalog, additional drug repositioning opportunities will arise through human genetic analysis. Additionally, disease genetics from rare Mendelian disorders represents another valuable source of novel drug targets [31]. Another rich resource of human disease genetics is computation-based candidate disease genetics discovery. We recently showed that computationally-predicted disease genetics can lead to novel drug discovery [21-22].
Top genetic pathways targeted by repositioned candidate drugs

Figure 6: Top fifteen pathways targeted by top 124 (top 5%) repositioned candidate drugs.

A comprehensive prediction system, additional data resources such as disease phenotypes, gene expression, drug side effects, and chemical structures can be incorporated into GenoPredict to further improve the performance.

Abstract

Psoriasis is a chronic, debilitating skin condition that affects approximately 125 million individuals worldwide. The cause of psoriasis appears multifactorial, and no unified mitigating signal or single antigenic target has been identified to date. Metabolomic studies hold great potential for explaining disease mechanism, facilitating early diagnosis, and identifying potential therapeutic areas. Here, we present an integrated disease metabolomic biomarker discovery strategy that combines mechanism-based biomarker discovery with clinical sample-based metabolomic profiling. We applied this strategy in identifying and understanding metabolite biomarkers for psoriasis. The key innovation of our strategy is a novel mechanism-based metabolite prediction system, mmPredict, which assimilates vast amounts of existing knowledge of diseases and metabolites. mmPredict first constructed a psoriasis-specific mouse mutational phenotype profile. It then constructed phenotype profiles for a total of 259,170 chemicals/metabolites using known chemical genetics and human metabolomic data. Metabolites were then prioritized based on the phenotypic similarities between disease- and metabolites. We evaluated mmPredict using 150 metabolites identified using our in-house metabolome profiling study of psoriasis patient samples. mmPredict found 96 of the 150 metabolites and ranked them highly (recall: 0.64, mean ranking: 8.73%, median ranking: 2.33%, p-value: 4.75E-44). These results show that mmPredict is consistent with, as well as a complement to, traditional human metabolomic profiling studies. We then developed a strategy to combine outputs from both systems and found that the oxidative product of linoleic acid, 13(S)-hydroxy-9Z,11E-octadecadienoic acid (13-HODE), ranked highly by both mmPredict and our in-house experiments. Our integrated analysis indicates that 13-HODE may be a mechanistic link between psoriasis and cardiovascular comorbidities associated with psoriasis. In summary, we developed an integrated metabolomic prediction system that combines both human metabolomic studies and mechanism-based prediction and demonstrated its application in the skin disease psoriasis. Our system is highly general and can be applied to other diseases when patient-based metabolomic profiling data becomes more increasingly available.

Data is publicly available at: http://nlp.case.edu/public/data/mmPredict_PSO

1. Introduction

The prevalence of skin disease exceeds those of obesity, hypertension or cancer. One in three Americans suffers from a skin disease, and ~2-3% of these individuals have psoriasis. Costs of treating psoriasis patients are believed to exceed $1B, including over $350M in prescriptions alone [1-4]. The pathophysiology of psoriasis is complex, and no unified mitigating signal or single antigenic target has been identified.

Human metabolomics is the comprehensive characterization of all metabolites found in the human body. Human metabolomics has great potential for explaining disease mechanism, facilitating early diagnosis, and identifying potential therapeutic areas. Common technologies for metabolomics include mass spectrometry (MS) and nuclear magnetic resonance spectroscopy (NMR) [5-6]. Human metabolites are highly heterogeneous. The Human Metabolome Database (HMDB), a comprehensive database of small molecule metabolites found in the human body, contains 42,032 metabolites of lipids, small peptides, amino acids, organic acids, vitamins, carbohydrates, nucleic acids, as well as metabolites derived from drugs, environmental contaminants, food additives, toxins, cosmetics, and other xenobiotics such as microbial or fungal symbionts [7]. Profiling the human metabolome is difficult owing to the challenges of reproducibility and knowledge generalization, as the human metabolome is affected by not only intrinsic but also many extrinsic factors such as sample collection, storage, processing and data analysis [8]. The NIH Common Fund Metabolomics Program was launched in 2012 with a primary goal to increase the national capacity to conduct metabolomics research [9]. Currently, the NIH Metabolomics Workbench Metabolite Database
We evaluated mmPredict using 150 metabolites identified by comparing involved tissue from psoriasis patients to components and five data resources. mmPredict: a combined genome- and phenome-wide metabolite prediction system, including three

Fig 1: (MWMD) contains metabolomics studies for a very limited number of diseases [10]. While current metabolomics profiling strategies can identify clinically significant metabolite biomarkers, it is limited in understanding the underlying mechanistic links between identified metabolites and diseases.

Here, we present a novel mechanism-based metabolomic biomarker discovery system, mmPredict, to complement current patient-based metabolomic profiling studies. We developed an approach to combine outputs from these two complementary strategies and demonstrate its utility in the clinical skin disease psoriasis. The output of this integrated system is a ranked list of metabolomic biomarkers that incorporate both clinical significance and interpretable molecular mechanisms. mmPredict integrates large amounts of data from human disease genetics, chemical genetics, mouse mutational phenomics, human metabolomics, and genetic pathways in order to predict disease metabolomic biomarkers. The underlying rationale for mmPredict is that, if the changes in metabolite-associated genes cause many phenotypes (reflected in mouse models) that are also involved in any given disease (psoriasis in this study), then the metabolite is likely to be involved mechanistically in the disease. In order to test the validity of mmPredict to traditional metabolomic profiling, we compared the output of mmPredict to our in-house metabolomic profile. Our in-house psoriasis metabolome was identified using a traditional metabolomics comparison study of skin samples obtained from the involved plaques of psoriasis patients (n=12) compared to skin samples obtained from age-matched healthy control subjects (n=9) and identified 150 significantly altered metabolites. mmPredict highly ranked psoriasis metabolites identified from our in-house metabolomic profiling study, indicating that these two strategies are consistent with, as well as complementary to, each other. We then developed a strategy to combine outputs from these two complementary strategies and identified psoriasis-associated metabolite biomarkers likely to have both mechanistic and clinical significance.

mmPredict performs both genome- and phenome-wide matching between metabolites and diseases. We compared mmPredict to a genome-wide- strategy that we recently developed to identify human gut microbial metabolite biomarkers for colorectal cancer (CRC) [11] as well as Alzheimer’s disease [12]. We demonstrated in this study that mmPredict is more effective in identifying clinically relevant metabolite biomarker for psoriasis than the genome-wide approach.

2. Data and methods

2.0 The overview of mmPredict

mmPredict matches psoriasis metabolites based on both genetic and phenotypic relevance. mmPredict consists of the following components: (1) mmPredict constructs mouse mutational phenotype profiles for a given disease (psoriasis in this study) using publicly available disease genetics and genomics databases; (2) it constructs mouse mutational phenotype profiles for a total of 259,170 chemicals/metabolites; (3) mmPredict prioritizes metabolites for a given disease based on the phenotype profile similarities between the disease and metabolites (Fig. 1).

![Fig 1: mmPredict: a combined genome- and phenome-wide metabolite prediction system, including three components and five data resources.](image)

We evaluated mmPredict using 150 metabolites identified by comparing involved tissue from psoriasis patients to healthy control skin in our in-house metabolomic study. We developed an approach to combine predictions from mmPredict and from our in-house metabolomic study to identify metabolites likely to have both clinical and mechanistic significance.
For comparison, we implemented a genome-wide metabolite prediction system mmPredict_Gen. The underlying assumption is that if a metabolite is associated with many psoriasis-associated genes, then the metabolite may be associated with the mechanism(s) causing psoriasis. We have previously applied this strategy to identify human gut microbial metabolites associated with colorectal cancer [11] as well as Alzheimer’s disease [12]. The difference between mmPredict and mmPredict_Gen is that mmPredict utilizes both genome- and phenome-wide information, while mmPredict_Gen prioritizes metabolites for diseases based on genetic profile similarities (Fig 2). We demonstrated in our study that mmPredict performed consistently better than mmPredict_Gen.

Fig 2: mmPredict_Gen: a genome-wide metabolite prediction system (five data resources are shown).

2.1 Data
We used the disease phenotype knowledge bases that we recently constructed, as well as publicly available data from the human metabolome, disease genetics, chemical genetics, functional protein interactions and signaling pathway databases to identify metabolites associated with psoriasis and its’ comorbidities.

2.1.1 Disease genetics and genomics data
We used two complementary databases to obtain genes associated with psoriasis. We identified 49 genes associated with common complex forms of psoriasis from the Catalog of Published Genome-Wide Association Studies (GWAS catalog), an exhaustive source containing descriptions of disease/trait-associated single nucleotide polymorphisms (SNPs) from published GWAS studies [13]. We identified 35 genes associated with rare Mendelian forms of psoriasis from the Online Mendelian Inheritance in Man (OMIM) database, the most comprehensive source of disease genetics for Mendelian disorders [14]. We used these two complementary resources of disease genetics to demonstrate the robustness of our algorithms and findings.

2.1.1 The Human Metabolome Database (HMDB)
HMDB is intended for applications in metabolomics, biomarker discovery and other applications and contains detailed information regarding small molecule metabolites found in the human body [7]. Currently, HMDB is the most comprehensive collection of metabolite data, containing 42,032 metabolites. We used HMDB to obtain a list of metabolites found in the human body.

2.1.2 Chemical genetics data
We used the STITCH (Search Tool for Interactions of Chemicals) database [15] to obtain chemical/metabolite-gene associations. We used chemical-gene associations found in the human body (1,466,636 chemical-gene pairs for 259,171 chemicals and 15,620 genes) and metabolites from HMDB to link human metabolites to human genes.

2.1.4 Genome-wide mutational phenotypes in experimental mouse models
We used gene-phenotype associations from the Mous e Genome Database (MGD) [16] to assess the phenotypic effects of metabolites. The Phenotypes/Alleles project in the MGD provides access to spontaneous, induced, and genetically engineered mutations and their specific phenotypic outcomes. Currently, MGD contains 278,553 gene-phenotype associations, representing 41,905 mutant alleles and 10,744 phenotypes. For example, the mutation of 13-HODE-associated gene myeloperoxidase (MPO) in mouse models is associated with 12 phenotypes, including ‘decreased inflammatory response,’ ‘atherosclerotic lesions’ and ‘increased monocyte cell number.’ The mutation of psoriasis-associated gene TRAF3 interacting protein 2 (TRAF3IP2) is associated with 80 phenotypes including ‘decreased inflammatory response,’ ‘increased pruritus,’ and ‘increased monocyte cell number.’ We have recently shown that systematic approaches to interrogate human genes to their mouse mutational phenotypes in MGD have
great potential in understanding both disease mechanisms and drug effects [17-19]. In this study, we leveraged the large number of gene-phenotype associations from MGD and performed genome- and phenome-wide analysis to infer phenotypic effects of metabolites on disease.

2.2 Methods

2.2.1 Construct mouse mutation phenotype profiles for input disease

We identified 35 psoriasis-associated genes from the OMIM database and 49 psoriasis-associated genes from the GWAS Catalog. We mapped these genes to their corresponding mouse gene homologs (e.g., TRAF3IP2 => Traf3ip2) using human-mouse homolog mapping data from the Mouse Genome Database (MGD) [16]. The mapped mouse genes were then linked to their corresponding mutational phenotypes (e.g., knockout) in mouse models (e.g., Traf3ip2 => 'increased pruritus') using gene-phenotype association data from MGD. For each mapped phenotype, we assessed its probability of being associated with the given set of genes (e.g., the phenotype “increased pruritus” is associated with 10 of the 49 psoriasis genes) as compared to its probability associated with the same number of randomly selected genes (e.g., the phenotype “increased pruritus” is on average associated with 0.5 of 49 randomly selected genes). The random process is repeated 1000 times and a t-test was used to assess the statistical significance.

2.2.2 Construct mutational phenotype profiles for chemicals

We built phenotype profiles for 259,170 chemicals/metabolites from the STITCH database in the same manner as described above (e.g., 13-HODE => MPO =>Mpo => 'increased monocyte cell number').

2.2.3 Prioritize metabolites for psoriasis and test the performance using in-house metabolomics study

Metabolite prioritization

We calculated the phenotypic similarity of psoriasis and metabolites. We compared four different approaches in calculating the similarities, including cosine similarity, overlap, Jaccard similarity [20], and ontology-based semantic similarity [17-19, 21]. We showed that ranking based on Jaccard similarity performed consistently better than the other three similarity measures used in this study. Therefore, throughout this study, the metabolite ranking values are based on the Jaccard similarity.

Evaluation of recall and ranking

We evaluated mmPredict in identifying and prioritizing metabolite biomarkers for psoriasis using our in-house metabolome study. We identified 150 significantly altered metabolites by comparing global metabolic profiles in skin samples from normal control subjects (n=9) and age matched psoriasis patient involved psoriasis plaques (n=12). We evaluated the algorithm for both identifying and ranking known metabolites using recall, mean ranking, and median rankings. Random expectation that the metabolites would have an average ranking of 50% was used to evaluate the significance of these rankings.

Evaluation of prioritization (precision-recall curve)

We evaluate mmPredict using an 11-point interpolated average precision measure, which is commonly used to evaluate retrieved ranked lists for search engines [22]. For each ranked list, the interpolated precision was measured at the 11 recall levels of 0.0, 0.1, 0.2, ..., 1.0. At each recall level, we calculated the arithmetic mean of the interpolated precision. A composite precision-recall curve showing 11 points was then graphed.

2.2.4 Develop a strategy to combine outputs from mmPredict and patient-based metabolomics profiling

We developed an approach to combine rankings from mmPredict and fold changes from the clinical metabolomic study. The output of mmPredict is a list of metabolites ranked by their percent ranking (“ranking_m”). For example, 13-HODE ranked at the top 0.23% among 259,170 chemicals. We then ranked the 150 in-house metabolites by their fold changes and calculated their percent ranking (“ranking_c”) among all metabolites. For example, 13-HODE was ranked at the top 0.67% (top one) among the 150 in-house generated metabolites. The combined ranking is a balance measure of rankings from both studies and is defined as: ranking_combined = 2*(ranking_m* ranking_c)/(ranking_m + ranking_c). We studied the top one ranked metabolite by performing both genetic pathway enrichment and mutational phenotype enrichment analyses.

3. Results

3.1. Understanding psoriasis genetics, genomics, and phenomics

We used mmPredict to perform both genome- and phenome-wide analyses to prioritize metabolites for psoriasis. To understand both genetic and phenotypic implications of psoriasis-associations genes, we began our study using Ingenuity Pathway Analysis (IPA) [23] to examine the top canonical pathways generated by searching for either rare
Mendelian psoriasis genes or common complex psoriasis genes. As shown in Table 1, the top diseases and biological functions identified dermatological diseases and conditions, with immunological and inflammatory response also being identified. Common cellular response pathways and cells (e.g., dendritic cells and janus activated kinase (JAK) signaling) as well as other skin and immunologically prominent diseases (e.g., graft versus host disease (GVHD), Rheumatoid Arthritis (RA) and Diabetes Mellitus (DM)) were also identified.

Table 2 outlines the top 10 phenotypes associated with psoriasis genes identified through either the OMIM or GWAS databases. As shown in the table, the top phenotypes are enriched for immune-response and skin-related phenotypes, confirming the observational and experimental data supporting psoriasis as a predominantly immune-mediated autoimmune disorder. Both genetic pathway enrichment and mutational phenotype enrichment analyses provided the rationale underlying mmPredict’s combined genome- and phenome-wide analysis. As shown in the following sections, genome-wide prioritization is not as effective as the combined approach.

3.2. mmPredict ranked clinically derived psoriasis-associated metabolites highly

The output of mmPredict is a ranked list of 259,170 chemicals. We also filtered the list of chemicals from HMDB by their origins. In HMDB, metabolites are classified based on their origins, such as “endogenous”, “food”, “microbial”, “drug”, “plant”, and “toxin/pollutant”. Only 4,057 of the 259,170 chemicals appeared in HMDB, including 2,067 endogenous metabolites. We evaluated the performance of mmPredict using the 150 clinically derived metabolites. As shown in Table 3, mmPredict found 96 of these 150 metabolites (recall: 0.64) and consistently ranked them highly for both the Mendelian form of psoriasis (mean ranking based on Jaccard similarity: 8.73%, median ranking based on Jaccard similarity: 2.33%, p-value: 4.75E-44) and common complex form of psoriasis (mean ranking based on Jaccard similarity: 9.08%, median ranking based on Jaccard similarity: 2.39%, p-
value: 1.35E-42). After filtering the chemicals by metabolites from HMDB, the rankings are still significantly higher than random expectation. However, the recall are lower, indicating that the list of chemicals from the STITCH database represents a more complete list of metabolites found in the human body than the list of metabolites from HMDB.

| Metabolite source | Psoriasis genetics | Recall | Mean Ranking | Median Ranking | P-value  
|-------------------|--------------------|--------|--------------|---------------|----------
| STITCH (259,170 chemicals) | OMIM | 0.64 | 8.73% | 2.33% | 4.75E-44 |
|                   | GWAS | 0.64 | 9.08% | 2.39% | 1.35E-42 |
| HMDB (4057 metabolites) | OMIM | 0.41 | 22.36% | 14.03% | 8.54E-13 |
|                   | GWAS | 0.41 | 23.25% | 14.56% | 8.54E-13 |
| HMDB (2067 endogeneous metabolites) | OMIM | 0.34 | 19.27% | 11.67% | 2.64E-14 |
|                   | GWAS | 0.34 | 20.42% | 12.63% | 2.16E-13 |

Table 3. Evaluation of mmPredict with 150 clinically derived psoriasis metabolites. The ranking was based on Jaccard similarity.

For comparison, we show in Table 4 that genome-wide prioritization alone is less effective than the combined genome- and phenome-wide implementation of mmPredict. mmPredict has consistently better mean and median rankings than mmPredict_Gene across three metabolites data resources.

| Metabolite source | Psoriasis genetics | Recall | Mean Ranking | Median Ranking | P-value  
|-------------------|--------------------|--------|--------------|---------------|----------
| STITCH (259,170 chemicals) | OMIM | 0.64 | 46.55% | 53.55% | 0.309 |
|                   | GWAS | 0.64 | 42.50% | 37.92% | 0.039 |
| HMDB (4057 metabolites) | OMIM | 0.40 | 44.24% | 45.42% | 0.184 |
|                   | GWAS | 0.40 | 39.21% | 40.46% | 0.008 |
| HMDB (2067 endogeneous metabolites) | OMIM | 0.34 | 39.84% | 36.64% | 0.024 |
|                   | GWAS | 0.34 | 35.09% | 30.93% | 0.001 |

Table 4. Evaluation of mmPredict_Gen with 150 psoriasis metabolites. The ranking was based on Jaccard similarity.

We further show in the plotted 11-point interpolated precision-recall curve that mmPredict is effective in enriching clinically derived psoriatic metabolites at 11 recall cutoffs (Fig. 3). At a recall level of 0.1, the mean precision of the metabolites is 0.156, which represents a 524% enrichment as compared to the precision of 0.025 for all metabolites (recall = 1.0). These results indicate that mmPredict enriched clinically identified metabolites among the top and its predictions are consistent with patient-based metabolomic profiling. The precision was calculated using the clinically derived metabolites and does not represent the true precision measure of mmPredict. The low values of the precision (e.g., 0.156 at recall of 0.1) indicate that many more metabolites are to be discovered and that mmPredict can complement patient-based profiling in identifying metabolites not captured in our in-house metabolomic study.
3.2. 13-HODE represents a metabolite biomarker mechanistically linking psoriasis to its cardiovascular comorbidities

mmPredict represents a mechanism-based approach to identify metabolites for psoriasis. Our in-house metabolomics study represents a standard approach to identify altered metabolites in psoriasis patients. Our combined scores from these two complementary studies identified 13-HODE as the highest ranked metabolite, indicating that this metabolite may be involved in psoriasis at both mechanistic and clinical levels. To understand how 13-HODE is mechanistically linked to psoriasis, we identified a total of 78 13-HODE-associated genes from the STITCH database. We performed pathway enrichment analysis using Ingenuity Pathway Analysis (IPA) to examine the top canonical pathways associated with 13-HODE. The top five canonical pathways identified by IPA are Atherosclerosis Signaling, Eicosanoid Signaling, Glutathione Redox Reactions I, Bupropion Degradation, and Acetone degradation I. The top five diseases and biofunctions are Organismal Injury and Abnormalities, Cardiovascular Disease, Gastrointestinal Disease, Inflammatory Disease, and Inflammatory Response. The pathway enrichment analysis shows that 13-HODE is involved in inflammatory response and cardiovascular diseases, common linkages associated with human psoriasis.

We then investigated the phenotypic effects of 13-HODE-associated genes by interrogating the associations of mouse phenotypes with mutations of HODE-associated genes. We identified a total of 1,214 phenotypes associated with mutations of the 78 13-HODE-associated genes. As shown in Table 5, the top ranked phenotypes associated with mutations of 13-HODE associated genes are clearly related to cardiovascular disease, immune response and abnormal skin morphology and function. These results indicate that 13-HODE may be mechanistically involved in both psoriasis and its' cardiovascular comorbidities.

Table 5. Top-ranked phenotypes related to CVD, immune system dysfunction, and abnormal skin morphology and function, and their rankings among all 1,214 HODE mutation-associated phenotypes.
We also categorized the 13-HODE-associated phenotypes (1,214 phenotypes were classified into 54 classes) and analyzed which phenotype categories are highly associated with HODE (the top 11 HODE-associated phenotype classes are shown in Fig. 4). Classes we found relevant to psoriasis and comorbidities include: 1) abnormal hematopoietic system (9.2% of all phenotypes), 2) abnormal skin morphology (5.0% of all phenotypes), 3) abnormal immune system (5.0% of all phenotypes), 4) abnormal cardiovascular system morphology (5.0%), and 5) abnormal cardiovascular system physiology (4.1%). Another skin-related class, abnormal skin adnexa morphology also ranked highly (3.3%). These results suggest that HODE may be a biomarker linking remote inflammation observed in the skin with cardiovascular diseases, immune system activation, and psoriasis.

Fig. 4: Top-ranked phenotype classes related to CVD (green), immune system dysfunction (blue), and abnormal skin morphology and function (azure).

Discussion and conclusions
We present a novel mechanism-based metabolomic biomarker discovery system, mmPredict, to complement current patient-based metabolomics profiling studies. We developed an approach to combine outputs from these two complementary strategies and demonstrated its utility in the human clinical disease psoriasis. The identification of metabolomic biomarkers and the understanding of their roles in psoriasis and psoriasis-related co-morbidities may provide insight into the basic mechanisms of psoriasis pathogenesis and enable new possibilities for psoriasis diagnosis, prevention, and treatment.

Both mmPredict and our strategy of combining these two complementary strategies for use in studying human metabolomics are general. We demonstrated its utility in psoriasis since we have performed in-house human metabolomic profiling on psoriasis patient and healthy control skin samples. We expect that mmPredict would be equally effective in identifying metabolite biomarkers for other diseases, albeit alternative sources of protein metabolites, such as serum or plasma may be necessary. However, to fully evaluate mmPredict and our integrated strategy in other diseases will require the gold standard of known disease-associated metabolite biomarkers, which are currently lacking due to the paucity of published disease specific metabolomic data. With the vast amounts of knowledge built into mmPredict, the only input needed for the system is a list of genes, therefore we expect that mmPredict can be applied to identify metabolite signatures unique for disease subtypes, disease progression, as well as treatment response given that the involved genes are available.

Computational algorithm design critically depends on the data incorporated into the system. In this study, we integrated disease genetics data with human metabolomics, chemical genetics, genetic pathways, and mouse mutational phenotypes. Our study shows that combined genome-phenome approach performed significantly better than the genome approach alone, indicating interrogating human genes to their functional effects on disease-specific phenotypes has major contribution in the improved performance. Currently, we are further improving mmPredict by incorporating other types of data, including higher-level disease and drug phenotypic data observed in humans.

Author’s contributions
QW and RX have jointly conceived, designed and implemented the algorithms, performed data analysis and algorithm evaluation, and prepared the manuscript. The metabolomics study was performed by TSM, KDC and NW. All authors read, edited and approved the final manuscript.

Abstract  
As genomic data are usually at large scale and highly sensitive, it is essential to enable both efficient and secure analysis, by which the data owner can securely delegate both computation and storage on untrusted public cloud. Counting query of genotypes is a basic function for many downstream applications in biomedical research (e.g., computing allele frequency, calculating chi-squared statistics, etc.). Previous solutions show promise on secure counting of outsourced data but the efficiency is still a big limitation for real world applications. In this paper, we propose a novel hybrid solution to combine a rigorous theoretical model (homomorphic encryption) and the latest hardware-based infrastructure (i.e., Software Guard Extensions) to speed up the computation while preserving the privacy of both data owners and data users. Our results demonstrated efficiency by using the real data from the personal genome project.

Introduction  
Due to the advancement of genome sequencing technology, the cost of generating genomic data has been reduced significantly. The increasing collection of genomic data might contribute to the research in various ways, e.g., discovering innovative treatments, improving healthcare, and facilitating resources for biomedical research\cite{1}. For example, genome-wide association studies (GWASs)\cite{2} aims to identify the association relationship between single-nucleotide variants or polymorphisms (SNPs) with some specific disease/phenotype. On the other hand, the scale and size of genomic data that are being collected also raise challenges in storing and processing them\cite{3}. The cloud computing\cite{4} provides an elastic solution with on-demand computation ability and flexible storage. But the sensitivity of genomic data make the privacy a major concern to outsource genome data on a remote cloud service\cite{5}.

Existing studies have shown that it is possible to recover sensitive individual information, such as personal identity\cite{6,7}, disease condition\cite{8-10}, facial appearance\cite{11} through human genome data. As we know, genomic data are also shared among blood relatives, there will be extended impacts on the whole family\cite{12,13}, if the genomic data of a single family member are disclosed inappropriately. According to Lin and Altman’s study\cite{14}, as few as 75 independent SNPs would be sufficient to re-identify an individual. Sweeney\textit{et al.}\cite{7} published a study to show that the demographic information of a large percent of participants in the Personal Genome Project (PGP) can be linked to publicly available records. Another study by Gymrek showed that even the surname of participants in a “de-identified” database (1000 genome project) could be inferred using a genealogy database and some short tandem repeats on Y-chromosome\cite{8}. Even aggregated statistics\cite{9,15,16} like allele frequency and test statistics can leak sensitive personal information. Homer’s attack\cite{9} and the log likelihood ratio attack\cite{15} are two well-known attack models, which shows statistical power to infer the membership of individuals in a case group (i.e., with certain disease). Most recently, Shringarpure and Bustamante\cite{17} showed the vulnerability of the genomic data sharing Beacon project\cite{17}, which is designed to share only the existence of variants across multiple databases. More specifically, through accumulated queries of a Beacon database, Shringarpure et al.\cite{17} designed a method to learn if a vulnerable patient may be included in the database. Given the knowledge of rare allele, Raisaro\textit{et al.}\cite{18} further improve the attack power for Beacon database, where the enhanced attack requires much less number of queries than that of the Shringarpure’s model.

Previous studies have demonstrated many risk factors in directly sharing human genomic data. To mitigate the privacy/security dilemma when outsourcing or disseminating genomic data for research studies, several protection technologies been proposed\cite{19}, such as differential privacy (DP)\cite{20,21}, Homomorphic encryption (HME)\cite{22} and Secure multiparty computation (SMC)\cite{23,24}. DP protects sensitive information through adding perturbation on the private data. Existing studies showed that DP based protection methods\cite{21,25} did not scale well to tackle high dimensional genomic data. HME method\cite{22} is an innovative cryptographic solution, which allows certain computations (e.g., addition and multiplication) to be carried on encrypted data directly and also generates encrypted outcomes. After decryption, the corresponding plaintexts of encrypted results will exactly match the results operated directly on original inputs.
without encryption. Built upon HME, researchers can delegate secure computation on an untrusted environment\textsuperscript{26} (e.g., public cloud services), where they can produce encrypted computation with encrypted results, without revealing their sensitive inputs. During the past few years, the efficiency and capability of HME have been significantly improved\textsuperscript{27-30}. Secure multiparty computation (SMC)\textsuperscript{23,31-33} is another widely used privacy-preserving computing techniques which establish interfaces for multiple parties to jointly compute functions over their own inputs without knowing others’. SMC is widely adopted to safeguard federated studies with sensitive data across multiple institutions\textsuperscript{34,35}. Many HME-based or SMC based privacy-preserving computing applications been proposed, for instance safeguarding machine learning on HME scheme\textsuperscript{36,37}, Homomorphic Computation of Edit Distance\textsuperscript{38,39}, Private predictive analysis on encrypted medical data\textsuperscript{37}, exact logistic regression for GWAS research\textsuperscript{30}, secure multiparty GWAS\textsuperscript{34,35,40-42}, secure distributed regression model learning \textsuperscript{33} etc.. However, current HME and SMC techniques still have challenges with sharply increased computation complexity when the dataset increases in size. For the large-scale genomic dataset, the performance overhead is not negligible and it is the critical problem limiting the design and implement for secure and privacy-preserving cloud genomic computing platform.

Another solution for secure outsourcing computation called “Software Guard Extension (SGX)\textsuperscript{43}” is made available very recently. There is a hardware protected secure region (so called “Enclave”) on Skylake or higher generation CPUs released by the Intel to provide security and integrity on an untrusted host, where privileged modules (e.g., operating system, virtual machine scheduler, etc.) might be potentially malicious\textsuperscript{44}. This approach provides an alternative way to protect private secrets on untrusted hosts through the “enclave” architecture\textsuperscript{45}. Private codes, sensitive data, and other secrets can be stored within enclaves and sealed outside enclave at any time. The access of secrets within enclaves are highly restricted by hardware access control (i.e., using a different instruction set from the main CPU) so that only authorized code has the privilege to access secrets within enclaves. This has attracted the attentions of many researchers recently, who conducted several related works on privacy-preserving cloud computation\textsuperscript{45-47}, multi-party collaboration for disease analysis\textsuperscript{48}, ancestry analysis\textsuperscript{49} secure logger for medical devices \textsuperscript{50} Those research outcomes demonstrated the feasibility of this alternative solution for outsourcing secure genomic computation. Thanks to its optimized hardware design, SGX can provide efficient computation and shows good promise on dealing with large scale genomic datasets.

But SGX still has many limitations as a new technology, which takes time to become mature and gain wider acceptance. One practical problem is that it only provides limited enclave space, large data cannot fit into that will have to be split and sealed outside enclave (encrypted and stored outside) to be processed in batches. Depending on the nature of the task, the process might need careful engineering to ensure optimal performance and meet high security guarantee. Another potential problem is that there are concerns about information leakage in SGX due to the side channel attack\textsuperscript{51}, cache timing attack\textsuperscript{42}, etc. Therefore, additional protections on top of SGX are still required to mitigate above concerns. Another issue is that most healthcare centers have not deployed SGX-enabled servers and models requiring mutual hardware trust are not yet practical.

Inspired by the idea of secret sharing\textsuperscript{52}, we developed a hybrid framework in this paper, which can distribute sensitive information between SGX and HME to achieve a better protection in an untrusted environment. More specifically, we mainly target on the secure count query of genomic data on untrusted hosts, which takes advantages of both HME and SGX techniques. The main contributions of our proposed hybrid methods are as follows:

- We present the first design of hybrid privacy-preserving framework that combines SGX and HME together to facilitate outsourced secure and efficient genomic count query operations.
- We proposed an innovative data provisioning method that split single genomic dataset into an encrypted index tree structure data within SGX enclave and a sealed record data of tree node counts outside the enclave. The query execution will be carried out within enclave through traversing the index tree structure and checking whether a query matches some specific branches. The addition for aggregating actual counts of the query is done outside enclave over the homomorphically encrypted count records via the Paillier cryptosystem\textsuperscript{53}.
- We proposed the dynamical HME key pair generation and exchange schemes incorporate with SGX techniques, which guaranteed the security and integrity of private paillier keys.
- Our proposed hybrid platform has been evaluated over real data from the Personal Genome Project \textsuperscript{54}, and experimental results demonstrated efficiency advantage of our proposed HME and SGX hybrid framework over the existing solution \textsuperscript{55}.

**Methods**

In this section, we present the proposed SCOTCH framework for securely executing count query on genomic data by
using the combined model of HME and Intel SGX. Figure 1 provides an overview of the proposed SCOTCH framework. Our framework is optimized for the dual objective of security and efficiency. Our secure model consists of four roles, including, Data Owner (DO), Authentication Service Provider (ASP), Cloud Service Provider (CSP) and authorized researchers (Researchers). Each interactor is responsible for performing different transactions to contribute the overall platform secure and functional. The interactors are discussed as follow:

**Figure 1:** The overview of the proposed SCOTCH framework

- **Authentication Service Provider (ASP):** A trusted entity, which can authenticate (1) data owner to securely outsource their sensitive and private data to a public cloud, (2) authorized researchers to initiate data analysis query and to securely receive the final results, and (3) the secure enclave that is running on the SGX-enabled hardware hosted by an untrusted Cloud Service Provider.

- **Cloud Service Provider (CSP):** An untrusted entity, which can communicate with all the other entities. It provides securely outsourced storage of encrypted genomic data from the data owner. Based a hybrid strategy using HME and SGX, the CSP will securely evaluate the encrypted query from an authorized researcher against the encrypted data from the data owner to obtain the encrypted final results.

- **Authorized Researchers (Researchers):** Individuals who have been granted the permission by the ASP to execute a query (i.e., the counts of multiple alleles of a genomic database). An authorized researcher sends the query to the CSP and receive encrypted results based on data from certain data owner.

- **Data Owners (DO):** Institutions or hospitals that possess databases upon which would like to outsource both storage and computation on the public cloud and allow authorized researcher to perform queries.

In our design, the framework workflow (see Figure 2) contains three major steps: Key Distribution, Data Provisioning, and Secure Query Execution. Key distribution is responsible for exchanging the HME encryption keys among CSP, DO and authorized researchers, DO will secure pack their private genomic data and upload to CSP through data provisioning, and the Query Execution presents the detail flow of how researchers execute secure query on CSP and count the results. In the remaining part of this section, we will elaborate our approach in detail.

**Step 1. Key Distribution.** A remote attestation procedure is required between ASP and CSP to create a trusted enclave environment. Using remote attestation, CSP can provide the evidences to other entities to prove its integrity and authenticities through the ASP. Only when CSP confirmed its identity and verified that it is running on a genuine SGX-enabled platform, DO or researcher can safely provisioning data or issue genetic query execution on CSP, respectively. After the trusted enclave is created, CSP generates pair of paillier cryptosystem keys within the enclave, the public key $k_{pub}$ will be distributed to DO and Researcher for further encryption of genomic data and queries. For the corresponding private key $k_{priv}$, it will be kept within the enclave, or could be sealed outside the enclave for long term storage purpose. The private key $k_{priv}$ can only be accessed by authorized codes within enclave. The hardware instructions in SGX will prevent malicious attempts from accessing $k_{priv}$.

**Step 2. Data Provisioning.** After the Key Distribution Stage, the CSP has been attested by ASP, and the public key $k_{pub}$ for encryption has already been disseminated to DO and Researcher. Then we can step to the data provisioning stage, which is used for preparing secure genetic dataset on CSP and enabling secure access interface to its users and owners. We assume that the DO hold the private genetic dataset in Single Nucleotide Polymorphism (SNP) sequences
format (see Table 1 as an example). Let us denote by $G = (s_1, s_2, s_3, ..., s_n)$ the genomic dataset held by a DO, where $s_i \in G$ represents the SNP sequence for the $i$-th individual in the dataset, denoted by $s_i = (a_1, a_2, a_3, ..., a_k, p)$, where an element $a_k$ represents a genotype at the $k$-th location, and the last element $p$ indicates whether the individual is associated to a specific disease, like cancer, as shown in Table 1, where each row corresponding to $s_i \in G$, and the columns in table corresponds to each element of $s_i$.

DO first parses its genomic dataset and builds an index tree using their data. We will build the index tree using the technique introduced in our previous work. Let us denote by $T = (n_1, n_2, ..., n_m)$ the index tree with $m$ nodes, where $n_j \in T$ is the $j$-th node in the tree, and each node is encoded as $n_j = (\text{index}, \text{sid}, \text{val}, \text{count}, \text{list})$, where the index is a unique ID for the node assigned by the Breadth-first search (BFS) traversal order. In addition, sid is the level/depth of the node in the tree, which corresponds to the location of each SNP and can be used to indicate the exact position that this SNP occurs in a query. Furthermore, val indicates the actual SNP which is encoded by a 4-bit vector to cover all possible SNP pairs. The element count is the times of the corresponding SNP occurs in the current position (sid) in the dataset. Finally, the variable list records the index to all children nodes of the current nodes. An example of the index tree for Table 1 is shown in Figure 3. The tree starts with a root node, and all genomic sequences are derived from root node.
Figure 3. An illustrative example of an Index Tree for genomic data from 5 individuals as shown in Table 1. In practice, since not all individuals have a unique SNP combination, the count (encrypted by HME) cannot be predicted directly from the tree structure.

Once DO completed the tree building process, DO extracts the count for each node $n_j$ denoted as $c_j$, then encrypts $c_j$ with the received key $k_{pub}$. Here, let us denote by $c^E_i$ the encrypted count such that $C^E = \{c^E_i \mid i \in \{1, 2, 3, ..., m\}\}$ represents all the encrypted counts. Then, we remove all the counts from the generated index tree (as shown in Figure 3) and only keep the structure information. The structure tree is then encrypted by $k_{pub}$ which is denoted by $T^E$. Finally, two encrypted data $C^E$ and $T^E$ will be uploaded to CSP for both storage and computation outsourcing.

Step 3. Secure Query Execution. After DO completes the data provisioning process, the Researchers can request query execution on the CSP. Our framework supports SQL like search query, which means researchers can use the search query as follows:

```
SELECT count(*) FROM GENDATABASE WHERE
pos_1 = SNP_1 AND pos_2 = SNP_2 AND pos_3 = SNP_3 .... AND pos_i = SNP_i, AND cancer = T/F.
```

The SQL like query will be wrapped into a query vector $q$ followed by an encryption. In addition, the encryption process will only encrypt the SNP values in the query $q$ by using the public key $k_{pub}$, where we consider the position information is public. The vector query and its encryption format are denoted as follows:

$q = \langle <\text{pos}_1, \text{SNP}_1>>, <\text{pos}_2, \text{SNP}_2>>, <\text{pos}_3, \text{SNP}_3>>, ..., <\text{pos}_i, \text{SNP}_i>>, <\text{cancer}, \text{T/F}>\rangle$

$q^E = \langle <\text{pos}_1, \text{SNP}_1^E>>, <\text{pos}_2, \text{SNP}_2^E>>, <\text{pos}_3, \text{SNP}_3^E>>, ..., <\text{pos}_i, \text{SNP}_i^E>>, <\text{cancer}, (\text{T/F})^E>>\rangle$

After receiving an encrypted query $q^E$ from the researcher, the CSP will pass $q^E$ into enclave, in the meantime, CSP will also load $T^E$ into its enclave space. Within the enclave, both encrypted query $q^E$ and encrypted index tree structure $T^E$ are decrypted using the private key $k_{priv}$ to get the plaintext query $q$, $T$. Query search is then executed on the enclave. Algorithm 1 presents the details of query algorithm within the secure enclave. The inputs for this algorithm are the search query and the index tree structure. The algorithm starts with an empty list $l$, and then steps into the loop. For each round, the second element of each pair from $q$ is pop out and stored in a temporary container Pair($<p1, p2>$). Then, we traverse on the tree $T$ to find the node that located at the $p1$ level of $T$ and its node val is equal to $p2$. If a node is found, the index of the node will be returned. Otherwise, an empty value will be returned. The outputs of the algorithm will be a list $l = (i_1, i_2, i_3, ..., i_n)$, including all indices of these nodes that satisfy the search query. In the next step, CSP will perform HME based aggregation outside the enclave based on this list.

First, CSP looks up the list $l$, and use the elements in $l$ as the index to retrieve the encrypted count of the corresponding node. Due to the HME property of Paillier Cryptosystem, suppose we have two message $m1$ and $m2$, if we encrypt the two message with Paillier public key and then perform multiplication of the two ciphertexts we will get the sum of the corresponding plaintexts. According to such homomorphic property, CSP will perform HME aggregation of the lowest level nodes in the list $l$ to compute the encrypted overall counts $Sc^E$, which will be sent to
enclave for re-encryption before releasing the results to researcher.

To perform re-encryption, Researchers need to create a different pair of Paillier key \((pk, sk)\) and share the public key \(pk\) with CSP. CSP pass the public key into enclave and then perform \(Sc^E\) decryption followed by an encryption step of \(Sc\) by using the new key and send back the ciphertext \(pk(Sc)\) to researcher. Researchers then decrypt the ciphertext and get the query count result.

```
Algorithm 1. Algorithm for Executing Search Query

Input : Search Query \(q\), Index Tree Structure \(T\)
Output: List of inodes that satisfy the search query, \(I\)

\[ L = T.getNodes(depth = 1) \quad // \text{Append all tree nodes with depth 1} \]
\[ cur = 0; \quad // \text{cur indicate the current depth(level)} , \]
\[ \text{Initiate cur with 0 indicate start with root node.} \]

\textbf{while} \( cur < \text{max_depth}(T) \) \textbf{do:} \quad // Break loop when reach leaf nodes
  \textbf{if} \( cur \textbf{ not in } q.\text{keys}() \):
    Update \( L \) with the children of current nodes in \( L \)
  \textbf{else}
    Update \( L \) with the children of nodes where \( node.val == q[cur] \)
  \( cur++; \)
return \( L \);
```

**Results**

In our experiment, a dataset retrieved from the Personal Genome Project\textsuperscript{44} with 173 individuals and 60 to 2000 SNPs were used to perform the evaluation. The association test based on case/control group in GWAS could be a downstream application of our model. More specifically, for the chi-squared association test, \[ \sum \frac{(Obs - Exp)^2}{Exp} \], where \( Obs \) represents observed allele counts and \( Exp \) represents expected allele counts, one needs to query the genotype counts of case/control groups to compute the necessary expected frequencies and observed frequencies used in the analysis. For all experiments, we used 1024 bits Paillier HME (i.e., 80 bits security) for data encryption and decryption. All results were obtained on a Windows 10 PC with SGX-enabled i7-6820HK CPU and 48GB memory, on which we simulated all entities in the proposed framework.

Figure 4 shows the time cost for structure tree building, count encryption, and structure tree encryption. All these building time is assumed as one-time job and DO takes charge of building jobs. Table 2 presents the result of total size of different files generated by HME. We can see the encryption of node count is the most time consuming task. As shown in Table 2, we need to encrypt all count number of the tree and the encryption result can be large. But it is only encrypted once, and therefore the consumption is acceptable.

In Table 3, we show the overall query processing time. In the experiment, we test two different sizes of datasets with 500 and 1000 SNPs, respectively. We tested the query size with number of SNPs ranging from 5 to 200. The experimental results showed that HME computation was more time consuming than these of the node comparison within the enclave. As shown in Table 3, HME addition costs and size of queries are inversely proportional. It is because a longer query usually results in less matched nodes in the deep level of the tree, which reduced the number of HME addition operations.

We compare the processing time required to execute a query in our proposed model with Hasan et al.\textsuperscript{55}. The experimental results showed that the size of SNPs has major impact on query processing time, thus, we used a larger number of SNPs instead of more individuals in our experiments. By using Hasan et al.\textsuperscript{55} model, a query consisting of 50 SNPs against a dataset of 300 SNPs each record requires around 6 seconds to process. In contrast, our proposed framework costs approximately 0.063 second to process the same query but against a larger dataset of 500 SNPs each record. Therefore, our framework is at least 95 times faster than Hasan et al.\textsuperscript{55} to process a secure query.

Discussion and limitations

Security Model: In this proposed framework, there are two private secret keys, i.e., the private genomic data from DO and the private search query from Researchers. As ASP only handles attestation and authentication, we consider ASP will not access any of the two secret keys. We consider the following potential leakage situations to show our model is secure and privacy-preserving.

1. **DO data leakage to CSP:** The tree is built on DO side and no other entities have the ability to access the raw data stored on DO. Thus, no one except for the DO can access data during tree building stage. In addition, the tree information will be split into two parts i.e., tree structure and counts of nodes. Both parts will be encrypted and remain protected by HME and SGX based secure hardware at the untrusted CSP side. Thus, CSP will not have the ability to access secrets of DO.
2. **DO data leakage to Researcher:** Researchers also do not have the ability to access data stored on DO, they are also not able to infer information in the tree building process.
3. **Researcher query leakage to CSP:** Researchers’ search queries are encoded and encrypted when sent to CSP. The query will remain sealed or encrypted on CSP outside enclave and can only become in plaintext when enters
a trusted enclave. Thus CSP do not have ability to access the query itself. The count of query operation is performed outside enclave, but the results are calculated through ciphertext via Paillier-based HME computation. Thus CSP also has no chance to infer or access the results of count queries.

4. **Researcher query leakage to DO:** Researchers do not have any interactions with DOs through the secure query execution stage. Thus there is no chance to leak query secrets to DO.

**Limitations:** The proposed SCOTCH framework has several limitations: First, With the increases of number of individual and SNPs, the branches of the structure tree will also increase significantly. Since we need to put the tree structure inside the enclave, the memory limitation of SGX may become an obstacle. When dataset scales up the computation complexity for our proposed increases accordingly. In this paper we only present the method for building tree structure based on position, no further optimization is included. However, based on our proposed method, one can apply bloom filter to optimize the algorithm when dataset scales up, which is an efficient method that can help us to speed up the the searching or re-organizing over tree structure based SNP frequency. Second, we still observe a significant storage overhead for homomorphically encrypted count information, as the count of each node needs to be encrypted independently. Moreover, the number of nodes will also increase, as the dataset increases. Third, even though the SGX-based framework can be constructed to defend malicious attacker, the proposed SCOTCH assume a semi-honest security model to cope with HME. Finally, we consider the position information of the querying SNPs to be non-private, which might not be always true. Advanced protection based on oblivious random access could be used to potentially mitigate such concerns. The above limitations warrant the further investigation along this line.

**Conclusion**

In this paper, we propose a hybrid secure framework based on both HME and SGX to conduct privacy-preserving genomic count queries for cloud computing. The proposed method provides an innovative data provisioning method on the combined hardware/software architecture, which encrypts private genomic datasets into two separate data structures, i.e., homomorphic encrypted tree structure and hardware sealed node counts. Such method reduces the storage overhead and improves the security and integrity of private data. A SGX-enhanced dynamic secure homomorphic encryption key pair generation method is also proposed to improve the security for key management. The results for our experimental studies demonstrated the efficiency of the proposed method. For example, it took less than 1 second to securely query 200 SNPs against a dataset with 1000 SNPs and 173 individuals. In comparison to the previous work 55, which required about 2 seconds to handle a query with 60 SNPs against a database with 240 SNPs, the proposed use only 0.061 seconds to handle a query with 75 SNPs against a database with 500 SNPs. It is worth mentioning that the complexity for tree search is mainly depends on the number of SNPs in the query and the database, while the number of individual in the database have very minor impact on the overall performance 55.

**Funding**

This work was funded in part by the Patient-Centered Outcomes Research Institute (PCORI) under contract ME-1310-07058, NHGRI R00HG08175, NIGMS R01GM114612, R01GM118574, R01GM118609, NLM R21LM012060, NIBIB U01EB023685, NSERC Discovery Grants (RGPI-2015-04147) and University of Manitoba Startup Grant.

**Authors’ contribution**

All authors approved the final manuscript. CW, YJ, XJ, NM and SW designed the method. CW, YJ and SW implemented the algorithms and devised the simulation experiments. CW, YJ, XJ, SW wrote a majority of the manuscript. FC, NM, MA and MS provided useful discussion, edits and critical suggestions.

Abstract

A major challenge in using electronic health record repositories for research is the difficulty matching subject eligibility criteria to query capabilities of the repositories. We propose categories for study criteria corresponding to the effort needed for querying those criteria: “easy” (supporting automated queries), mixed (initial automated querying with manual review), “hard” (fully manual record review), and “impossible” or “point of enrollment” (not typically in health repositories). We obtained a sample of 292 criteria from 20 studies from ClinicalTrials.gov. Six independent reviewers, three each from two academic research institutions, rated criteria according to our four types. We observed high interrater reliability both within and between institutions. The analysis demonstrated typical features of criteria that map with varying levels of difficulty to repositories. We propose using these features to improve enrollment workflow through more standardized study criteria, self-service repository queries, and analyst-mediated retrievals.

Introduction

There is a long history of using paper-based health records to identify potential research subjects. The advent of electronic health records (EHRs) has greatly facilitated researchers’ access to relevant patient data, especially when data are transferred to specialized data repositories or warehouses. Researchers may use such information for estimating the availability of eligible research subjects in some larger target population (cohort estimation), identifying potential patients for enrollment in a research study (cohort identification), or finding patients whose existing data (whether in summary or detailed form) can be used to explore research questions (data reuse). What most such endeavors have in common is a defined, study-specific set of patient characteristics, known as eligibility criteria. These criteria include those that must be present for a patient to be included as a study subject (inclusion criteria) or render the patient unsuitable for inclusion in the study (exclusion criteria). The use of EHR data for subject identification (for any purpose) will typically begin with querying a repository to find patients who meet inclusion criteria and then remove those patients with exclusion criteria.

Ideally, a researcher can access a repository in “self-service” mode to complete the search and retrieval processes independently. However, the required queries are often too complex for this approach and may require the assistance of a data analyst who is familiar with the data and tools and can mediate between the researcher and the repository. Even then, the process may be challenging. Eligibility criteria may be expressed in complex arrangements that are not amenable to automated searching, or they may require data that are either not accessible through query tools or are not recorded in the health record. Studies of matching enrollment criteria using EHR repositories have demonstrated success rates ranging from 23% to 44% due to requirements for temporal restrictions, calculated conditions, or inaccurate medical diagnostic coding.

For example, a study might seek patients with diabetes mellitus on escalating doses of insulin who arrive in the emergency room with elevated blood glucose levels but will be ineligible if they receive treatment prior to enrollment in the study. In this hypothetical case, the researcher or analyst can automatically identify patients with diabetes mellitus who have received insulin previously but can only determine whether they have received escalating doses through complex queries or manual analysis of records of patients who appear to be at least minimally eligible. Finding patients through the repository breaks down completely when a study requires patients who present to the emergency room with new and acute problems, since repository data are only retrospective.
Subject recruitment is further complicated because not only must potential subjects be identified immediately, but they must be enrolled before receiving treatment. It is unreasonable and unethical to expect clinicians to interrupt patient care and delay potentially lifesaving treatment in acute settings. Researchers with such complex, time-sensitive eligibility criteria must often resort to educating front-line health professionals (or posting paper reminders), hoping that clinicians will remember in time to enroll their patients as study subjects. Automated alerts tied to EHRs can be used for simple eligibility criteria but will be difficult to implement in more complex situations that are challenging, even for experienced data analysts.

One solution mimics the practice of using an initial screening protocol in which a large set of potentially eligible patients is identified, and each individual record is examined subsequently against more specific criteria. For the EHR repository version of this method, the researcher or analyst performs an initial query to identify patient records that meet some criteria and then reviews full records manually for the remaining criteria, perhaps flagging patients who might be eligible if they appear in care settings (such as the hypothetical patients with diabetes above) for further evaluation. This multi-step process can be facilitated by characterizing eligibility criteria in advance as either being amenable to retrieval with repository tools (“easy”), requiring some more elaborate mechanism (“hard”), or a combination of the two (“mixed”). If a researcher specifies criteria in this manner in a research protocol, repository users can then perform an initial retrieval step (especially when the user is an analyst rather than the researcher) to identify an initial set of patients. This cohort then passes on to the next stage in the process for application of additional study criteria through other means.

The categorization of study criteria by level of difficulty has been previously demonstrated. Three reviewers from a single research institution with combined expertise in clinical medicine, research, EHRs, and querying databases for study cohorts demonstrated high agreement when assigning levels of difficulty to study criteria. We have now expanded the original study to include a similar set of expert reviewers from a second research institution. The purpose of this follow-on study is to further characterize the use of these categories and determine if the prior findings are generalizable. Demonstrating inter-institutional reliability and examining differences in categorization between institutions are important steps in determining the overall feasibility of our proposed phased approach for identifying study cohorts.

Methods

We obtained the ClinicalTrials.gov (NCT) identifiers for a convenience sample of ten studies conducted at the University of Alabama at Birmingham (UAB) that were chosen for a separate study of the use of EHR data for cohort prediction (unpublished data). We then incremented each NCT ID successively until the next ID in sequence matched another study in ClinicalTrials.gov. For example, the NCT ID NCT01098981 would be incremented to NCT01098994 to find the next additional study. These twenty studies provided the eligibility criteria that served as the data set for our study (Table 1). The NCT record for each study was examined to identify its eligibility criteria (Figure 1) which were manually copied from a Web browser into a spreadsheet. Unnecessary words were removed from each criterion to make it easier to identify those that were essentially redundant. Duplicate criteria were then removed, and the remaining criteria served as the set to be reviewed for the study.

The authors of this study served as experts for rating the eligibility criteria. We included three experts each from medical schools within two academic research institutions, University of Alabama School of Medicine (UASOM)
and Northwestern University Feinberg School of Medicine (NU), to improve the generalizability of our findings and explore factors that might be institution- or repository-specific.

- JJC is a physician who was the principle architect of the National Institutes of Health’s Biomedical Translational Research Information System (BTRIS) and has extensive experience using it to match patients to research criteria.
- WJL is a physician (formerly at UASOM) who is a research fellow with extensive experience with electronic health records and moderate experience with UASOM’s i2b2 (Informatics for Integrating Biology to the Bedside) repository.
- MCW is a systems analyst architect with responsibility for and experience using both i2b2 and PowerInsight (Cerner Corporation, Kansas City, MO), the clinical data warehouse attached to the EHR used by UASOM.
- LVR is a clinical research associate at NU who leads the implementation of the i2b2 instance within the Northwestern Medical Enterprise Data Warehouse (NMEDW) and trains faculty and staff on its proper use.
- AYW is a physician with extensive experience developing and implementing health information standards and moderate experience using EHRs and using the i2b2 repository within NMEDW.
- DGF is a research fellow at NU with considerable experience researching and using cohort selection queries for clinical trial recruitment.

Each author reviewed the resulting criteria and rated them with an ordinal scale from one to four (Table 2) that was assessed whether a typical clinical data repository, such as i2b2, BTRIS or PowerInsight, could identify study subjects matching each criterion based on information available in a typical EHR system. Given the complexity of some criteria, in which multiple clinical concepts or properties are represented together (e.g., classes of diagnoses, severity of disease in addition to presence of disease), ratings were assigned based on the highest level of difficulty. For example, if a criterion named a diagnosis and then specified its severity against a separate evaluation scale and a rater assigned 1 and 3 respectively for each sub-criterion, the overall rating for this item would be 3. Reviewers were instructed to leave the rating blank if there was not a clear answer. The ratings were compiled and summarized to determine the characteristics of criteria that could be readily used with EHR repositories versus those that could not.

Table 2. Rating Scale for Eligibility Criteria. Each criterion was assessed by each rater for its suitability for retrieval from an electronic health record data repository.

<table>
<thead>
<tr>
<th>Rating</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>1 – “Easy”</td>
<td>The criterion could be used easily to identify subjects in an EHR data repository, assuming the data were present, using the repository’s user interface</td>
</tr>
<tr>
<td>2 – “Mixed”</td>
<td>The criterion could be partly retrieved using the repository’s user interface but then would require further manual review</td>
</tr>
<tr>
<td>3 – “Hard”</td>
<td>Matching the criterion would require manual review of the record</td>
</tr>
<tr>
<td>4 – “Impossible”</td>
<td>“Time of enrollment” – The repository would not be likely to include sufficient information to match patients to the criterion, either because the source EHR would not be likely to contain the information or the repository would not include the information in a timely manner</td>
</tr>
</tbody>
</table>

Since this study involved a fully crossed design, in which each criterion was rated by multiple coders using an ordinal coding system, we calculated the intra-class correlation score (ICC). This analysis was performed using R v3.3.1 and the irr package v0.84 with results integrated using StatTag v3.0. Additionally, we analyzed the number of “near agreement” results across institutions. We defined “near agreement” within an institution as a criterion in which two of the three ratings matched exactly, and the discrepant score was only offset by one category. Likewise, “near agreement” across all raters was classified as at least four of the six raters having matching scores, and the discrepant scores were only offset by one category each.

Results

Criteria Data Set

The 20 clinical trials used in this study are listed in Table 1. The ClinicalTrials.gov records for these twenty studies were cleaned to remove blank spaces, formatting, bullets, numbering, and other redundant text which did not affect meaning. Leading clauses with age and gender criteria (e.g., “women” in “women who are pregnant”) were removed, as these criteria are indicated separately in ClinicalTrials.gov and are already straightforward to retrieve. Other text, such as “with” in “with diabetes mellitus” and “taking” in “taking aspirin,” was removed to yield distinct concepts (e.g., diseases or medications). This process yielded a set of 301 criteria, of which 292 were found to be conceptually unique and were reviewed by each rater (1,752 ratings total). Example ratings are shown in Table 3.
Table 2. * indicates criteria for which there was complete or near agreement, included in further analysis. Raters used “X” or “?” to indicate that the meaning of the criterion was unclear or that the categorization was unknown.

Aggregate Criteria Ratings

Aggregate ratings are summarized in Table 4. For UAB raters, the ICC was 0.91 (95% CI: 0.88, 0.93) for 286 criteria (excluding 6 criteria with blank responses). Of 286 criteria, 232 (81.12%) demonstrated complete or near-complete agreement (2 reviewers at a site agreed completely while the third disagreed by only one category). For NU raters, the ICC for agreement was 0.92 (95% CI: 0.90, 0.93) for 292 criteria. Of 292 criteria, 262 (89.73%) demonstrated complete or near-complete agreement.

For all raters from UAB and NU collectively, (including 286 criteria), the ICC for consistency was 0.92 (95% CI: 0.90, 0.93) and the ICC for agreement was 0.92 (95% CI: 0.90, 0.93). Of the 286 criteria where all raters provided a response, 181 (63.3%) indicated complete or near-complete agreement (at least 4 reviewers agreed completely while the others differed by only one category). All ICC results were statistically significant (p < 0.00001).
Table 4. Individual and combined aggregate ratings for University of Alabama at Birmingham (UAB) and Northwestern University (NU).

<table>
<thead>
<tr>
<th>Characteristics of Easy Criteria</th>
</tr>
</thead>
<tbody>
<tr>
<td>These criteria were defined as those that can be used easily to identify subjects in an EHR data repository, assuming the data were present, using the repository’s user interface. In general, these were easily related to the categories of data that are provided by repositories like i2b2 and BTRIS, such as laboratory results, vital signs, diagnoses, procedures, and allergies. The raters generally rated as “easy” criteria that contained defined, single concepts, such as diseases like “glaucoma” or individual laboratory tests combined with discrete values, such as “hemoglobin ≥ 9 g/dL.” They also selected “easy” for general descriptions that could be addressed through class-based queries, such as “Abnormal laboratory tests,” “Anti-cancer treatment prior to trial entry,” and “History of solid organ or hematological transplantation.” There was general agreement that criteria involving complex phenotypes were considered “easy” if they could be addressed through an assemblage of individual easy criteria, such as “infection with human immunodeficiency virus (HIV), Hepatitis B, or Hepatitis C” or “Aspartate aminotransferase (AST) and alanine aminotransferase (ALT) ≤ 5 × the upper limit of the normal range (ULN).”</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Characteristics of Mixed Criteria</th>
</tr>
</thead>
<tbody>
<tr>
<td>Mixed criteria were defined as having elements of easy and hard criteria, and these criteria can be partly retrieved using the repository’s user interface but then would require further manual review. These criteria generally included some mention of an “easy” criterion, coupled with some restriction or co-occurring state or procedure that either was not itself an easy criterion, or the relationship between the two components can only be carried out by a manual review. Most mixed criteria involved the presence of some medical condition with restrictions on the state, such as severity (e.g., “Severe cardiovascular disease (defined by NYHA ≥3”), chronicity (e.g., “current manic episode with a duration of ≥ 2 years”), or failure to respond to treatment (e.g., “Active or untreated latent tuberculosis (TB).”). Some criteria consisted of an “easy” condition paired with a “hard” criterion, such as “pregnant or breast feeding” and “Seizure disorders requiring anticonvulsant therapy”. There were also cases of findings that would be expected to appear only as narrative text in a diagnostic procedure report. In these text reports, the procedure could be readily identified, but detecting the findings or test results would require manual review, such as in “At least one primary molar tooth with caries into dentine involving two dental surfaces (diagnosed according to International Caries Detection and Assessment System - ICDAS, codes 3 to 5”), “homozygous for the F508del-CFTR mutation”, and “Normal electrocardiogram (ECG).” Finally, there were some criteria that combined “easy” laboratory findings with “hard” ones, such as “Estimated glomerular filtration rate (eGFR) ≥ 50 mL/min according to the Cockcroft-Gault formula for creatinine clearance.”</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Characteristics of Hard Criteria</th>
</tr>
</thead>
</table>
| Hard criteria were defined as those which would require manual review of the patient record. These criteria span the breadth of EHR findings that typically appear in clinical notes and procedure reports. Some hard criteria were encountered as parts of “mixed” criteria, such as “females who are breastfeeding”. Others were statements of patient condition that would not be reflected in a typical problem list, such as “prisoner”. Scale-based assessments, such as “Pre-morbid modified Rankin score of 0-1” and “Eastern Cooperative Oncology Group (ECOG) performance status of 0 or 1” were common. Finally, some criteria might be found in the Assessment portion of clinical notes or require the researcher to use the clinical record to make the assessment, such as “Candidate for phototherapy or systemic...
therapy” and “Any other clinical condition or prior therapy that, in the opinion of the Investigator, would make the individual unsuitable for the study or unable to comply with dosing requirements.”

Characteristics of Impossible (Point of Enrollment) Criteria

Criteria were “impossible” or “point of enrollment” if the repository would not be likely to include sufficient information to match patients to the criterion. While some of the “impossible” criteria related to the time factor of the data (such as “Parents/children who refuse to participate in the study” and “presenting within timeframe for intravenous tPA treatment approved by local regulatory authorities but no more than 4.5 hours from onset of symptoms”), other cases depended on the raters’ opinions about whether relevant data are reliably found in EHRs.

Researchers may be surprised that physical findings they would consider basic were considered by the raters to be generally absent, such as “Facial Hair”, and “good health.” Similarly, the raters agreed that information a researcher would typically obtain from a prospective subject or caregiver, such as “patients with impaired decision making ability”, and “Able to swallow tablets,” would likely not be documented in routine clinical care.

Differences in Ratings between Institutions

There were systemic differences in ratings between UAB and NU (Table 3). For example, for criteria specifying that a disorder, medication, or laboratory result must be present at screening, UAB reviewers unanimously rated these criteria as “easy” while NU reviewers rated them as “impossible.” There were additional criteria which the NU reviewers consistently deemed more challenging than the UAB reviewers. There were other criteria that UAB reviewers found more difficult than NU reviewers.

General Recommendations

The data presented above can be summarized by separating out “easy,” “mixed,” “hard,” and “impossible” criteria into explicit lists (see Table 5). This list, in turn, can be used by those developing eligibility criteria such that they can anticipate the workflow needed to identify potential research subjects using repository query tools, manual record review, and real-time interventions at recruitment sites. Potential uses for this list are explored further in the Discussion section, below.

Discussion

The use of EHR data for clinical research is a rapidly evolving phenomenon. The development of methods for “large pragmatic trials” is especially dependent on EHR data. However, the methods for defining eligibility criteria remain largely unchanged in practice, with little apparent attention paid to the fact that criteria elicited from patients completing questionnaires might differ fundamentally from those elicited from EHR.

---

* A search of PubMed on March 10, 2016 for articles with the phrase “electronic health record data for research” yields 722 citations from 1996 to 2005 and 10,303 citations from 2006 to the present.
Much informatics research has examined the semantics of clinical research eligibility criteria. Projects such as the Ontology of Clinical Research (OCRe)\textsuperscript{19} and the Agreement on Standardized Protocol Inclusion Requirements for Eligibility (ASPIRE)\textsuperscript{20} have defined broad classes of criteria (such as demographics, disease-specific features, functional status, etc.) with the intent of making them computable for comparison across multiple studies. The semantic complexity of these classes of criteria has been studied in depth by Ross and colleagues.\textsuperscript{21} Weng and colleagues provided a comprehensive review of this work\textsuperscript{22} and extended it with classification of criteria through use of the National Library of Medicine’s Unified Medical Language System (UMLS) semantic types,\textsuperscript{23} UMLS semantic network,\textsuperscript{24} and National Institute of Health’s (NIH) Common Data Elements.\textsuperscript{25} To our knowledge, however, there have been no systematic studies of how such criteria translate operationally into the potential capabilities of EHR repository query tools.\textsuperscript{2,4}

We did not set out to create a reusable criteria rating scale, but rather sought to find a specific set of criteria that could be used for further analysis. Nevertheless, we experienced high interrater correlation in the use of our scale within and between our two institutions. The sets of researchers have diverse backgrounds (medicine, informatics, and information systems) and draw on experience with three very different repositories (PowerInsight, i2b2 and BTRIS). This result suggests the raters were tracking a real and meaningful concept and that a standardized and generalizable scoring metric could be generated and applied at other institutions. Examples of criteria on which we agreed and disagreed are included in Table 3 for the reader to judge whether our rating method appears generalizable.

We identified characteristics that affect the difficulty of applying different criteria. Based on these findings, we can develop strategies to convert mixed, difficult, or impossible criteria into easier categories. For example, many criteria consist of combinations of simpler criteria or are bound by restrictions such as severity or time constraints. Separating combined criteria into individual components would likely make them easier to apply. Also, specifying clinical trial criteria using controlled terminologies (and increasing the use of structured data entry in EHRs) can promote improved automated patient matching. A shared library of shared queries for criteria can improve the querying process.

There were interesting systematic differences in ratings between the two institutions. Some criteria consistently or even unanimously received completely opposite ratings at the two institutions. In particular, criteria specifying a condition that must be present at the time of screening were unanimously rated as “easy” at UAB but “impossible” at NU. This difference illustrates that the wording of inclusion and exclusion criteria may be ambiguous, subject to individual interpretation, and a source of systemic inconsistency. UAB reviewers may have interpreted “screening” to indicate the time a researcher performs an initial query on the EHR repository, and the correct information would be searchable in the EHR. NU reviewers may have interpreted “screening” to mean the time that a patient presents for an initial screening encounter with a study coordinator. Because the relevant EHR data are retrospective, they may not be current at the time of a screening visit. This discrepancy does not invalidate the use of our categories for criteria. Instead, it highlights that criteria must be written so that their meanings are expressed clearly and unambiguously. It would be revealing to examine other systematic differences in ratings and differences in repository management and query processes at the two institutions to uncover other possible reasons for these differences.

Our examination of a randomly collected set of enrollment criteria suggests that a majority can be readily classified as having some components retrievable from EHR repositories (i.e. rated “easy” or “mixed”). While not necessarily representative, it does imply a large degree of inclusion and exclusion criteria are accessible via structured data. Our preliminary work in the adjacent field of cohort selection queries leads us to suggest that a significant amount of potential participant identification could be accomplished with intelligent use of these structured data.

The most interesting category may be those criteria widely rated as “mixed,” in which a “first pass” or approximate identification may be possible using structured data. This rating therefore represents an obvious break point in complexity. We suggest future research focus on such criteria, ideally looking to separate or better explicate what can be solved with structured data and EHR retrieval and what might must be retrieved with either full chart review or patient screening.

We do not make any claims, given our sample size and sampling method, about the actual ratios between easy, hard and impossible (time of enrollment) criteria across the spectrum of clinical trials. But, it seems logical to take advantage of the knowledge that such distinctions exist for developing the methods to be used for matching patients to criteria when EHR data repositories are being used for at least part of the process. A potential next step is to develop an interactive “wizard” with a graphical user interface that prompts researchers to enter criteria in structured ways that progress in order of increasing complexity. For example:
The wizard would ask first for easy elements that can be addressed readily with a repository search tool:

- What laboratory test result would you like, and with what range of values?
- What class of medications should the patient be taking (or not taking) and for what duration?
- What procedure should have already been or not been performed?
- Are diagnoses from billing data sufficient or are higher-quality sources (such as problem lists) required?

The wizard would then address more complex elements needing manual review of records found with initial criteria:

- What calculation would you like performed on the previously specified laboratory test result?
- What should the indication for the previously specified medication be?
- What findings should be present in, or absent from, the text report for the previously requested procedure?
- What complex phenotypic pattern should the patient have?

The application would then proceed to elements that can only be ascertained at the time of enrollment:

- What acute event will the otherwise eligible patient have (or not have) at the time of presentation?
- What will the patient have to agree to do (or not do) in order to be eligible for enrollment?

This wizard would then produce a coherent set of eligibility criteria that could specify a multi-staged enrollment process that starts with a set of data queries, proceeds to manual review of full records, and then specifies what additional information will be needed on specific potential subjects through direct contact, perhaps by flagging them in an EHR’s alerting system to notify the researcher when they appear in a patient care setting.7
